When the heavy water encounters the quiet water of Lake Mead, in a confined canyon where the cross-section increases gradually, its velocity will be reduced without turbulence, and the cross-section of the moving stream must increase in the same proportion. In the narrow box canyons which occur in Lake Mead, the bottom stream is confined and the plane of contact with light water will be narrow, thus making any mixing very slow. The velocity of the heavy water under the quiet light water is a function of the difference of specific gravity and the slope of the bottom, which latter is a constant for any given location in the lake. The velocity of the stream of heavy water will be a direct function of the difference in gravity whereas its depth will be inversely proportional to its velocity. Friction between the two classes of water complicates the problem, and the inertia of the heavy water prevents any motion until the difference in gravity attains some minimum value; but once motion is started the same inertia will maintain it until this difference has decreased to a value less than was required to initiate the movement. This fact would explain the movement in surges. Furthermore, since the increase in specific gravity is due to a mechanical mixture, rather than to a solution, the settling of the fine particles in the quiet water of the bottom during periods of negligible movement would tend to decrease the force required to start the flow.

---

[21] "Predetermining Extent of Sewage Field in Sea Water", *Transactions* Am. Soc. C. E., Vol. 94 (1930), p. 1036.

The actual behavior could best be found by means of experiments with a model, and it would also be well to make regular specific gravity observations at Grand Canyon, and at Willow Beach beginning a few days after heavy water was noted at Grand Canyon. Sub-surface samples from different parts of the lake, especially at both the upper and lower ends of the wide sections, should yield interesting data regarding the difference in behavior in the box canyons and the open sections of the lake.

When the difference in specific gravity is very small, the depth of the stream of heavy material should be great and, in the valleys, it would spread well out of the old stream bed, thus increasing the plane of contact so much that mixing would be increased enough, practically, to stop the flow beyond the valley. Any model for this study should contain alternate box canyons and wide valleys to study this effect. With this information it might be possible to determine the shapes of reservoirs which would be expected to pass turbid water through them, and compare these with Lake Mead, or with any other reservoir which passes turbid water through it.

MORROUGH P. O'BRIEN,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Recent theories dealing with the suspension of solid material in turbulent flow, treat the problem as one of statistical equilibrium in which the transverse components of velocity carry more material upward than downward, because of the increase of concentration in the downward direction, and thus counteract the constant settling tendency. Provided that the upward velocity components exceed the settling velocity of the material, a steady state of suspension may be attained. From this viewpoint a possible explanation of the flow of turbid water through Lake Mead may be that the greater density of the water carrying suspended material caused it to follow the bottom at a sufficiently great velocity to result in a turbulent flow capable of re-suspending the solid particles as they settled out. Thus, the inflowing stream might be held to the bottom in its course through the reservoir. This phenomenon is essentially different from the flow of cold or saline waters because the mixture is not permanent.

An approximate computation of the order of magnitude of the quantities involved may be made by assuming that the usual friction equations apply without allowance for the energy dissipated in the circulation set up in the overlying water. The resulting equation would be,

$$V = \sqrt{\frac{g_m}{k} \times \frac{p}{100} \times \frac{s-1}{s} R\,S} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

---

[22] Prof. of Mech. Eng., Coll. of Eng., Univ. of California, Berkeley, Calif.

in which V is the mean velocity; g_m is the gravitational force per unit mass; k is a friction coefficient; R is the hydraulic radius; S is the slope of the bottom; p is the percentage concentration; and s is the specific gravity of the material in suspension. If the layer of water is thin in proportion to its width, R may be replaced by T, the thickness. The discharge is bVT, in which b is the width. When $S = 0.0007$, $s = 2.65$, $k = 0.003$, and $b = 400$ ft, the depths and velocities for three days of high concentration are as given in Table 3. At best, these values are only rough approximations not only because of the simplified theory used, but also because of insufficient data. No allowance was made for differences in temperature between the reservoir and the inflowing stream, the width was assumed as 400 ft, and the slope is only an average value, and yet the results are within reason. The Reynolds number is high and these flows should be turbulent, but the vertical density gradient would probably reduce the turbulence below that which would occur in a clear stream of the same depth and mean velocity.

TABLE 3.—COMPUTED VELOCITY AND THICKNESS OF SILT CURRENT.

Description	April 11	September 4	September 30
Percentage by weight	3.16	5.02	4.14
Discharge, in cubic feet per second	15 600	8 630	18 100
Computed thickness, T, in feet	21.5	12.5	22
Computed velocity, in feet per second	1.8	1.7	2.1

At a velocity of 1.5 ft per sec (which is below the computed velocities) the flow would traverse the 90-mile length of reservoir in a little less than four days. During this interval, material as small as 5 microns would settle out of still water, and the stream would lose its identity before reaching the tunnels unless the material is kept in suspension by the transverse velocities of the turbulence. The approximate average magnitude of these transverse velocities would be $0.15 \times 1.5 = 0.22$ ft per sec, or 80 ft per hr and some particles larger than 50 microns might be transported.

Using the same methods one may compute a lower limit of discharge and concentration which would maintain particles of a given size in suspension, but the result would be greatly affected by the temperature. If the incoming stream is colder than the water in the reservoir, capacity for maintaining particles in suspension is increased both because of the increased density of the water and the decreased settling velocity of the particles. If the inflow is warmer, the capacity for suspension is reduced and this effect may account for the absence of turbid outflow during the high-water period of May and June.

It is to be hoped that this paper will arouse sufficient interest among those concerned with reservoir operation that information will be obtained to form the basis of a general theory. It appears possible to develop a combination of theory and experiment which would permit computation of the flow of sediment through reservoirs with known inflow conditions, but to do so will require extensive field data.

JOHN C. PAGE,[23] M. AM. SOC. C. E. (by letter).—Since the authors completed their paper, additional information has been obtained from field records and the observations of employees of the U. S. Bureau of Reclamation which may throw further light on this interesting phenomenon.

Storage in, and controlled release of water from, Lake Mead was started on February 1, 1935. The water discharged from the reservoir through the tunnel at river grade was clear until February 15, when the water became muddy and did not clear until the following day. This occurred again on February 19 and from February 23 to February 25. In all instances, there were storms on the lower water-shed preceding the discharge of the turbid water. The silt content in the first two runs was light, being recorded as approximately 10 000 ppm at the gaging station 1¼ miles below the outlet.

No measurements of silt content were taken for the third run, but samples were taken in the reservoir, just up stream from the inlet of the diversion tunnel, to determine the elevation of the silt-laden stratum. Sampling across the channel showed that this layer occupied the bottom of the original river channel, being about 2 ft in depth in the center. The surface of the stratum was level and was marked so definitely that a change of 6 in. in the elevation of the sampler changed the sample from clear to cocoa-colored. The dried silt from a sample taken about the middle point of this layer amounted to about one-fourth in volume of the total sample. At the time of this third occurrence, a streak of muddy water, visible on the surface, extended through the center of the reservoir for approximately 3 miles below Boulder Canyon, clear water appearing on both sides. Undoubtedly, it extended a greater distance, but was not visible. Boulder Canyon is 20 miles up stream from the dam.

Turbid water again flowed from the reservoir on March 24 and April 21. The temperatures of the water at the outlet of the tunnel increased from 52° F to 63° F during this period. The silt content varied from about 3 100 to 11 400 ppm, measured at the rating station below the dam and checked closely with the silt measurements taken at Willow Beach. Nine samples were taken at different depths for each reading. The silt content was found to be uniform for all samples, indicating that a thorough mixing occurred at the outlet gates. Previous to the passage of the water through these gates, and under similar conditions of silt load in the river, the silt content of the surface sample was about 78%; and the middle sample 85% of the bottom sample.

No measurements were made during the turbid releases in September and October, 1935, or from April 22 to May 1, 1936. Water was being released both from the bottom of the reservoir and through the gate-opening in the base of one of the intake towers 260 ft above the old stream bed during the April–May period. No turbid water came from the Arizona canyon wall outlet works which connected with the intake tower gate. The muddy water emerging from the low-level tunnel on the Nevada side and the clear water from the outlet works on the Arizona side did not mix completely until after they had passed the gaging station. During the period of this flow, the temperature of the water was 50° F from the bottom of the reservoir, 58° F from the outlet works, and 55 to 57° F at the gaging station.

---

[23] Commr., U. S. Bureau of Reclamation, Washington, D. C.

Recently, samples have been taken between the dam and the up-stream coffer-dam, and another set approximately 4 000 ft up stream from the dam. The silt stratum near the dam has its surface at about Elevation 650, whereas the silt surface farther up stream is about Elevation 695. The question has been raised concerning the possibility of silt flowing over the coffer-dam. The top of the up-stream coffer-dam is at Elevation 720, the reservoir bottom at approximately Elevation 615 near the dam, and the bed of the old river channel about Elevation 640. It is possible that the surface of the silt stratum was at one time higher than the top of the coffer-dam and since that time has lowered, due to the settling of the silt when undisturbed.

Temperature measurements recently taken near the dam at the time of the silt sampling show an abrupt rise of from 10° F to 20° F near Elevation 650. From this elevation downward the higher temperature is maintained until the bottom is reached. Measurements of specific gravity and electrical conductivity also show pronounced increases near Elevation 650. A brief summary of these data is given in Table 4.

TABLE 4.—CHARACTERISTICS OF WATERS OF LAKE MEAD MIDWAY BETWEEN UP-STREAM INTAKE TOWERS, MAY 21, 1937.

Elevation, in feet, above mean sea level	Clarity	Temperature, in degrees Fahrenheit	Conductivity (ohm reciprocal)	Specific gravity
1 066*	Clear	65.7	0.00128	1.0010
690	Clear	48.5	0.00141	1.0013
665	Clear	48.4	0.00141	0.0014
655	Clear	50.1	0.00142	1.0014
640	Muddy	60.1	0.00166	1.1732
620	Muddy	63.5	0.00161	1.1787

* Surface

Although there is not sufficient information available to arrive at definite conclusions concerning the phenomenon, it is evident that, under certain conditions, silt-laden water will pass through a reservoir without intermingling, although the length of the reservoir is as much as 100 miles. The silt that passes through Lake Mead is colloidal in character and differs greatly from the type normally carried by the stream. Under normal conditions the silt is abrasive, dark in color, and so heavy that 98% of it will settle out in a 2-hr period. The silt that has passed through the reservoir has a clay-like consistency, is lighter in color, and is difficult to remove from the water even by filtering. It is the writer's opinion that this lighter material comes from localities where the soil is predominantly clay and contains a high percentage of salts. The material is carried to the river, generally, by cloudbursts. Its ability to pass through the reservoir seems to be derived from its colloidal and chemical characteristics.

The abrupt change in temperature at Elevation 650 in the waters near the dam may be due to the silt stratum, but the increased temperature is possibly due to the presence of warm springs. These springs, having a temperature as high as 130° F, were encountered in the canyon during construction. The heavy layer of colloidal clay in suspension may have an insulating effect which tends to delay rapid temperature diffusion.

JOHN H. BLISS,[24] ASSOC. M. AM. SOC. C. E. (by letter).—The passage of silty water through a reservoir of clear water in a more or less definite stratum, with little diffusion of the two, is a phenomenon which has not received much attention but which merits considerable study. Messrs. Grover and Howard have presented a very interesting paper on its occurrence through the waters of Lake Mead, and have suggested the possibility of utilizing such phenomena to reduce silt accumulations within the storage area of reservoirs.

Since its completion in 1915, there have been frequent passages of silt through the Elephant Butte Reservoir of the Rio Grande Project, in New Mexico, most of them occurring in the summer and fall when the flow of the Rio Grande was comparatively low and the torrential discharge of tributaries above the reservoir was relatively great.

The silt-laden waters that seem to be chiefly responsible for this phenomenon are contributed by two large intermittent tributaries, namely, the Rio Puerco, which drains an area of about 5 000 sq miles on the west side of the Rio Grande and empties into it about 45 miles above the head of the reservoir; and the Rio Salado, which drains an area of about 1 500 sq miles also west of the river and enters a few miles below the Rio Puerco. As their names imply ("Puerco" meaning "soiled" or "dirty," and "Salado" meaning "salty"), both streams carry extremely silty water of high saline content during periods of run-off. Analyses of the waters of the Rio Grande at the San Marcial Gaging Station at the head of the reservoir indicate that these tributaries may carry 150 tons or more of silt and a concentration of total dissolved salts of more than 3 tons per acre-ft of water discharged. It is interesting to note that these two streams, particularly the Puerco, have their sources immediately to the east of those arid regions drained by the Little Colorado River and the southern branches of the San Juan River, which latter streams the authors believed to be the chief contributors of the finely divided silt causing the turbid flows through Lake Mead. In this connection the authors' reference to silt passage through the Zuni Reservoir on the head-waters of the Little Colorado may also be cited.

The phenomenon of the difficulty with which two waters of different density may unite is of rather common occurrence. Any one who has seen a muddy torrential flow enter a stream of clear water has probably observed that the two flows may often be readily distinguished for considerable distances down stream. The San Acacia diversion dam of the Middle Rio Grande Conservancy District is constructed across the Rio Grande about two miles below the mouth of the Salado and ten miles below the Rio Puerco. The gate-tender at the dam has noted several instances when the flows of these tributaries have appeared at the dam practically unmixed with the main river discharge. On one occasion, the line of demarcation between the two flows was described as quite noticeable, being almost as distinct as if they had been separated mechanically. It was further stated that such tributary waters might appear on the right, or entrance, side of the channel, or they might pass under the main stream and appear on the opposite side.

[24] Engr., State Engr.'s Office, Santa Fé, N. Mex.

Since 1931, officials of the Rio Grande Project and the Division of Western Irrigation Agriculture, of the Bureau of Plant Industry, U. S. Department of Agriculture, in co-operation, have obtained and made complete analyses of the waters of the Rio Grande at several stations, including San Marcial above the reservoir, Elephant Butte immediately below the dam, and Leasburg diversion dam about fifty miles below. Although the saline content of the water is the primary consideration in these analyses, incidental silt determinations have been made at the first two of these stations. Periodic sampling at these points, together with an endeavor of the U. S. Bureau of Reclamation to keep a daily record of all appreciable silt passages through the lake, provide the means of studying some of the details of these occurrences. L. R. Fiock, Project Superintendent, has records of turbid flows through the reservoir for somewhat less than half the years since its construction. There is reason to believe, however, that there may have been other occasions when tributary waters have passed through the reservoir unobserved. At such times the quantity of silt carried may not have been sufficient to be noticeable, the clue to such passage being an increase in salt content of the water released from the reservoir.

During the six years that complete analyses have been made of the waters passing Elephant Butte only five periods out of more than twenty major tributary discharges were recorded as silt flows through the reservoir (see Table 5). However, as the sampling period was monthly (since 1924, weekly), the periods between the dates of sampling are long enough so that no records have been obtained during periods when silt flows of short duration might have passed through the gates. As an example, in 1931, monthly samples only were taken at Elephant Butte, except that in September a two-day flow of silt through the reservoir was recorded. During the latter part of September and October of that year there were at least four tributary discharges which might have caused turbid discharge. At Leasburg Station, where eight samplings were taken during that period (silt determinations not being made), all but one sample showed an increase in total dissolved salts carried. On October 12, the salt concentration of the water had increased 100%, the increase on other days of sampling being less marked. The data are not conclusive, because the discharge from the

July–September, 1936	..	..	†	..	....	No published record of any silt or salt flows through reservoir during period.

* Three periods of flow—about 75% of total discharge of river.

† Four rises of from 1 000 to 5 000 cu ft per sec from Rio Puerco; those from Rio Salado are unrecorded.

reservoir was sharply reduced about September 19 and stopped entirely on October 5, thereby changing considerably the regimen of flow at the Leasburg Station; but the indications are that enough saline tributary flow found its way through the reservoir to increase the salt concentration of the water below the dam appreciably. Whether this water was silty or even murky is not recorded, but at least, there was not enough coloration so that turbid discharge was noted and silt samples were taken at the outlet gates.

Since the discharges of the Salado and Puerco always involve increased salt as well as silt concentration of the river water, it is impossible to state to what extent each of these two factors contributes toward this phenomenon. As the authors have suggested, it is probable that, because of the greater quantity carried, silt has much the more pronounced effect of the two in increasing the specific gravity of the waters. There appear to be instances, however, in which flows have passed through Elephant Butte carrying increased quantities of salts and but very little or no silt. Although data are insufficient for proof, it seems probable in such cases that the silt gradually settles from the influent in its passage through the lake, leaving only the dissolved salts to maintain the increased density of the solution and pass through the gates.

As Mr. Fiock[25] has inferred, temperature apparently has little effect upon the specific gravity of the turbid influent. The average temperature of the waters near the bottom of Elephant Butte is about 57° F, whereas the average summer temperatures of the discharges into the reservoir are several degrees higher—in the 60's or 70's. The effect of temperature, therefore, must be slight in comparison with other factors, as its tendency is in a direction opposite to that of the observed phenomena.

W. F. Resch, Project Hydrographer, has informed the writer that soundings were made during one period of silt passage which indicated that the flow beneath the clear waters of the reservoir followed a definite stratum with little mingling of the two layers. As the outlet gates are at the bottom of the dam, it is probable that the silt flows do occur on, or close to, the flow line through the lake.

The data, although not definite, indicate that it takes the turbid water four to five days to find its way through the reservoir, a length of 30 to 35 miles, suggesting an average velocity under water of 0.5 ft per sec, or less.

The conclusions to be drawn from a study of the passage of silt through the Elephant Butte Reservoir would seem to be: (1) That any discharge into the reservoir whose waters are of sufficient density, due to very fine suspended silt (and also to salt), will potentially pass through it in an essentially unaltered condition; (2) those flows which are below this minimum will tend to pass through the lake, but will gradually lose their identity and may or may not appear at the outlet gates; and (3) under certain conditions, discharges may find their way through the reservoir, progressively leaving their silt load behind, and may appear below the dam with only an increased salt content to mark their passage. These conclusions are tentative and are subject to confirmation by further investigation and study. They are substantially in accord with the authors' findings, however. The bearing of Conditions (2) and (3) upon the passage of appreciable quantities of silt through reservoirs is slight.

---

[25] *Transactions* Am. Geophysical Union, 1934, Pt. 2, p. 472.

The suggestion that, by proper attention to gate location and the approach conditions thereto, turbid waters might be encouraged to pass through reservoirs and thereby reduce accumulations of silt within their high-water lines, is one which should receive considerable study. It is related to, and, must be investigated in conjunction with, the problem of silt conservation and the aggradation of stream channels.

If a reservoir could be operated so that peak releases could be made whenever turbid waters were available at the outlet gates, considerable quantities of silt might be prevented from settling in the reservoir area. Under ordinary operating conditions, however, it is unlikely that enough change in releases could be made economically to remove much additional silt above that ordinarily carried through the gates. Furthermore, as no greater concentration of silt can be passed through a reservoir than appears in the influent above, the problem resolves itself into one of whether the inflowing water or the reservoir volume usurped by the deposited silt is the more valuable. Under certain conditions, the disposal of even part of the silt burden of a turbid stream behind retention or storage dams would seem to be advantageous, particularly in those arid Western States where consumption of large quantities of water for irrigation has resulted in the serious problem of rapidly aggrading stream channels which threaten the very existence of agriculture along their banks.

A compilation of data pertaining to the quantity of water above and below Elephant Butte Reservoir since 1930, showing conditions at the time of appreciable tributary inflows to the reservoir, is given in Table 5. The data are not sufficient to show the sources of the rises, but those listed are believed to have come chiefly from the Rio Puerco and Rio Salado. The dates of such tributary flows, their average discharges in cubic feet per second, and their percentages to total river flows as listed, are approximate values for comparative purposes only, the discharges being so variable and the time element so uncertain that exact figures are difficult to obtain. The data from which comparisons may be made of changes in silt and salt quantities in their passage through the reservoir are not good, either, because of the extreme variations of these quantities during the various stages of tributary flow. The need for additional and more definite information is evident.

B. H. MONISH,[28] ESQ. (by letter).—The failure of fluids of different densities to mix when flowing in contact with each other at appreciable relative velocities has been recognized as a problem for many years, but it is only comparatively recently that active interest has been shown in the phenomenon. This is particularly true in the field of applied hydraulics. The authors of this paper are to be commended on a clear presentation of carefully collected data. Workers in fluid dynamics have made mathematical analyses of the stability of streams of superposed fluids of different densities, and it was along the lines suggested by one of these analyses that the writer attempted a study of the data presented in this paper.

---

[28] Assoc. Engr., National Bureau of Standards, U. S. Dept. of Commerce, Washington, D. C. Publication of discussion approved by the Director, National Bureau of Standards, U. S. Dept. of Commerce.

As a criterion of mixing between any two superposed fluids of different densities, when the density and velocity vary continuously from one fluid to the other, L. Prandtl[27] has given the expression:

$$\theta = \frac{-g\dfrac{d\rho}{dy}}{2\rho\left(\dfrac{du}{dy}\right)^2} \quad\text{(2)}$$

in which θ = a dimensionless coefficient which exceeds a certain value when no mixing occurs; $\frac{d\rho}{dy}$ = the density gradient between the fluids; $\frac{du}{dy}$ = the velocity gradient between the fluids; ρ = the density of the fluid at that element at which $d\rho$ and du are taken; and, g = the acceleration due to gravity.

This criterion cannot be applied directly to the problem at hand, since the density and velocity gradients are not obtainable from the data. Hence, it is necessary to modify the criterion so that it will be expressed in terms of observed quantities. Linear velocity and density gradients were assumed over some characteristic (but unspecified) length, L, obtaining instead of Equation (2), the expression,

$$\theta = -\frac{gL}{2\,U^2} \times \frac{\Delta\rho}{\rho} \quad\text{(3)}$$

or, modifying the criterion by the factor, $-\frac{1}{2}$,

$$\theta = \frac{gL}{U^2} \times \frac{\Delta\rho}{\rho} \quad\text{(4)}$$

in which U is the mean relative velocity between the two fluids and $\Delta\rho$ is the difference in density between the current and the still water. Equation (4) will be recognized as the product of a Froude number and a density ratio, two familiar dimensionless quantities.

Since L is not determinable from the data, it was postulated that it is some dimension similar to Prandtl's "mixing path", or the distance through which a particle of fluid moves into the surrounding fluid when effecting a transfer of energy, and that this distance is dependent on the mean velocity, U, of the current, and the kinematic viscosity, ν, of the liquid composing the current, as follows: $L \sim \frac{\nu}{U}$, or,

$$L = k\frac{\nu}{U} \quad\text{(5)}$$

---

[27] "Einfluss stabilisierende Kräfte auf die Turbulenz", von L. Prandtl, Vorträge aus dem Gebiete der Aerodynamik und verwandter Gebiete, p. 1, Aachen, 1929.

in which k is a numerical constant. This expression merely amounts to assuming that the Reynolds number for this phenomenon is constant. Substituting Equation (5) for L in Equation (4) and again absorbing the constant in θ:

$$\theta = \frac{g\,\nu}{U^3}\left(\frac{\Delta\rho}{\rho}\right) \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which $\Delta\rho$ = the density difference between the stream and the still water in the reservoir; ρ = the density of the lighter liquid (reservoir water); and, ν = the kinematic viscosity of the lighter liquid.

Again taking advantage of the fact that all observations were made in the same reservoir and on the same liquids, Equation (6) can be further simplified by absorbing the constant quantities, g and ν, in the constant. Recognizing that any particle which is entirely borne, surrounded, and supported by a liquid over the range of action studied should be considered a part of that liquid and as affecting the properties of that liquid, $\frac{\Delta\rho}{\rho}$ could be computed from the data given, but it is sufficient to note that this ratio is expressed with sufficient accuracy over the range of values of n considered by the expression, $\frac{\Delta\rho}{\rho} \sim n$, or,

$$\frac{\Delta\rho}{\rho} = k_2 n \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

in which n = the silt load, in percentage by weight, of the total sample; and k_2 = a numerical constant. This leaves only U to be converted into the form of some quantity given in the data studied.

In any given channel, U will be dependent on the flow, the exact proportionality being unknown, but unimportant for immediate purposes, since the order in which the values of the final criterion and of the critical number arrange themselves will be unchanged by any relation that may logically be assumed. As a matter of convenience, the relation was assumed that would hold if the flow were in accordance with the Froude law, $Q \sim U^3$; or,

$$Q = k_3 U^3 \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which Q is the flow of the river, in cubic feet per second; and k_3 is a numerical constant. Substituting Equations (7) and (8) in Equation (6) (absorbing the constants, k_2 and k_3 in C):

$$C = \frac{n}{Q} \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which C is a numerical criterion of mixing.

Ten peak flows were selected from Fig. 2 of the paper and C was computed by Equation (9). The results are given in Table 6. It will be noted that whenever there was a silt flow through the reservoir, C was greater than 200×10^{-6}, and, in each case, when there was a peak flow at Grand Canyon which was not followed by a silt flow through the reservoir, C was less than 140×10^{-6}. Thus, the critical value of C for the reservoir condition in 1935 was between these values. The critical value of C for the final conditions of a full reservoir, or for some other reservoir, will not necessarily lie between these same limits, but the same form of criterion will hold.

An analysis of recorded silt flows through Elephant Butte Reservoir, New Mexico, for 1919, 1923, 1927, 1929, 1931, 1933, and 1935 shows that the same form of criterion applied to that reservoir for each of these years except 1929. The critical value of C found for this reservoir is approximately twice that found for Lake Mead. The cause of this discrepancy is being made the subject of further study, but undoubtedly this difference is due in part to the different sizes and settling rates of the silt particles entering the two reservoirs. A river that carries a large percentage of fines in its silt load would not drop as much of its load on entering a reservoir as one carrying a smaller percentage of fines and, hence, would maintain a density great enough to cause a silt flow through the reservoir with a comparatively small total silt load.

The criterion as used is dimensional and is not unique, and, therefore, is not a true criterion in the strictest sense; nevertheless, it is felt that the significance shown by the ratio, $\frac{n}{Q}$, in the cases tested is not entirely fortuitous.

As the bottom gates of Boulder Dam are now closed and, in all probability, the quantities of water discharged will never be great enough to raise the silty water to the outlet towers in easily detectable quantities, it would be necessary to detect a silt flow through the reservoir in some other manner, and there is no reason to believe that such flows will not occur in the future, the muddy water forming a submerged pool near the dam. This might be done by lowering a photo-electric turbidimeter unit into the reservoir or (as most silt flows through a reservoir occur in the summer, when the river water is warmer than the bottom reservoir water) by lowering a resistance thermometer. If it was desired to study the application of Prandtl's theory of flow as quoted, or some of the similar theories, it would be necessary to make velocity and density determinations over cross-sections of the current and the immediately surrounding reservoir. Since, to the best of the writer's knowledge, no device has been developed for indicating on the surface the density of water at any considerable depth, it is necessary to resort to sampling for density determinations, which would allow analyses to be made to determine what caused the density difference and from what tributary or part of the system the contributing causes arose.

The whole forms an interesting problem. Any possibility of increasing the life of a reservoir by training silt flows through it must certainly wait on a fuller understanding of the phenomenon, an understanding to be obtained only by careful observation and study of such phenomena whenever and wherever they occur. Theories and laboratory studies must be substantiated by field data before full reliance can be placed on them.

The authors mention the flow of unmixed or of partly mixed river water through Lake Mead. This is entirely in accordance with theory. As may be seen from Equation (2) the vertical distance, y, over which density and velocity gradate, may have any value from nearly zero to infinity. Conditions might exist in which a stable current would be accelerated, causing mixing until the relations of $\frac{d\rho}{dy}$ and $\frac{du}{dy}$ were such that stability was again reached. After such acceleration and mixing, stable conditions might not be reached a second time, and one would have the case of a silt flow through part of the reservoir followed by mixing and eventual deposition at an intermediate point between the river and the dam.

The author's estimate of the silt carried through Lake Mead by the recorded flows is conservative. Experiments made at the National Bureau of Standards[28] show that clear water will scour a sand bed faster than water carrying fine silt, due to the cementing action on the bed material of the fine particles carried in the turbid water. The method used by the authors of subtracting the load scoured from the river bed below the dam from the total load carried by the silty water gives results which are low by an appreciable amount.

D. M. Forester,[29] M. Am. Soc. C. E. (by letter).—The passage of turbid waters through reservoirs is a phenomenon which has seldom been considered and, in fact, generally not known. Quite often it is assumed that the discharge of turbid water or silt through the discharge gates has been the result of current changes and slides within the reservoir. The flow of turbid water with its apparent resistance to mixing is a common occurrence in settling or clarification basins of water treatment plants. During the early stages of the filling of Lake Mead, when light conditions were satisfactory, the writer could distinctly see the flow of turbid water along the old river channel when observed from an altitude of 300 or 400 ft above the stream bed.

The records of the water treatment plant at Boulder City, Nev., with its intake approximately 1 000 ft down stream from the discharge portals, very closely confirm the observation at the Willow Beach gaging station. These records do not, however, indicate a noticeable variation in the total hardness content of the water during the periods of high turbidity. Analysis of Colorado River water since February, 1935, have recently become available for public inspection in the offices of the U. S. Geological Survey.[30] These analyses show wide variation between the inflow to Lake Mead and the outflow from Boulder Dam. During the first year of storage in Lake Mead the range of the total dissolved solids at the Willow Beach gaging station was 57% of that at Grand Canyon. During the second year the range was 39 per cent. The first-year range at the Grand Canyon gaging station was from 242 ppm to 1 332 ppm and, at Willow Beach, from 276 ppm to 897 ppm. During the second year, the range at Grand Canyon was from 258 ppm to 1 215 ppm and at Willow Beach from 393 ppm to 762 ppm. The gate in the tunnel was closed on May 1, 1936, three months after the beginning of the second year.

[28] "Experimental Study of the Scour of a Sandy River Bed by Clear and Muddy Water", by Chilton A. Wright, M. Am. Soc. C. E., *Research Paper No. 907, Journal of Research*, National Bureau of Standards, Vol. 17, No. 2, August, 1936.

[29] With U. S. Bureau of Reclamation, Yuma, Ariz.

The dissolved solids and the suspended solids entering and flowing from the lake appear to vary in somewhat similar manner and both indicate that the mixing action between the inflowing water and the water within the reservoir is not pronounced over a short time period.

A statement by O. A. Faris, M. Am. Soc. C. E.,[31] that the flow of silt along the reservoir bottom is due to its having a greater specific gravity than the main body of water in the reservoir, would appear to be conclusive. However, the discharge of turbid water does not occur at all times. At Lake Mead, from March 1 to October 31, 1935, the inflow was never less than 0.11% by weight (1 100 ppm) of suspended solids, the maximum being 5.09% (50 900 ppm) and averaging 0.91% (9 100 ppm). The outflow suspended solids content varied from 2.16% to 0.002%, averaging 0.17%, indicating a deposition of 0.74 per cent. At periods of maximum inflow of suspended solids and corresponding maximum outflow, the indicated deposition was much higher.

From present available information it would appear that the flow of turbid water through a long reservoir is dependent upon the quantity of suspended solids and their particle size. The degree of concentration would directly affect the specific gravity of turbid water. The flow would also be affected, to a lesser degree, by temperature conditions and perhaps by dissolved salts.

Comparison of deposition of the various particle sizes was not given by the authors; however, it is reasonable to assume that deposition of suspended solids would be in proportion to their size.

Any steps which may ultimately lead to the maintenance and conservation of original reservoir capacity cannot be otherwise than valuable. It is the writer's opinion that other economic values, especially in irrigation and municipal supplies, usually would outweigh the advantages secured by increasing the silt discharge through the normal, or low-level outlets.

A. D. LEWIS,[32] ESQ. (by letter).—Several features treated in this paper have been described by the writer in connection with similar occurrences in South Africa.[33] It should be noted that for several years past the standard practice at Lake Arthur Reservoir has been to remove a portion of the incoming silt through the valves during the flood by a process which is termed "bottom-flow tapping." There cannot be the least doubt that in certain circumstances there is a flow of flocculated silt along the bottom of the reservoir under the comparatively clean water. Observations as to the conditions of the actual flow along the bottom at different points along its course are exceedingly difficult, especially in the case of reservoirs in South Africa which are fed by very flashy floods in intermittent rivers. As far as local observations have gone, it appears that in small floods the depth of the flow of concentrated silt along the bottom is seldom greater than 3 ft within 0.75 mile from the dam walls, and its velocity is probably less than 0.5 ft per sec. The analysis of the silt that reached and passed through the valves given in *Communication No. 5*[33] showed that most of it was flocculated clay. After deflocculation, 78% consisted of particles of smaller diameter than 5 microns, and 83% of these particles were of smaller diameter than 2 microns.

The first conclusion one is inclined to draw is that bottom flow is essentially associated with flocculated clay. The experiments and observations in *Communication No. 5,* suggest some reasons why bottom flow should be possible with flocculated clay in certain states of concentration. When the flocculated clay occurs in concentrations greater than a lower limit which lies between 1.5% and 5% and less than an upper limit which is about 25%, it appears to form with the water enclosed a separate mobile liquid with a defined boundary. It is possible that in concentrations greater than the lower limit the flocculated particles are so close together that they are capable of some cohesion, which increases as the concentration increases and makes the escape of the enclosed water more difficult and the settlement of the particles in still water slower. While the flocculated mass is between these approximate limits of concentration it has a mobility which permits its flow as a separate liquid with a sharp boundary surface. The conditions of flow would naturally be governed by such factors as the concentration and temperature of the liquid and the slope and shape of the bottom of the reservoir.

Flow becomes very sluggish and suddenly almost ceases near the upper limit of concentration, which the writer has termed the "critical point," and the concentration at this critical point is generally about 19 lb per cu ft. At this point the process of settlement might be said to give way to a process of compaction. In concentrations less than about 1.5%, the top particles settle at a rate of about 2 ft per hr without impeding each other, and they pile up on the bottom into a mass which is probably not very mobile and, therefore, not capable of producing bottom flow. In concentrations between 1.5% and 5%, a sharp surface forms at a position which is farther from the bottom as the concentration increases. In concentrations greater than 5%, the sharp surface forms at the top and no independent settlement of particles is possible even at the top; the silt settles as a whole with a sharp upper surface. If the liquid entering the reservoir, and having a concentration of flocculated silt greater than the lower limit, can glide smoothly under the clear water already in the reservoir without dispersion or mixture with the clean water (which would reduce the concentration to less than 1.5%), then it is possible to picture the mobile liquid flowing along the bottom of the reservoir with just sufficient turbulence to prevent settlement, and a concentration beyond the "critical point" of about 25%, until it is checked at the dam, if no great discharge is taking place through the outlets of the dam. There, in the stiller water, settlement will occur, and the time of settlement to the "critical point" is represented by the formula:

---

[32] Director of Irrig., Union of South Africa, Pretoria, Union of South Africa.

[33] *Communication No. 5* to the Second Congress on Large Dams, Washington, D. C., 1936, entitled "Silting of Four Large Reservoirs in South Africa."

$$t = \frac{c\,L}{15} + 1.2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

in which t is the time of settlement, in hours, to the "critical point"; c is the initial concentration, expressed as pounds of dry silt in 1 cu ft of silty water; and L is the original length of the silty column, in inches.

If the silty concentration is not drawn off within this time, the mass will lose its mobility and will not flow through the outlets. A certain degree of concentration by settlement at the dam wall is necessary; otherwise, an unnecessary quantity of water will be wasted in getting rid of the the silt. In the actual practice of bottom-flow tapping at Lake Arthur Reservoir (although, actually, a maximum of 25% concentration has been obtained in the liquid extracted), in endeavoring to secure the maximum extraction of silt with the minimum wastage of water by regulating the opening of the bottom valves, it has seldom been possible to achieve a greater concentration than 15% over a long period. If, therefore, the water entered the reservoir with a concentration of 5% of flocculated clay, it would be necessary to waste about one-third of it in order to get rid of the silt that reaches the wall by means of bottom-flow tapping; but it should be remembered that, even if this silt had remained in the dam, it would have entrapped a considerable volume of water which could never be extracted as clear water through the valves.

With the foregoing picture of the process of bottom-flow tapping in mind, it is interesting to examine Table 1 and Fig. 2 of the paper. In no case was there any bottom-flow discharge when the percentage of suspended matter entering the reservoir was less than 1.7 per cent. There was no such discharge during the four months of high flow from May to August; all the discharges were during small floods in the remainder of the year. This might be due to the fact that the saline content of the water entering the reservoir was sufficient to cause flocculation during the latter periods, but not sufficient during the former period, as would appear to be indicated by Fig. 2(a).

If, however, there was flocculation during the former period, the concentration was usually less than 1.5% and, therefore, too low to permit bottom flow. According to Table 1, if the last six days of August, which had their effect in September, are excluded, on only eight days in the four summer months did the concentration exceed 1.5 per cent. The highest concentration during this period was on June 2, namely, 1.90%, and as the flood at that time was about 50 000 cu ft per sec, it is possible that even if the clay were flocculated, the turbulence on entering the reservoir would have been sufficient to reduce the concentration to less than 1.5 per cent.

It is assumed that throughout 1935 all the discharges occurred through outlets very low in the dam, which would permit extracting the silt below the level at which concentration would occur in still water above the dam. It is understood that, at a later date, all discharges were at a much higher level, and if the foregoing "picture" is correct, it is to be expected that the bottom-flow discharge will not again take place until the reservoir has been filled with settled silt nearly to the level of the outlets that are in use.

In view of the nuisance that such silt may be when the water is drawn off for domestic purposes or for driving turbines, a practical consideration is that it is desirable to have low-level valves that can be opened sufficiently to discharge at a concentration of about 15% when bottom flow is taking place, and, secondly, that when clear water is required from the reservoir for domestic or other purposes reliance should not be placed solely on valves at low levels which might tap the bottom flow, but a series of valves should be provided at such levels that clear water can be tapped at higher levels during periods of bottom flow.

G. C. Dobson,[34] M. Am. Soc. C. E. (by letter).—After reading this interesting paper, it occurred to the writer that an examination of the many reservoir silting surveys made by the Section of Sedimentation Studies, Division of Research, United States Soil Conservation Service, should throw considerable light on the subject of the passage of silt-laden water through reservoirs. It would seem that, if this silt-laden water passed through the reservoir as an underflow or density current along the bottom, the distribution of silt within the reservoir would be entirely different than if it was diffused generally with the water already stored in the reservoir. If this phenomenon of underflow appeared only rarely, under certain special conditions, but occurred where these special conditions involved very heavy silt loads, the arrangement of silt in the bottom of the reservoir should indicate this condition also.

Fifty-five detailed reservoir surveys, distributed fairly well throughout the United States, have been made in the three years, 1935, 1936, and 1937. The objectives of these surveys did not include the study of underflows or density currents so that any evidence found on this subject is incidental. A thorough analysis of this mass of data and a gathering of exhibits to prove certain theories was not the object of this examination, the intention being rather to review these data and, in a general way, to reveal what they indicate as to the existence of this phenomenon not only in the Southwest, but in other sections of the United States. Several of these reservoirs are too small to be of any benefit in this study. Some others are of such pronounced "channel" type that they are of little value in studying this distribution of silt. However, there are a sufficient number left to give a fair picture of the conditions throughout the country.

---

[34] Asst. Head, Sedimentation Studies, Div. of Research, Soil Conservation Service, U. S. Dept. of Agriculture, Washington, D. C.

Sufficient time has not elapsed since the impounding of Lake Mead to warrant a silting survey, although a complete original-capacity, contour survey has been made for this purpose by the Soil Conservation Service. A detailed survey of Elephant Butte Reservoir was made in 1935 in cooperation with the U. S. Bureau of Reclamation. This reservoir has been noted by a number of writers as the outstanding example of underflow currents in the United States.

In studying the profile of Elephant Butte Reservoir, showing the maximum depth of silt above the valley floor, it is noted that because of the great fluctuations in the elevation of water surface and the consequent flooding and drying of the area above the narrows, little can be learned from this section of the profile. Thus about 28 miles of the upper part of the profile is eliminated, leaving about 15 miles from the lower end of the narrows, which are about five miles long, to the dam where the distribution of silt should show the effects of density currents if they exist. At the lower end of the narrows the maximum depth of silt on the valley floor is 30 ft. This depth decreases to 12 ft at a point 7 miles down stream where it begins to increase somewhat irregularly until it reaches a depth of 20 ft just above the dam.

The most noticeable point, however, in the arrangement of silt in this reservoir is shown on the cross-sections taken between the dam and the narrows. Regardless of the depth of the silt, or the width or shape of the cross-section, the upper surface of the silt is practically level.

Pausing for a moment to consider what one would expect to find in the distribution of silt, it would seem that, if the silt-laden water flowing into a reservoir entered into general diffusion with the water already stored, a section across the reservoir should show a distribution of velocity which, at least, would be somewhat similar to that within a section taken across the river above its entrance to the reservoir. The area of the reservoir section would be so large compared to the area of the river section that the resulting average velocity would be very low, and it would be difficult even to surmise whether the difference between maximum and average velocities would be more or less pronounced than within the river section. Furthermore, it would seem logical to suppose that the part of the reservoir section formed by the submerged river channel would affect the distribution of these velocities, but that this effect would become less and less as the reservoir sections became larger. In the case of a meandering stream channel in a submerged alluvial bottom, where the channel formed only a small percentage of the total reservoir cross-section, the influence of the channel would be lost, and the slow currents moving down the reservoir would tend to take the shortest route, disregarding the meanderings of the channel. If this is true, the depth of silt within a cross-section would be affected considerably by the depth of water although not necessarily directly proportionally to it; probably it would be more nearly proportional to some power of the depth, slightly greater than one. There would be a tendency for the low places, particularly the channel, to fill faster so that the upper surface of the silt would tend to approach a level line in cross-section.

If the silt-laden water were to pass through the reservoir as an underflow, it would seem very probable, because of the greater density, that at any section within the reservoirs this underflow would fill the low places, and its upper edge, if it were clearly defined, would be level from bank to bank. If, as supposed, these underflows occur only at flood time, they would be of sufficient volume to overflow the submerged channel, but the cross-sectional area of the underflow would form only a small part of the area of the total cross-section. The influence of the submerged channel on this flow would be much more marked than on a diffused flow so that, it seems probable, the maximum velocity of this underflow would follow the submerged stream channel even in its meanderings in a submerged alluvial valley. Deposition of sediment from an underflow would undoubtedly occur more or less continuously in its flow down the reservoir and, on a cross-section, the depth of this deposition should bear about the same relation to the depth of the underflow that it would to the total depth of the reservoir in diffused flow. Here, again, there would be a tendency to fill the low places faster, causing the upper surface of the silt to approach a level line. The point to be noted, however, is that, in this latter case, the tendency would be much stronger than in the former and it would seem probable that in a comparatively short time underflow conditions would produce a level floor of silt in the reservoir, while in the case of a diffused flow, the tendency would be so slow that it might not reach this condition until the reservoir was practically full of silt.

Because of the great difference in the effective velocities in these two types of flow one would expect to find a marked difference in the longitudinal distribution of the silt. The low velocities of diffused flow should produce heavy deposits in the upper part of the reservoir gradually decreasing in depth, possibly extending all the way to the dam. The pattern would depend, of course, on many factors, such as the length of travel and general shape of the reservoir. The higher velocities of density flow would be expected to carry the silt much farther into the reservoir on an average and probably all the way to the dam, it might even form the deepest deposits immediately above the dam.

Since the level floor of silt was the most striking feature found in the survey of Elephant Butte Reservoir, this condition was looked for in other reservoirs. In only two other cases was it found to a pronounced degree. These examples were the San Carlos Reservoir, on Gila River, in Arizona, and the Gibraltar Reservoir, near Santa Barbara, Calif. Another striking feature was noticed in the profile of the Gibraltar Reservoir. This reservoir is only about four miles long. The upper half of the profile is very irregular for reasons somewhat similar to those described for Elephant Butte, but in the lower 7 000 ft, the depth of silt increases down stream from 27 ft to 85 ft at the dam. The gradient of the channel in this reservoir is very steep which probably accounts for this rapid increase in silt toward the dam. The lower 7 000 ft of this reservoir seems to be rapidly approaching a level floor of silt longitudinally as well as transversely. The down-stream slope of the silt surface is only about 0.00076 whereas the effective slope of the original channel is about 0.0062.

Aside from these three reservoirs, the surveys show no marked cases of level silt surfaces. At the other extreme is Black Canyon Reservoir, on Payette River, near Emmett, Idaho, where the cross-sections show the deepest deposits of silt at the points of greatest depth, and where these depths of silt are only slightly greater than proportional to the total depth of water. This condition is shown generally throughout the reservoir. In profile, heavy deposits are found in the upper parts of the reservoir as would naturally be expected of a stream carrying sand bed load. These delta deposits extend a considerable distance down into the reservoir. From the lower end of the delta to the dam, there is a gradual lessening in the average depth of the silt.

A condition prevailing in many reservoirs, particularly in those of the Piedmont Region in the Southeast, is a distribution of silt indicating in general a diffusion of the silt-laden water with the water already stored in the reservoir, but showing evidence also that at times there have been underflows. It must be admitted that this evidence is not very pronounced and might be due to other causes. In many of these reservoirs, without regard to length, or the varying shapes of the cross-sections, the profiles, when taken along the thalweg or lowest points of the submerged channel, show a surprisingly constant depth of silt. This is generally true regardless of the meanders of the channel in a submerged alluvial plain. On the cross-sections the depth of silt within the submerged channels seems to be considerably greater than one would expect as a result of settlement from diffused flow. Outside the channel, the distribution of silt seems to be nearly proportional to the depth of water in the reservoir, but there are some places where deposition on the banks of the submerged channel is greater than at other points on the valley floor, indicating that there is some tendency of the silt to deposit in formations similar to natural levees characteristic of the banks of alluvial streams. In a few cases, this heavier deposition was found on what appeared to be a natural levee in the original bottom of the reservoir. One explanation of this might be that for some unknown reason the velocity of the underflow at these points was greatly decreased, resulting in an enlargement of its cross-section and the overflowing of the submerged channel with a still greater reduction in the lateral velocities causing rapid deposition on the near banks. However, as these apparent natural levees of silt are not generally prevalent and are not very pronounced, their value as evidence is questionable.

Another very noticeable feature in these reservoirs is that a negative gradient in the profile of the original channel, as when emerging from a deep pool, is parallel to the silt surface, which shows as great a depth at the high point as at the low. If the distribution of silt in a reservoir was greatly affected by mass flow of the silt itself, it would be expected that the pools in the original channel would be filled and the high points would show less silt. Further evidence bearing on this question of mass flow of the silt is to be found on the cross-sections of the great majority of these reservoirs where almost uniform layers of silt of considerable depth exist on slopes many times steeper than the gradient of the river or the floor of the valley.

The phenomenon discussed in this paper is too little understood by the Engineering Profession. The authors have rendered a worthy service in presenting the subject in such a thought-provoking manner.

William W. Rubey,[35] Esq. (by letter).—The flow of muddy or saline or cold water through lakes is of interest to all who are concerned with the natural processes of streams. The formation, in 1937, of a committee of the National Research Council for the study of density currents is evidence of the wide interest in this subject among engineers, physicists, and geologists. To geologists, bottom currents through bodies of standing water are important because, if such currents are common to-day, they must have influenced materially the character and distribution of sediment deposited on (or swept from) the beds of lakes, estuaries, and seas in the past. The best means of appraising the importance of these currents in the past is a knowledge of the conditions that accompany their formation to-day. This paper with its data on muddy flows through Lake Mead is thus a very welcome contribution.

From what is known about the conditions that determine whether fluids of different density will mix turbulently or flow separately, it appears that, for simple homogeneous fluids, the controlling factors are the differences in density and velocity of the two fluids,[36] and that, for complex gradational fluids, the controls are the density gradients and velocity gradients in transitional layers.[37]

The available data for Lake Mead reveal nothing whatever about the thickness of a possible transitional layer or layers between lake water and muddy current. Studies in progress by the U. S. Bureau of Reclamation at Lake Mead, and by others elsewhere, should eventually furnish the required information on this point; but until this information has been assembled, it seems permissible to consider the lake water and the muddy current as two essentially homogeneous fluids, only one of which has an appreciable velocity. Thus, when the density difference between them is great enough and the current velocity low enough, the two fluids are separated by a surface on which waves move down stream. Increasing the current velocity or decreasing the difference in density breaks up these waves and causes mixing.

[35] Geologist, U. S. Geological Survey, Washington, D. C.

[36] "Handbuch der Ozeanographie," by O. Krümmel, Vol. 2, p. 62, 1911.

[37] "On the Stability of Superposed Streams of Fluids of Different Densities," by S. Goldstein, *Proceedings*, Royal Soc., London, Vol. 132, Ser. A, pp. 524–525, 1931.

By this concept, the boundary between lake water and muddy current is determined by the same principles that govern wind waves at a water surface[38] and current ripples on a sandy stream bed.[39] At high winds the tops of the waves break into fine spray; at high current velocities the sand ripples are swept away and the sand is picked up and carried along, mixed with the stream water. Just as the differences of density between muddy currents and lake water are much less than the differences of density between water and air or between sand and water, so the critical velocities that cause instability and mixing of the muddy currents should be much less than the critical velocities that make wind waves or sand ripples unstable.

The available data permit no close estimate of velocities of the muddy currents that moved through Lake Mead in 1935, but published and unpublished records of the U. S. Geological Survey and the Bureau of Reclamation afford a basis for computing approximate densities of the inflowing and outflowing waters. Inasmuch as water densities were almost certainly one of the fundamental factors that controlled the existence of muddy currents that year, these data appear worth recording in connection with this paper.

The principal variations in density or specific gravity of the river water were those caused by variations in the content of suspended matter. Values of density at different concentrations of suspended matter, calculated on the basis of 0.996 gram per cu cm for pure water (at 84.2° F) and 2.6 grams per cu cm for suspended solids,[40] agree fairly well with the authors' observed values (see Table 2), giving a maximum disagreement of 0.0022 gram per cu cm, and an average of about 0.0010 gram per cu cm. (These disagreements are probably due, in part at least, to differences in salinity.) Assuming these densities for water and solids, 1% of suspended matter should make a density increase of 0.0062 gram per cu cm, 3%, an increase of 0.0188 gram per cu cm, and 5%, an increase of 0.0217 gram per cu cm.

Two other relatively minor causes of variation in density of the river water need to be considered—salinity and temperature. The effects of salinity were estimated (see heading in paper, "Dissolved Matter") on the assumptions that daily sulfate determinations are approximately proportional to total dissolved matter and that total salinity affects density about the same as if it were all sodium sulfate (0.0011 gram per cu cm for

1 000 ppm). The resulting estimates of density are believed to be in error by not more than 0.0006 and commonly about 0.0003 gram per cu cm.

Observations on temperature of the river water at Grand Canyon Gaging Station began April 20, 1936, and unpublished records are available from that date through July 31, 1937. For the period, April 20 to July 31, for which there is a 2-yr record, the 1936 and 1937 records show closely comparable water temperatures day by day, and it seems fair, therefore, to assume that water temperatures changed in about the same manner in 1935. The detailed records show fair agreement with uniform changes from 43° to 75° between March 1 and July 1, from 75° to 81° between July 1 and August 1, from 81° to 75° between August 1 and September 1, and from 75° to 52° between September 1 and October 31. Densities estimated from uniform rates of temperature change between these respective dates show a maximum of 0.0006 and a mean departure of about 0.0002 gram per cu cm, from densities estimated from the detailed temperature records. For the Willow Beach Gaging Station below Lake Mead, the water temperatures used were those of the water discharged from the lake during the same period.[41]

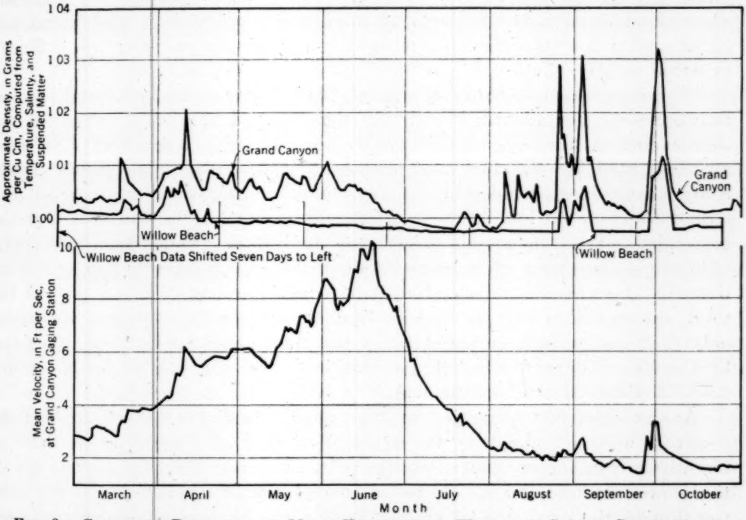

FIG. 6.—COMPUTED DENSITY AND MEAN VELOCITY OF WATER AT GAGING STATIONS ON COLORADO RIVER ABOVE AND BELOW LAKE MEAD, MARCH 1, TO OCTOBER 31, 1935

By combining the effects of the three variables (suspended matter, salinity, and temperature), the daily densities of the water at the two gaging stations above and below Lake Mead were estimated for the period, March 1 to October 31, 1935. These calculated values of density are believed to be in error by not more than about 0.002 and commonly about 0.001 gram per cu cm.

---

[41] See Fig. 3, p. 737.

Fig. 6 shows clearly that the density of the river water at the upstream (Grand Canyon) station was not the sole factor that caused muddy currents through Lake Mead. Likewise, if the water discharged from the lake between periods of muddy water is taken as representative of the lake water, the difference in density between river water and lake water was not the sole factor either. It is true that densities greater than 1.011 grams per cu cm at Grand Canyon were always accompanied by muddy discharges through the reservoir. However, from the duration of individual muddy flows, it is clear that, at times, densities of 1.005 to 1.008 grams per cu cm (and density differences of 0.004 to 0.010) were sufficient, whereas on June 2, for example, a calculated density of 1.0104 grams per cu cm and a density difference of 0.012 grams per cu cm were not sufficient to cause muddy flows.

Of course, these densities of the rapidly flowing water at Grand Canyon Station were not identical with the densities of the same water in the slower current through the reservoir down stream. Important differences are suggested by the fact that the muddy discharges at Willow Beach Station contained considerably less suspended matter than was carried past Grand Canyon Station. This suggestion is confirmed by the fact that the suspended matter in muddy discharges at Willow Beach consisted chiefly of particles less than 20 microns in diameter (see heading, " Sizes of Particles "), whereas this finer sediment at times was only a small part of the total suspended matter at Grand Canyon Station up stream. Evidently, only the finer particles brought in by the river could be kept in suspension by the slower current through the reservoir, and the coarser sediment was dropped somewhere along the way.

Accordingly, the densities of the muddy water after it reached the reservoir were estimated on the assumption that all suspended particles at Grand Canyon larger than 20 microns in diameter (Fig. 2) settled out in the slower current below. These estimated densities show no closer relationship to the existence of muddy flows than do densities calculated from total suspended matter at Grand Canyon. Density differences of less than 0.002 gram per cu cm (estimated from the finer material only) resulted in muddy flows in March and April, but differences of 0.003 to 0.004 gram per cu cm did not cause muddy flows in June and August.

The authors carefully show that the sizes of suspended matter at Grand Canyon were determined in the laboratory from carefully dispersed samples, whereas in the natural river water the finer sediment was partly flocculated into larger masses which settle more rapidly. Inasmuch as the salinity of the river water changed during this period, the degree of flocculation presumably changed also. Thus, the finer material brought into the reservoir in June and August may have been flocculated into larger masses that were dropped by the slower current, with the coarser sediment. If so, the density of the muddy water, after it reached the reservoir, cannot be estimated from the quantity and size of sediment at Grand Canyon without data on variations in the degree of flocculation also.

Whatever may have been the effect of variations in the degree of flocculation, variations in the velocity of the muddy currents themselves were presumably a contributing factor in the formation of currents through the reservoir, for the velocity of these currents would be expected to vary somewhat depending on the density and stage of the incoming water. However, reliable estimates of rate of flow through the reservoir are difficult to obtain from existing data. The earlier muddy flows of 1935 required about 5 to 7 days, and the later flows about 7 to 9 days, to travel from Grand Canyon to Willow Beach. During this time the length of the lake increased many miles, and variations in velocity through it cannot be estimated with the degree of accuracy required to test their effect.

Lacking reliable data on the velocities of currents through the lake, it seemed that the velocities of incoming water up stream might possibly be a factor in the formation of the muddy currents. Accordingly, the mean velocities at Grand Canyon Station were read from daily gage-height records. These mean velocities (see Fig. 6) are probably fairly accurate because, during the period, February 26 to November 3, 1935, the cross-section and mean velocity of the stream at Grand Canyon Station were measured on 117 days (from unpublished records of the U. S. Geological Survey).

On comparing water densities at the two stations with mean velocities at Grand Canyon Station (Fig. 6), it is evident that low or intermediate velocities above the lake accompanied flows of muddy water through it and that, in general, high velocities accompanied the absence of such flows during May and June. It is equally evident, however, that the mean velocities and densities at Grand Canyon Station afford no satisfactory criterion for the existence of the muddy currents. The period of low velocities and high densities, August 6 to 18, was not followed by muddy discharge through the reservoir, although velocities were then lower than, and densities were as great as, those that caused muddy flows in March and April.

The evidence presented herein is largely negative. The available data show no well-defined relationship between the existence of muddy currents through Lake Mead, on the one hand, and the density, density difference, or density and velocity at Grand Canyon, on the other. It seems clear that, in future investigations of the conditions that accompany muddy currents through a lake, direct observations on the degree of flocculation of sediment in the incoming water, and on the velocity or the slope of the muddy currents themselves, will also be desirable.

J. C. STEVENS,[42] M. AM. SOC. C. E. (by letter).—In calling to the attention of the profession one more interesting phenomenon with which the silt problems of the West are replete, the authors of this paper have "started something."

---

[42] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

The silt problems in the West are manifold. How and where does silt originate? How is it transported? What space does it occupy in reservoirs? What part do the cultural activities of Mankind play? What steps can be taken to hold it intact in the basins? Can it be prevented from entering reservoirs, or can it be removed therefrom once it has entered?

The phenomenon so interestingly described by the authors is only one of a great number of silt problems that should be "run to earth" and made controllable in some degree by human agencies.

The records of 1935–36 indicate that during moderate and low-water periods of inflow, a slug of fine silt brought into the reservoir by a tributary may remain intact and pass entirely through the reservoir. At Lake Mead these slugs appeared to originate in the basin of the Little Colorado River. There is no reason to doubt that the same part could be played by the San Juan River or by the Virgin River if a summer cloudburst could produce sufficient run-off with an attendant quantity of fine silt.

The spring floods on both the Colorado River and Rio Grande originate from melting snows in the upper reaches of the water-shed. The sediments at such times are predominately coarser than those on the lower tributaries. In June, 1935, the average daily load passing Grand Canyon was about 1 800 000 tons per day of which only about 400 000 tons, or 22%, was less than 20 microns in diameter. The flood of September 29 to October 5, however, brought in a maximum of about 2 000 000 tons per day, of which 1 800 000, or 90%, was less than 20 microns in diameter. The latter produced noticeable silt discharge whereas the former did not.

It is hoped that more data will be published regarding the silt flow through Elephant Butte Reservoir. The papers by Messrs. Lawson[5] and Fiock,[6] referred to by the authors, do not give details. The writer is of the opinion that if the silt flows of the past were compared with up-stream summer floods it would be found that most of these silt flows follow floods on Rio Puerco and Rio Salado, and, as in the case of the Colorado River, they will not coincide with the spring floods which carry the coarser material.

There appears to be no doubt that the phenomenon of silt discharge results from an intimate mixture of water and fines of such coherency that the specific gravity of the entire mobile prism is increased until it flows along the lowest channel of the reservoir, quite independent of the temperature differences between the reservoir and flowing water. The slowness with which fluids of different densities mix has been well demonstrated by some experiments on both liquids and gases made at the University of California. Diffusion among mixtures of varying densities was found to be surprisingly slow.

It appears that the stream of water-silt only issued from the reservoir through the tunnels with entrances at stream level. Since the tunnels were closed, no silt has been discharged, indicating that, at the dam, this mixture has been unable to rise the 250 ft necessary to flow through the penstocks or the outlet works.

Although the total quantity discharged was only 2.5% of that coming into Lake Mead in 1935, the fact that any at all was discharged is too important not to be investigated further. These fines probably would not occupy nearly so much space in the reservoir as an equal weight of coarser material; nevertheless, the question arises as to whether it might not have been worth while to have left gates in the tunnels that could be opened at such times, instead of having them plugged permanently. On other reservoirs, the proportion of silt that could thus be discharged might have greater significance and would raise the question as to the wisdom of maintaining stream-level outlets.

Another phase of this problem concerns the quality of the water passing through a reservoir in this manner. Such a concentration of fines may render the water unfit for irrigation on certain soils as it makes them "slick" and effectively seals them against air and water drainage. Prolonged use of such concentrates or intermittent use over long periods of time is quite certain to be detrimental to almost any type of soil; hence, from this standpoint, it might be better not to permit such silt slugs to pass through a reservoir.

Each basin must be studied on its own merits in these regards, in which the geological, chemical, mechanical, and physical factors must be analyzed carefully. All these problems of silt are of tremendous importance to the West and it is "high time" that an orderly, well-planned approach to their solution was begun without further delay.

In its report on "Drainage Basin Problems and Program, 1936," the National Resources Committee included as one of its principal study projects a thorough investigation of the silt problem in the Colorado River Basin, and recommended an early allotment of $1 000 000 with the understanding that several million dollars would ultimately be required for an extended period of research.

In order to secure co-ordinated results, it would seem essential that such an investigation be headed by an agency or board composed of the chiefs of the several Federal bureaus now engaged, independently, in investigating some phase of the silt problem, as well as a number of non-Federal engineers and scientists, to the end that the elements of engineering, hydrology, chemistry, plant biology, geology, and soil mechanics will be adequately represented and that co-ordinated conclusions will be secured.

The answers to some angles of this problem are being sought independently by certain Federal agencies, among them the Soil Conservation Service, the Forest Service, the U. S. Geological Survey, the Bureau of Reclamation, the Bureau of Agricultural Engineering, the Bureau of Plant Industry, and the Grazing Division. There is little or no co-ordination of effort among these agencies, however. A co-ordinating board would concern itself solely with the research phase of the problem and would enlist the services of all agencies concerned, including the several hydraulic laboratories. To the latter could be assigned special problems, while the field research could be conducted by Federal agencies. Such an investigation of the silt problems in the Colorado River Basin would be equally valuable for the Rio Grande Basin, and all other silt-producing basins in the Arid West.

C. S. JARVIS,[43] M. AM. SOC. C. E. (by letter).—Experience with operation and maintenance of numerous small reservoirs had led a number of engineers, including the writer, as early as 1914, to expect the passage of heavily silt-laden water as a separate stream through the clear water of large reservoirs. Regarding the small reservoirs as hydraulic models, they concluded that large reservoirs should respond to the treatment so commonly used for maintaining the capacity of small storage projects in arid regions, where both the erosion rate and the water values are relatively high. As early in his career as 1897, the late Arthur P. Davis, Past-President, Am. Soc. C. E., had proposed the use of such expedients as hydraulic giants and sluicing for the removal of such silt.[44]

Serious consideration was being given in 1914 to the plans for installing a flushing conduit to extend several miles up stream from the dam to the narrowest section of the storage basin, with a view to trapping the sediment and conveying it through the deepest part of the reservoir to the outlet. The prevailing opinion among the consultants was that the heavier, silt-laden inflow would follow the valley trough and would convey a considerable portion of the suspended load to the river channel and irrigation canals, thereby prolonging the life of the storage project and adding fertility to the irrigated land.

A corollary to the axioms recognizing the impoverishment of soils through erosion would acknowledge the values in soil fertility to be restored through desilting reservoirs by sluicing and spreading the suspended load upon the land surface.

In the writer's discussion[45] of "The Silt Problem of the Zuni Reservoir," a plan was outlined for maintaining a turbid outflow to keep pace with, and correct, the silting process. At that time (1920), the passage of turbid water through Elephant Butte Reservoir, if observed at all, had not been widely heralded. It is recognized that disadvantages would attend the silt-laden outflow, due particularly to increased wear of turbines and to silting of canals supplied from the reservoir.

Computations in connection with Fig. 2 disclose the fact that the occasions when turbid water was discharged from Lake Mead were a few days after heavily silt-laden inflow had occurred at Grand Canyon, with suspended matter representing 2% to 5% by weight. By inference, one may assume that it requires a pronounced difference in specific gravity of inflowing and impounded water to build up the inertia or momentum sufficiently to maintain the unmixed flow through the reservoir. As described by Mr. Fiock,[6]

---

[43] Cons. and Hydr. Engr., SCS, Washington, D. C.

[44] "Irrigation near Phœnix, Arizona," by Arthur P. Davis, *Water Supply Paper No. 2*, 1897, pp. 81–83.

[45] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 883.

"Observations have revealed that the silt-laden water flows along the bottom of the lake in a very thin sheet (less than 5-ft depth), or through the lowest portions of the floor of the Reservoir much as water itself flows under air, and apparently does this without diffusing into the water already in the lake, as it retains certain distinct characteristics which are evident and have been observed as it is discharged from the outlets."

If the 6 000 000 tons of silt discharged from Lake Mead during 1935 represent 2.5% of the average annual load brought into the lake, then the total annual silt inflow is about 240 000 000 tons, or nearly 660 000 tons per day, or 7.6 tons per sec. On the basis of 16 000 000 acre-ft of annual inflow, or nearly 22 600 cu ft per sec, the weight of average inflow, in tons per day, is 61 517 000. Therefore, it appears that the average load of suspended matter represents $\frac{660\,000}{61\,517\,000} = 1.07\%$ of the weight of water.

If it is necessary to maintain 2% or more of silt content in order to insure turbid flow through the lake, it would require some kind of turbulence, such as may be produced by dredging pumps or hydraulic giants, to displace the required 7 tons or more of sediment per sec, during the intermittent periods of operation. Obviously, for such conditions, the dredging would continue not more than one-half the time to keep pace with sedimentation, or proportionately less for partial benefits.

Let it be assumed that suitable types of floating dredging plants have been provided to agitate and to bring into suspension one-fourth of the annual silt inflow, or 60 000 000 tons, representing nearly 2 tons per sec throughout the year, but capable of greater output during actual working hours. Also, assume 1 000 000 acres as susceptible of irrigation from Lake Mead (about 500 000 acres in Imperial Valley, 100 000 acres in the Yuma Project, and 200 000 acres in Mexico, a total of 800 000 acres in 1936), the major portion of 60 tons per acre per yr would be en route to enrich the irrigated land.

If the amortized cost of installation, together with maintenance and operating expense for the necessary floating plant and mechanical equipment, should amount to \$2 000 per day, or \$730 000 per yr, the charge per acre served would be only \$0.73. The actual value of the fertile elements delivered with the turbid water should be several-fold more than the cost, while other benefits realized would be the prolonged usefulness of reservoir capacity, and the checking of accelerated channel erosion below Boulder Dam resulting from the recent clarification of effluent.

R. E. REDDEN,[46] ESQ. (by letter).—The Engineering Profession should indeed be grateful to Messrs. Grover and Howard for the presentation of facts and conclusions relative to the transportation of silt through reservoirs and the worth-while suggestion that a study be made of the little understood phenomena. It is in answer to the authors' invitation for discussion and related information that the writer submits data and conclusions on the passage of a flood through Echo Reservoir in Utah.

---

[46] Professional Engr. and Geologist, Coalville, Utah.

On August 6, 1934, a mud flow produced by a heavy local storm which hit at Rockport, Utah, about thirteen miles up the Weber River from Echo Reservoir, entered that body of water at 10:30 P.M., and 10 hr later, after apparently following the river channel, passed through the needle-valve gates below the dam. The flood water passing through the gates was reddish-brown in color, very thick, with suspended matter, and gave off a putrid odor.

From the automatic water-stage recorders on the river, and from data gathered by witnesses (including the writer) average velocities for the flood in the river above the reservoir and through the reservoir have been computed. The average velocity of the flood water above the reservoir was 4.4 ft per sec., whereas the average velocity through the clear water in the reservoir was 0.22 ft per sec.

The greater specific gravity of the flood water, due to the character of the suspended matter, is ascribed for its not mixing with the clear water of the reservoir. The intensely putrid odor of the flood water as it poured into the stilling-basin from the gates, is attributed to the gases locked up in the mass of suspended matter and is additional evidence that the two waters remained unmixed.

Floods are not uncommon in the mountainous valleys of Utah. They are of rather short duration, carry variable loads of débris and, in general, do no great damage; however, a few mud flows have taken human lives and caused considerable property damage. In the main, these mud flows have not been caused by the much over-worked word, "over-grazing." Burned over and over-grazed areas add to the intensity of the mud flow if centered within the local area of maximum precipitation. Field observations of mud flows suggest that they may occur on any steep area during a general or local storm where a localized belt within the general storm area receives a maximum precipitation in the form of hail, which is characteristic of flood-producing storms. Hail, as such, is not readily absorbed by the soil mantle; hence it piles up as temporary immobile precipitation, which is partly melted and lubricated by the "tapering-off" rain, a few minutes later, and rushes down the slopes, dragging with it a portion of the soil mantle to join together below in one mad rush down the local canyons.

Floods entering reservoirs built on streams in Utah have generally deposited their loads on the bottom of the reservoir; however, many instances are known in which the silt-laden waters have appeared at the outlet gates. These records show that this phenomenon is more noticeable on certain drainage areas, which gives rise to the question of the difference in the soil mantle, and which, in turn, is dependent upon the geology of the water-shed area.

It is expected that future studies will show that flood loads from certain formations of a particular geological age have a large influence upon the phenomenon of floods passing through reservoirs of clear water without intermixing.

Weber River and Echo Reservoir.—Weber River heads in the Uinta Mountains in Utah and drains an area of 732 sq miles above Echo Reservoir. It has a maximum discharge of about 4 000 cu ft per sec. The reservoir was built across the channel of Weber River and completed for a storage capacity of

74 000 acre-ft in 1930. On the day of the flood the reservoir held 4 100 acre-ft. The depth of the water at the dam and outlet was 30 ft.

During the spring run-off, the river, at times, carries considerable material in suspension. However, during these periods of high-water run-off, the water discharging from the needle-valve gates during the filling of the reservoir has remained clear, with few exceptions. Only part of the high water entering the reservoir is discharged for irrigation rights below the dam. The remainder is stored in the reservoir. The old river channel meanders over the floor of the reservoir and the length of the submerged channel, when the reservoir is at full stage, is about 4.5 miles. The temperature of the water discharging from the reservoir on July 26, 1934, ten days before the flood, was 60° F, whereas the temperature of the water in the reservoir, 0.5 ft below the surface, was 65° F. The maximum temperature of the atmosphere was 94° F, and the minimum was 44° F. No temperature tests were made on the day of the flood. During the late summer, when the reservoir is being emptied, the discharge water is slightly turbid.

Record of the Flood.—Between 3:30 and 3:50 P.M., on August 6, 1934, a typical thunder storm centered 1.5 miles west of the valley at Rockport. This heavy storm was part of a general storm which covered an area of about 100 sq miles. Floods came down eight short canyons west of the State highway and spread out over the narrow river valley. These mud flows lost their bed load before entering the Weber River, but retained their suspended load down the river and, for the most part, through the reservoir.

The distance from the center of the flood area on the Weber River to the U. S. Geological Survey water-stage recorder at Coalville, Utah, was 12 miles. The recorder showed the first abrupt rise at 8:05 P.M. The record of stream flow for 12 hr, beginning at 8:00 P.M., is as shown in Table 7.

TABLE 7.—FLOOD RUN-OFF, WEBER RIVER AND CHALK CREEK, UTAH

August 6, 1934	DISCHARGE, IN CUBIC FEET PER SECOND		August 7, 1934	DISCHARGE, IN CUBIC FEET PER SECOND	
	Weber River, at Coalville, Utah	Chalk Creek		Weber River, at Coalville, Utah	Chalk Creek
8:00 P.M.	26	....	2:00 A.M.	73	9.0
8:05 P.M.	227	....	4:00 A.M.	63	....
9:00 P.M.	246	1.5	6:00 A.M.	56	....
9:30 P.M.	....	56.0	8:00 A.M.	49	....
10:00 P.M.	201	40.0	9:05 A.M.	33	....
12:00 P.M.	105	14.0	9:30 A.M.	....	3.0

The average velocity of the flood water in the river over the distance of 12 miles was 3 miles per hr, or at the rate of about 4.4 ft per sec. The distance covered by the river from the gaging station to the upper end of the reservoir was nearly 4 miles, making the time of the entry of the flood into the clear water of Echo Reservoir at 10:30 P.M.

A storm of similar intensity struck on Chalk Creek, 8 miles east of Coalville, a short time after the heavy storm at Rockport (see Table 7). Chalk Creek enters the Weber River 0.5 mile below the gage, making very little difference in the time at which both floods entered Echo Reservoir.

The thick muddy water entered the clear water of the reservoir at 10:30 P.M., and passed through the needle-valve gates below the dam at 8:30 A.M. The length of the submerged river channel was about 7 900 ft, which would establish an average velocity of 730 ft per hr, or nearly 0.22 ft per sec for the flood through the reservoir.

The quantity of flood water, as determined from the water-stage recorders, which flowed into the upper end of the reservoir before any of it appeared below the dam, was 102 acre-ft. A body of water 7 900 ft long by 110 ft wide by 5 ft deep would contain approximately 102 acre-ft. The channel of the Weber River before the reservoir was built would average very close to 110 ft wide and 5 ft deep. It seems not far wrong to state that the flood water followed the old river channel through the reservoir.

The color of the flood water above and below the reservoir was reddish-brown. When it was whorled out of the needle-valve gates and into the stilling-basin the violent agitation seemed to liberate a very putrid odor which was stifling near the stilling-basin. It was noted that clay particles, which apparently had remained in suspension through the reservoir, settled out near the lower end of a protected section of the stilling-basin. Evidence was against these particles being in the stilling-basin before the flood water came through. The unlocking of the gas and the breaking up of whatever affinity these clay particles had for each other may shed some light on some of the factors affecting these phenomena.

Conclusions.—When the thunder-storm hit at Rockport, the downpour of hail and rain fell on soil weathered from the thin-bedded clay shales of the Upper Jurassic Age which are reddish-brown in color and contain a high percentage of colloidal clay. This fine material absorbs a large quantity of water and remains in suspension for many hours. The rolling, slipping action which the clay, sand, and coarse material received on its way down from the mountain sides and steep hollows, produced a mud flow having a maximum density of fine particles suspended in an emulsion of colloidal clay and water, which, in turn, supported the bed load of coarser material. Only the suspended load was carried down the river. The flood lost little of its load down the river, as was noted the following day. This dense liquid mass, more or less tied together, seemed to confine itself to the submerged river channel through the reservoir and failed to mix to any extent with the clear, less dense water, notwithstanding the marked decrease in the velocity of the flood water through the reservoir as compared to the velocity in the river above it.

Had the mud flow been composed of different materials, a product of a different geologic age, it would have lost its identity in the reservoir as some other floods have done.

The writer agrees with the authors that further study on the flow of water through reservoirs will be of practical significance with respect to engineering problems. It seems reasonable that some changes in design and position of the outlet works may be needed where culinary water is to be taken from reservoirs to be built on streams which are subject to seasonable floods.

RAYMOND A. HILL,[47] M. AM. SOC. C. E. (by letter).—Judging from similar conditions at Elephant Butte Reservoir on the Rio Grande, little is to be gained by the passage of silt through Lake Mead. From the former reservoir, water carrying large quantities of suspended matter has been discharged for several days in almost every year, but the total quantity of silt so removed is only a small part of the accumulation in the reservoir. Even if the life of Elephant Butte Reservoir thus becomes greater than would have been the case if no silt flows had occurred, it will make little difference whether the lost capacity is replaced, for example, in 1960, or a year or two later. Furthermore, only the finest particles are held in suspension and these tend to seal the soil when such water is used for irrigation. Likewise, to increase the quantity of silt that may naturally pass through Lake Mead would probably not be welcomed by irrigation water users, and definitely would be disadvantageous to those communities that will take their domestic supplies from the Colorado River.

Although the passage of silt through Lake Mead, therefore, is of itself unimportant, the phenomena which produced such silt flows are important.

---

[47] (Quinton, Code & Hill-Leeds & Barnard), Los Angeles, Calif.

The impression might be gained from the authors' presentation that water flowed through Lake Mead without mixing only at times when the discharge at Boulder Dam was turbid. Actually, it is evident from the chemical analyses of the water entering the reservoir and discharged from it that the flow of saline water through Lake Mead is of usual, rather than unusual, occurrence. The writer, therefore, would re-phrase the first conclusion of the authors to read: "The passage of water in considerable quantities through a reservoir without mixing has much more than scientific interest and importance."

Variations in Salinity.—For several years the U. S. Geological Survey has taken daily samples of water from the Colorado River at Grand Canyon Station above Lake Mead and at Willow Beach Station below the reservoir. The percentage of sulfates has been determined for each sample and complete water analyses have been made of composites of each consecutive 10-day group of samples. Table 8(*a*) contains the analyses of the composites made up from daily samples taken at Grand Canyon Station during the months of June to October, 1935, inclusive; Table 8(*b*) contains similar data for the waters at Willow Beach Station from August 1 to November 30, 1935, inclusive. The constituent ions are recorded in milligram equivalents per liter, rather than in parts per million, for convenience of geochemical classification. The total discharge of the Colorado River at each station for the successive 10-day periods is also recorded in acre-feet.

The data from Table 8 are shown graphically in Fig. 7, which is an enlargement of part of a geochemical chart. This form of plotting is not in general use and some explanation of it is probably warranted. The small inset is an outline of a geochemical chart which esentially consists of two trilinear diagrams and a diamond-shaped diagram adjoining them. The left-hand triangle is used for plotting the percentage reacting values of the cations; the right-hand triangle is similarly used for plotting the percentage reacting values of the anions. Since the percentage reacting values of the cations and of the anions always total unity, the cations in any water can be represented by a single point on one trilinear diagram, and the anions by a single point on the other equilateral triangle. When these are projected to an intersection on the diamond-shaped figure, the resulting position represents the geochemical grouping characteristic of the water. The diamond, itself, is made up of two trilinear diagrams having a common base, and the sum of the perpendiculars from any point likewise equals unity. For comparison, the range of the points plotted at the enlarged scale is indicated on the inset.

It may be demonstrated that: (*a*) On each trilinear diagram, and on the diamond-shaped diagram, the mixture of two waters must plot on the straight line connecting the plotted positions of each of the waters; and (*b*) the plotted position of the mixture must be at the center of gravity when all quantities are expressed in ton-equivalents. Ton-equivalents bear the same relation to total tons as milligram equivalents bear to parts per million, and the magnitude is fixed by the following relation:

$$T_e = \frac{Q \times m_e}{736} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

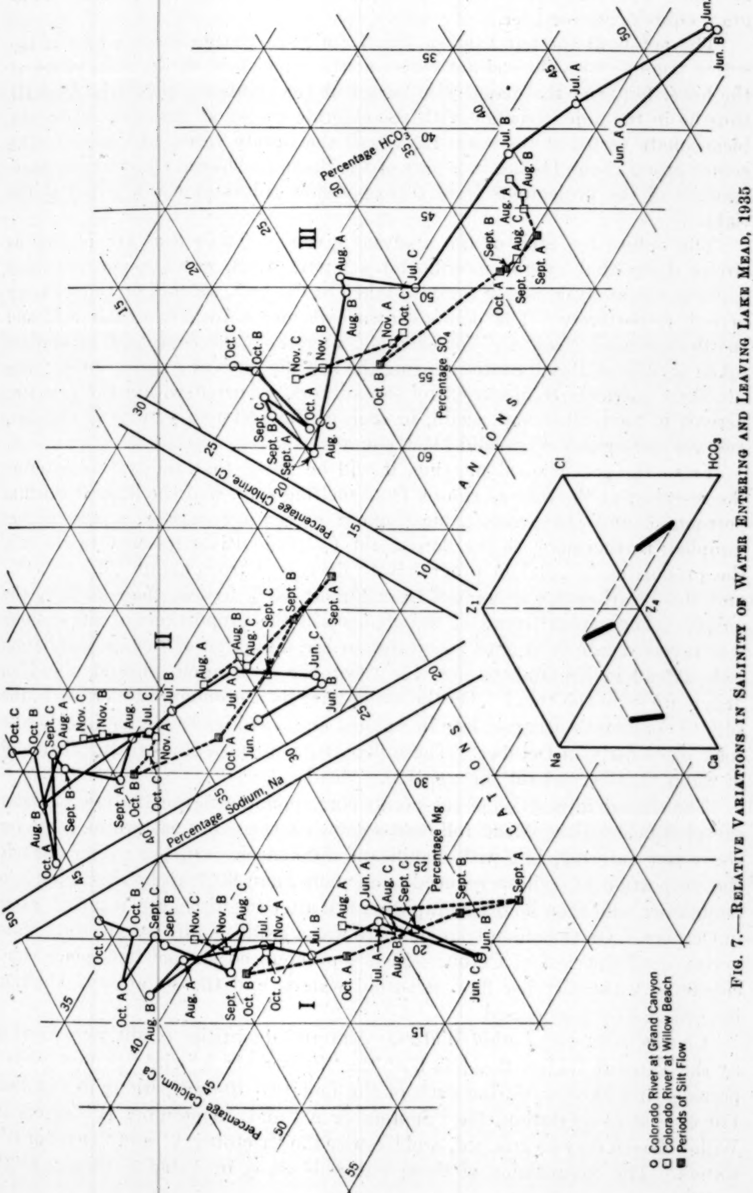

FIG. 7.—RELATIVE VARIATIONS IN SALINITY OF WATER ENTERING AND LEAVING LAKE MEAD, 1935

in which T_e = ton-equivalents; Q = quantity, in acre-feet; and m_e = milligram equivalents per liter.

The points at the left hand of Fig. 7 (in Zone I) thus lie in a part of the cation triangle with the sodium vertex at the upper left, the calcium vertex at the lower left, and the magnesium vertex at the right; the points in Zone III thus lie in the anion triangle with the chloride vertex at the upper right, the bicarbonate vertex at the lower right, and the sulfate vertex at the left. The center group (Zone II) lies in a part of the diamond-shaped chart at the intersections of the projections from corresponding points at the left and at the right.

The values for each of the analyses given in Table 8(*a*) are plotted as circles designated by the month and a letter, A, B, or C, depending upon whether the analysis was of samples taken in the first, second, or third 10-day period, respectively. The points shown by squares are from Table 8(*b*) and the designation, "Aug. C," for example, represents the composite of samples taken at Willow Beach Station during the last ten days of August, 1935. The silt flows particularly discussed by the authors, occurred within the first two periods in September and, again, in each of the first two periods of October, and are distinguished by solid black squares.

From the geochemical plotting, it will be noted that the waters entering the reservoir at the time of run-off from melting snow had the highest calcium percentage and the greatest bicarbonate percentage of any of the waters sampled; furthermore, as the flow of the Colorado River lessened in the fall, the proportion of calcium progressively decreased from about 55% to 34%, and the bicarbonates decreased from almost 55% to less than 20% of the anions. The general trend of the changes in the proportions of the cations was reversed late in August just prior to the discharge of turbid water from Lake Mead in September; also, the "October A" sample showed a sudden departure from the trend. On the anion triangle a pronounced increase in the sulfate percentage occurred late in August, and a sudden reduction in chlorides took place early in October. These departures furnish clues to the character of water that carried silt through Lake Mead.

The change in position of the points corresponding to the analyses of water sampled below Lake Mead followed somewhat the same pattern as those for the water entering, but with significant differences. On the cation triangle the proportion of sodium reduced from more than 30% to less than 25% in September, and then increased rapidly until after the discharge of turbid water in October. On the anion triangle there was a gradual shift toward the sulfate vertex until the first of October; then a pronounced change took place coincident with the October flow of turbid waters, and the sulfate and chloride percentages both increased.

Characteristics of Turbid Waters.—Material quantities of silt were carried by the water at Willow Beach in both the "September A" and "September B" periods, and likewise during each of the first two 10-day periods in October. For ease of computation, the "September A" and "September B" waters at Willow Beach may be grouped, and likewise the "October A" and "October B" waters. The composition of these waters is given in Table 9, Columns (2) to (5).

The authors have concluded from other data that about eight days elapsed between the time that very silty water passed Grand Canyon Station and the time when this water reached Willow Beach. Accordingly, water that passed Grand Canyon late in August and early in September should have been characteristic of the water leaving the reservoir during the time of the turbid flow in September; but from Fig. 7 it is obvious that either the "August C" water at Grand Canyon Station did not produce the turbid outflow from Lake Mead in September, or considerable mixing or dilution took place. Furthermore, with reference to the cation plotting, it is apparent that part of the turbid water at Willow Beach in September had a very low percentage of sodium, because the average sodium percentage of the September turbid water was less than the sodium percentage of even the spring flood waters.

TABLE 9.—ANALYSIS OF COLORADO RIVER WATER

Description	AVERAGE QUALITY OF WATER AT WILLOW BEACH, IN 1935, FROM:				SPRING FLOOD WATER IN RESERVOIR RELEASE		WATER THAT CARRIED SILT THROUGH LAKE MEAD, IN 1935, FROM:

Total	5.74	100.0	8.48	100.0	4.33	100.0	18.00	100.0	18.00	100.0
Quantity of water, in acre-feet	396 000		391 000		....	....	....	....	....	....
Quantity of salts, in ton-equivalents	3 090		4 500		....	....	....	....	....	....

These apparent anomalies make possible the calculation of the quantity and character of the water that carried silt through the reservoir in September. After repeated trial and error, it was found that a mixture of 355 000 acre-ft of spring flood water, carrying 2 080 ton-equivalents of salt, with 41 000 acre-ft of water, loaded with 1 010 ton-equivalents and having a high calcium sulfate content, would produce the quantity and quality of water measured at Willow Beach from September 1 to September 20, 1935. The spring flood water was evidently itself a mixture, in equal quantities, of the water that entered Lake Mead in the last ten days of June and the first ten days of July, 1935. The composition of these waters is shown in Table 9, Columns (6) to (9).

In October, 1935, the passage of silt through Lake Mead was produced by a water of markedly different characteristics from those of the water which produced the silt flow in the preceding month. From Fig. 7 it will be noted that there was a marked increase in sodium percentage at the time of turbidity in October, as distinguished from a decrease when silt was discharged in September. The direction of shift of the "October A" and the "October B" points for Willow Beach on divisions of Fig. 7 is toward the "October A" point for Grand Canyon Station. These directions likewise depart from those for the ten days immediately preceding and immediately following, which also is indicative of some change in conditions coincident with the passage of silt through the reservoir. There thus seems to be justification for the assumption that the water which carried the silt through Lake Mead in October was, in part at least, closely similar to the "October A" water at Grand Canyon. Actually, the water which produced the silt flow was found to be that given in Table 9, Columns (10) and (11).

A simple mixture of this water and of the spring flood water would not satisfy the criterion that the mixture of "October A" and "October B" water at Willow Beach Station should lie at the center of gravity of the points corresponding to the spring flood water and the October silty water entering the reservoir. It was observed that the clear water released from Lake Mead between the times of the two silt flows had substantially the same proportion of anions as the turbid water released in September. This indicated that some of the calcium sulfate water which carried silt through the reservoir in the first part of September was still passing through the reservoir without its silt load in the latter part of that month.

This assumption is borne out by the fact that the various criteria can be satisfied by mixing with the water entering the reservoir in October, some of the water characteristic of the September run. Actually, the 4 500 ton-equivalents of salts carried past Willow Beach from October 1 to October 20 were evidently made up of 1 630 ton-equivalents of salts of the character carried by the water which entered the reservoir about July 1, 510 ton-equivalents of salts characteristic of those in the water which came into Lake Mead late in August, and 2 360 ton-equivalents of salts carried by water which passed Grand Canyon about the end of September, 1935. The corresponding quantities of water are as follows: "June C" water, 137 000 acre-ft; "July A" water, 137 000 acre-ft; September silt-run water, 21 000 acre-ft; and 96 000 acre-ft of the water which directly caused the flow of turbid water in October, 1935.

Minimum Silt Percentage.—In September, roughly 40 000 acre-ft of water carried 2 000 000 tons of silt through Lake Mead, equivalent to an average of 50 tons per acre-ft. It would appear from this that the water which brought the silt to Willow Beach Station was that which passed Grand Canyon Station on August 26 and on September 4, and that little of the suspended load at Grand Canyon on the intervening days found its way through the reservoir. Again, in October, roughly 2 500 000 tons of silt were carried through by less than 100 000 acre-ft of water, or more than 25 tons per acre-ft. The days of high silt percentage at Grand Canyon were September 30 to October 3, inclusive, during which time the discharge of the Colorado River was almost as great as the quantity of water that apparently passed through the reservoir with its silt load. In general, the data indicate that silt was not carried through Lake Mead when the water entering the reservoir contained less than 2.0% of suspended matter, and then only if the proportion of fine particles was relatively large.

Passage of Clear Saline Water.—Reference was made in the foregoing discussion to the passage of clear saline water through Lake Mead without material mixing except at the outlets. In the writer's opinion, this is of far greater practical importance than the removal of silt that might otherwise deposit in the reservoir.

With reference again to Fig. 7, and particularly to the points on the segment of the anion triangle, it is apparent that the clear waters released from the reservoir in August, in September, in October, and in November, 1935, were not characteristic of the great body of water that entered during the flood run-off in the spring. The points for the flow at Willow Beach in the month of August lie roughly on a line between the "June C" and the "July C" water at Grand Canyon Station, indicating that the water in the river several miles below Boulder Dam was a mixture of spring flood water and of the flow entering the reservoir late in July. The clear water at Willow Beach in the last ten days of September, 1935, definitely must be a mixture of the spring flood water and some other water having a much higher sulfate percentage. Actually, the data indicate that some of the calcium sulfate water which produced the turbid flow early in September was continuing to flow under the lake without its silt load in the latter part of that month. The water at Willow Beach near the end of November appears to be somewhat similar to the water entering the reservoir in September, but the concentration of salts in this water is less than two-thirds of the concentration in the water entering. There must have been, therefore, dilution or mixing of the water characteristic of that entering Lake Mead late in September, with other water which came into the reservoir during spring floods.

It is not necessary that this mixing should take place in the reservoir, and probably this was not the case. The outlets at Boulder Dam presumably drew both from the saline water which was flowing along the bottom toward the dam and from the large mass of water lying above the saline flow. This could be true, of course, regardless of whether one outlet or a series of outlets were in service, although it would be more likely to occur with outlets open at different elevations.

This phenomenon of the passage of saline water along the floor of the reservoir is also suggested by the upper graph in Fig. 2 of the paper, in which it is shown that the quantity of sulfates at Willow Beach steadily increased from September to the end of November, 1935, approaching the concentration of sulfates in the water at Grand Canyon Station, regardless of the fact that most of the water in Lake Mead entered there during months of run-off from melting snow.

Various estimates have been made of the quality of water that will be available for domestic and other uses from the Colorado River after regulation in Lake Mead. Such estimates have naturally been based upon the assumption that there would be complete mixing of the relatively pure flood waters with the saline low-water flow of the Colorado River. Analysis of the data now available (1938) indicates, on the other hand, that the saline waters tend to flow through the reservoir rather than to mix, and that the spring flood waters tend to "ride on top." Since May 1, 1936, the tunnel gates at Boulder Dam have been closed and the lowest outlet is far above the original stream bed. The question naturally arises: Will the normal release from Lake Mead be materially more saline than the weighted average inflow and will the best water be wasted at the time of spill or release for flood control?

NATHAN C. GROVER,[48] M. AM. SOC. C. E., AND CHARLES S. HOWARD,[49] ESQ. (by letter).—Since the publication of this paper interest in density currents has been manifested through correspondence, published discussions, and the creation of a specific committee (Interdivisional Committee of the National Research Council on Density Currents) for their further study. The discussions have served to emphasize the inadequacy of information with respect to the phenomena of density currents and the probable theoretical and practical value of further study of them. Several interesting and important aspects have been presented. In general, the discussions have disclosed: That there have been instances of flows of turbid water through reservoirs under a variety of conditions that cannot be evaluated because of lack of observational information; that there may be many instances of stratification of water in reservoirs due to differences in density, in many of which turbidity is not involved; and, that there is an important and unexplored field of scientific research in relation to density currents and stratification in reservoirs which may have both scientific and practical significance.

Mr. Faris has described a flow of turbid water through Lake Kemp and mentioned the presence of silt in depressions in Medina Reservoir. Messrs. Page and Forester have given valuable information concerning the visibility of the flow of the turbid water through the center of Lake Mead during the period before the depths of water were too great. Messrs. Faris, Dobson, and Lewis have described similar flows of turbid water through other reservoirs and discussed conditions of deposition in reservoirs which are indicative of other such flows which may not have carried through to the places of discharge. Messrs. Jones, Scofield, Creager, Bliss, and Stevens have discussed the conditions under which the flows have occurred in Lake Mead and other reservoirs and Mr. Palmer has suggested the similarity of the conditions causing turbid flows and those of lack of mixing or of stratification of fresh and salt water. Mr. Houk and Professor O'Brien have discussed the phenomenon on the basis of temperature differences. Mr. Monish has suggested a modification of Prandtl's expression for the criterion of mixing, and Mr. Rubey has made several computations to show the combined effects of the quantities and nature of the suspended matter, and the salinity and temperature of the water. He has also considered the effects of variations in velocity as it was measured at the Grand Canyon gaging station about 160 miles above the head of the lake.

---

[48] Chf. Hydr. Engr., U. S. Geological Survey, Washington, D. C.

[49] Chemist, U. S. Geological Survey, Washington, D. C.

Mr. Jarvis has referred to earlier considerations of the subject and has suggested the practicability of creating turbulence as a means of putting the silt into suspension for passage out of the reservoir. The information presented by Mr. Lewis in his discussion and in the paper to which he refers,[33] is very valuable in outlining the efforts that have been made to eliminate silt from certain reservoirs in South Africa.

Mr. Page has presented additional information concerning conditions in Lake Mead during certain periods when the flows of turbid water took place. On the information available, the writers do not now agree with Mr. Page that the higher temperature of the relatively warm water near the bottom of the lake is explained by the warm springs known to be present near the dam site. The source of the heat producing this higher temperature in the lake water is not positively known, but water of the observed temperature appears to the writers to have extended over too large an area to be considerably influenced by the relatively small discharge of water from warm springs. It may be significant that the temperature of this stratum of warm silty water is 68° to 70°F which is approximately the mean annual temperature at and near Boulder Dam.

The writers believe that the submerging or covering of certain areas mentioned by Mr. Jones was of little or no importance in causing the silt flows since the material carried past Willow Beach during the flows was much finer than would be expected to result from sliding or scouring in those areas.

Mr. Monish has discussed the extent of mixing that might be expected under different conditions of flow and suspended matter. He has computed limits for the critical values of mixing which seemed to hold for the flows of turbid water observed at Lake Mead in 1935, and has shown that these values might not be the same for another year, nor for another reservoir. He has computed his values from records obtained at the Grand Canyon station which were the best available to him. Such computations, based on records of water and silt that actually came through the reservoir, would be of interest since it appears to be reasonably certain that the sizes and conditions of flocculation of the particles are of importance in their effect on rates of settling. Mr. Rubey has made a careful study of the available data and was not able to explain the flows of turbid water by consideration of densities or density differences, or by the densities and velocities of the water measured at the Grand Canyon gaging station. He has emphasized the need for observations on the degrees of flocculation and the velocities or slopes of the turbid water within the reservoir. Mr. Stevens has suggested that an agency or board be created to co-ordinate investigations of the Colorado River Basin, and that the results of comprehensive studies in the Colorado River Basin would have value in connection with studies of the Rio Grande and other silt-bearing streams of the arid West. Professor O'Brien has suggested that some of the solid particles were first carried to the bottom and, later, were resuspended as a result of turbulent flow and then were carried through the lake in the turbid flows. Mr. Lewis has suggested that the matter in solution causes flocculation during periods of turbid flow, which, in turn, causes bottom flow.

Mr. Hill has presented tables and graphs to show that the water flowing out of Lake Mead during part of 1935 was a mixture of the water that entered during the spring flood with other water in the lake. He has raised the question: "Will the normal release from Lake Mead be materially more saline than the weighted average inflow and will the best water be wasted at the time of spill or release for flood control?" Mr. Hill has also suggested that the passage of the more concentrated water through the lake may be of greater practical importance than the passage of turbid water.

Mr. Redden described a flood on the Weber River in Utah, in August, 1934, after which turbid water passed through Echo Reservoir, and stated that although the river often carries considerable suspended matter the water discharged at such times was usually clear, and that of many known instances when silt-laden waters appeared at the outlet gates of reservoirs in Utah, the phenomenon is more noticeable on some rivers than on others.

Samuel B. Morris, M. Am. Soc. C. E., has furnished, by personal letter to the writers, a general description of some observations made on Morris Reservoir, in California:

> "The Morris Dam completed in 1934 creates a reservoir in San Gabriel Canyon 20 miles east of the City of Pasadena. The reservoir is four miles long and of maximum depth of 250 feet. Storage capacity is 38,360 acre-feet and surface area 417 acres. Following winter storms the water in the reservoir clarifies and becomes stratified. Temperatures at the bottom of the reservoir will generally be 50 to 55 degrees while surface temperatures will be 5 to 10 degrees warmer by April. In the spring of 1935 a flood discharge of warm water entered the reservoir and flowed along the bottom to the flood release outlets at the base of the dam discharging a muddy stream while the surface water in the reservoir remained clear. After two or three days the reservoir became cloudy throughout and of constant temperature.
>
> "Apparently the warm silt-laden flood water was heavier than the colder water in the reservoir. After two or three days, however, sufficient of the silt was precipitated to cause the warm water to be lighter in specific gravity than the cool water above it. This caused the warm water to rise and the reservoir 'turned over' thoroughly mixing its contents and giving a constant temperature throughout. This is similar to the condition which usually occurs in the late fall of each year when the surface water becomes cooler than the deeper water."

Since the publication of the paper, two reports concerning the delta of the Colorado River[50] have appeared. These reports present considerable information on the nature of the silt carried by the Colorado River, which will be of value in future studies of silt movement.

In the spring of 1937 the National Research Council appointed an Interdivisional Committee on Density Currents which may serve as the co-ordinating agency suggested by Mr. Stevens. Meetings of this Committee were held in June, 1937, to formulate a program of field and laboratory studies. Intensive programs were planned for the Elephant Butte Reservoir and Lake Mead. During the summer of 1937, observations were made at the Elephant Butte Reservoir, but there have been no apparent movements of turbid water through the reservoir during that year. The results obtained during the year show variations in concentration of the water in different parts of the reservoir, but the complete data are not available to show the extent or the nature of the stratification.

---

[50] "The Colorado Delta," by Godfrey Sykes, *Publication 460*, Carnegie Inst. of Washington; pub. jointly by the Carnegie Inst. of Washington and the Am. Geographical Soc. of New York, 1937; also, "Delta, Estuary, and Lower Portion of the Channel of the Colorado River, 1933 to 1935," by Godfrey Sykes, *Publication 480*, Carnegie Inst. of Washington.

Samples of water and records of its temperature were collected in August and September, 1937, in co-operation with the U. S. Indian Service, on the Gila and San Carlos Rivers above the San Carlos Reservoir and at the outlet of Coolidge Dam. Although some of the samples of the inflowing water had more than 1% of suspended matter (of which a large part consisted of particles with diameters less than 20 microns), no suspended matter passed through the dam during this period. The mean daily discharge of the San Carlos River during the period was less than 100 cu ft per sec for all but four days. The flow of the Gila was somewhat larger, and in the two months of the study more than 250 000 tons of suspended matter was carried past the Calva gaging station at the head of the San Carlos Reservoir. The failure of turbid water to pass through the reservoir may have been due to the small quantity of suspended matter and the small flow.

No turbid water has passed through Boulder Dam since the gates at the bottom of the reservoir were closed on May 1, 1936. Periodic observations have been made by the U. S. Bureau of Reclamation to ascertain the temperature and position of turbid water in different parts of the lake. Most of these observations have been made in the canyon section immediately above the dam, but, since the summer of 1937, additional observations have been made in Boulder Canyon, 20 miles above the dam, and in Virgin Canyon, 50 miles above the dam. The observations show that there has been a body of turbid water at the bottom of the lake, as mentioned by Mr. Page. Temperature observations made as a part of the sampling program show a marked increase in the temperature of the water at the points of transition from clear to turbid water. Samples of the turbid water show that the quantities of solid material increase with the depth. The bottom samples have been so thick that they could be poured into a bottle only with difficulty. Mechanical analyses of the suspended material taken from the bottom of the lake at several places show that the material consists chiefly of very fine particles, more than 90% being less than 20 microns in diameter. In July, 1937, there was about 20 ft of the silty water in Virgin Canyon and about 35 ft in Boulder Canyon. Observations made in Virgin and Boulder Canyons, in September and November, 1937, and in January, February, and March, 1938, showed varying quantities of turbid water in both canyons.

On the basis of several observations made at different parts of the lake Table 10 has been prepared showing approximate elevations of the lake bottom and of the top of the silt layer during the period July 1, 1937, to March 12, 1938.

These results indicate fluctuation at the upper stations in the level of the top of the silt which probably represents flowing of silt toward the dam. The observations made at Pierces Ferry in February, and at the other stations in February and March, seem to indicate such a flow of turbid water. The notes submitted with the description of the sampling program for February included the following:

"As the head of navigation was approached there was a distinct line between the clear and turbid water. There were stretches in this vicinity constantly bubbling as if the air entrapped in the rocks on the bottom of the lake was still being released. Where these bubbles came up they carried with them a cloud of muddy water to the surface.

"When the heavy rains starting around March 4 began to bring up the flow of the Virgin and Colorado Rivers, an attempt was made to pick up its effect in the lake by sampling on March 5, 9, 11, and 12. In the sampling of March 9, at Virgin Canyon there was noticed an upstream surface current. At 259′ depth below the surface there was no noticeable deflection of the sampler cable but at 275′ depth below the surface the sampler cable showed a very decided downstream inclination as if encountering a strong downstream current."

Observations made at Boulder Dam and at Cape Horn, about 3 200 ft above the dam, show considerable fluctuation in the level of the top of the silty water. The data for Boulder Dam indicate that it may be difficult to observe, accurately, the elevation of the bottom of the lake, because the material deposited on the bottom appears at times to be consolidated, and, at other times, to be so stirred up or loosened that the sounding weight penetrates it to a greater depth. During the periods of observation the top of the silty water near the dam has been below the top of the old diversion dam, which is still (1938) in place.

* At head of navigation (about 110 miles above Boulder Dam) on this date there was considerable silt at bottom (Elevation 1 068 ft).

† November 16: No silt layer in Las Vegas Wash area of lake; bottom elevation, 936 ft; no silt layer in Callville Wash area of lake; bottom elevation, 1 026 ft.

The samples collected in Virgin Canyon show that the water in contact with the silt was more concentrated in September than in July. The quality of the water in the September samples from the bottom of the lake in Virgin Canyon was similar to that in a turbid flow observed at Grand Canyon a few days prior to the sampling in Lake Mead. These comparative data would seem to indicate that there had been a density flow through the lake, from the head of the lake, as far as Virgin Canyon, at least, and that the time required for the flow over that distance was about six days. Samples collected in Boulder Canyon in September indicate a possible movement of turbid water to that point, but the evidence for Boulder Canyon is not quite so satisfactory as that for Virgin Canyon. In addition to the samples taken in the deeper parts of the lake, samples of water have been taken at the surface in several parts of the lake and, for some sampling periods, at several depths in order to obtain information on the dissolved constituents at different parts of the lake and at different depths.

The stratification, or its opposite, the thorough mixing of the water in a reservoir, and the season of the year when such mixing occurs, may affect greatly the chemical quality of the water, whether wasted or drawn from the reservoir for use, and may determine the level from which it might be desirable to draw the water. In the summer of 1937, the surface water in Virgin Canyon, Boulder Canyon, in the lake between these canyons, and in the wide part of the lake at the mouth of Las Vegas Wash had practically the same concentration and was similar in composition to the water which flowed past the Grand Canyon station during the spring flood. At considerable depths below the surface during the same period the water had a concentration of 700 to 800 ppm of dissolved matter, which is practically the same as that of the water released from the reservoir during the fourteen months ending February 28, 1937. The presence of such a large body of water of uniform chemical composition seems to indicate that at some time, and by some means, the water in the lake became well mixed. During the summer of 1937 this large body of mixed water had a temperature of about 53°F and the uniformity of this temperature in different parts of the lake may be another indication of the thoroughness of the mixing. Temperature measurements made by the Bureau of Reclamation show that in January, 1937, the water at all depths at the dam had a temperature of about 55° F. During the summer the water at the surface of the reservoir was warmer, of course, and, in July, midday temperatures of the water at the surface were as high as 90° F.

The depth-temperature curves in the vicinity of the dam show temperatures decreasing from the surface to a depth of about 200 ft where about 52° to 54° F were observed during the summer months. Below about 200 ft the same temperature was observed as far down as the top of the layer of turbid water where there was a sharp increase in temperature. It is not known how great an effect the mixing caused by a temperature "turn-over" may have on density currents and stratification; but the evidence seems to indicate that in the early winter of 1936–37 the entire mass of water in the reservoir came to a temperature that was essentially uniform, and it seems likely that the water throughout practically the entire reservoir was of essentially uniform chemical composition.

It is not known whether the turbid water (if there was any at that time) lying at the bottom of the lake was involved in the "turn-over" of the winter of 1936–37; but it seems probable that its density may have been so great that little or none of it was so involved. The water brought into the lake by the spring floods carried considerable quantities of suspended matter, but usually those floods carry larger particles, chiefly, which settle quickly. The spring run-off was low in dissolved matter and its temperature was somewhat higher than that of the water previously stored in the reservoir. It seems likely, therefore, that the incoming flood water with its lower density, because of lower content of dissolved matter and higher temperature, spread out over the surface of the lake and mixed only slightly with the main body of stored water.

Observations made by the Bureau of Reclamation during January, 1938, at different points in the lake showed that temperatures ranging from 56° to 59° F, at the surface and in the top 100 ft of the lake, were quite uniform, and that at greater depths they varied between 53° and 56° F. In March, the temperature of the water at most depths was between 52° and 55° F. It seems likely that the top layers of water (possibly the upper 100 or 150 ft, at least) were mixed during a "turn-over" in the winter of 1937–38, but the available data are not sufficient to show that the "turn-over" affected greater depths. Samples of water collected at different depths show variations in the quantity of dissolved matter which would indicate that the mixing of the water was not thorough. The values of specific conductance given in Table 11 indicate the degree of concentration of the water at different depths.

The stratification throughout the lake is apparent from these data. The average values given are representative of values having a small range. At all sampling points the more highly concentrated water is found near the bottom of the lake, but the total quantity of such concentrated water is a small fraction of the entire body of water in the lake.

In a region where there is sufficient range in temperature to cause a "turn-over," the yearly cycle of a storage reservoir of large capacity that carries over

† Samples from the bottom of the lake.

considerable depths of water from year to year appears to the writers to consist of at least two phases: (1) The annual "turn-over," which so thoroughly mixes the water near the surface that it becomes essentially uniform in chemical qualities and in temperature, and which does not involve, perhaps, a stratum at the bottom of the lake (where the water with its load of silt may be of such density that it does not mix with the remainder of the water at the time of the "turn-over"); and (2) the inflowing flood water that contains less dissolved matter and is less dense than the water already in the lake and, therefore, spreads over and rests upon it. During the summer, also, temperature differences develop which lead to more or less definite stratification which persists until the next "turn-over," when the cycle starts again. Into this cycle that is relatively uniform in the times and types of changes, there come the non-uniform and erratic turbid discharges carrying such fine silt and of such relatively great density that they flow as fairly definite streams along the bottom of the reservoir under the lighter clear water.

The apparent mixing of the lake water at times, and its failure to mix at other times, is of interest in relation to density currents which may not involve flows of turbid water but, instead, may involve flows of water of such varying concentrations of dissolved salts that they may be of concern to the users of the water discharged from the lake, as Mr. Hill has shown.

Any serious study of the problem of stratified flow will require the closest co-operation between laboratory and field. Data obtained from observations made under field conditions furnish the only sure knowledge of such complex phenomena. Because of the complexity, field measurements must be directed by laboratory experiments and theories in order to obtain necessary pertinent facts without an undue waste of time and effort.

Theories and criteria of stratified flow have been developed in laboratories, and values of the criteria, seemingly independent of the size of the surrounding apparatus, have been obtained from laboratory experiments. One such theory was described by Mr. Monish who made an attempt to apply it to the data presented in the paper. The application involved several assumptions as to density and velocity distribution, which are not immediately susceptible to proof or disproof and which could be verified only by their determination under field conditions, including measurements of the magnitude and direction of currents and of the densities and viscosities of the waters in the reservoir so as to chart and define, completely, the strata under consideration. In order to expedite the task of obtaining such data and the necessary correlation as to places of measurements, it would be necessary to devise a combined current meter, direction indicator, and distant-indicating hydrometer—a difficult but not impossible task. A sonic depth-finder might be an aid in determining deposition of silt in a large and deep reservoir.

Assuming that these measurements have been made and have confirmed the criterion of stability found by the laboratory, the next step might be an attempt to control the currents.

Further study should include a large amount of field work to ascertain the position and extent of the stratum of turbid water and of the strata of water of different densities throughout lakes of various sizes. In a reservoir as large as Lake Mead, observations must be made in wide and narrow parts of the lake as well as systematically at the lower and upper ends. The continued study of the characteristics of the incoming water will be of fundamental importance in the interpretation of the results obtained from the studies within the lake. It would seem desirable to have observations made in reservoirs which would be typical of classes so as to have information on the effect of climate, topography, reservoir characteristics, and inflow characteristics on the occurrence of the phenomenon of density currents.

PRACTICAL USE OF HORIZONTAL GEODETIC CONTROL

By R. C. Sheldon,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Philip Kissam, Ralph Z. Kirkpatrick, E. B. Roberts, H. W. Hemple, J. C. Carpenter, George D. Whitmore, R. M. Wilson, Julius L. Speert, and R. C. Sheldon.

Synopsis

An argument for the increased use of the horizontal geodetic control system, is offered in this paper. It contains: (1) An "Introduction," including suggestions to the engineer when he is beginning to use this control; (2) a description of the origin and use of such a system, followed successfully on the Panama Canal for twenty-four years; (3) an analysis of the errors developed by using the system of control in the Canal Zone; (4) an analysis of the errors developed by using the same system near the Fortieth Parallel of Latitude; and (5) the writer's conclusions.

Introduction

Recent Progress in Geodetic Control Work.—Since 1930 there has been a large increase in the activities of those organizations working on geodetic control in the United States. The main triangulation net of the United States Coast and Geodetic Survey is nearing completion, giving chains of triangulation stations spaced at not more than 25-mile intervals. In addition to this main net many intermediate triangulation chains and traverses have been established by various other organizations, and, more recently, by the State Relief Agencies. Some States have begun to tie their extensive highway surveys to the National Net.

All work already done, and much more that is planned for the near future, either has been, or is soon to be, reported on the basis of geodetic co-ordinates. It is time that engineers interested in surveying engage in some discussion to determine the best methods of using this control system. At present (1937), the only engineers who use the geodetic control, as it should be used, are those employed in the Mapping Divisions of the U. S. Coast and Geodetic Survey, the United States Geological

Survey, the Hydrographic Office of the United States Navy Department, and other Federal agencies that produce maps covering large areas.

Engineers Do not Use Geodetic Control.—The American engineer and surveyor refuses to work with geodetic positions. The published information on the subject has many statements explaining the need for Statewide plane co-ordinate systems, such as the following (11)[3]: "Of course, if all engineers would use geodetic computations, there would not be need for such aids, but they do not favor this method of handling the situation."

The reason for this reluctance to use geodetic control is apparent to any engineer who has attempted to adapt it to every-day survey work. If he finds a geodetic control point in the vicinity of his work he generally wants to use it. Then he goes through the following cycle: He looks up the position of the point in the geodetic reports and finds it given in degrees, minutes, seconds, and in decimal parts of seconds; in some cases the seconds are given in meters. In any case, he must go to the textbooks for information as to the number of meters in a second or in a minute of latitude and longitude, before he can base his survey on the point. There he finds: (*a*) Pages of material on the methods used in reconnaissance for the triangulation; (*b*) more pages on the methods of observation; (*c*) lengthy descriptions on the measurement and accuracy of base lines; (*d*) some sketchy information as to the computations; (*e*) detailed description of the relatively simple operation of precise leveling; and (*f*) a reference to the Government publication from which the information given, was taken. Finally, he abandons the system, reasoning that if the computation of seconds to meters is too complicated for the author of a textbook on surveying, it is too complicated to use.

The publications of the Government organizations covering the subject (see Appendix), if taken as a whole and carefully studied, give a complete picture of the necessary process; but, unless one has all of them at his disposal and studies them thoroughly, he is likely to become confused and decide that geodetic control is to be used for surveys covering large areas only. The beginner will not find a clear step-by-step explanation as to how to tie a local survey to geodetic co-ordinates, except by the use of plane co-ordinates.

Plane Co-Ordinates Used as Substitute.—Realizing the necessity for tying their work to the national net, some of the more progressive cities have made geodetic control surveys of their area; but as a basis for actual work they have substituted plane co-ordinates, which are about to be adopted as a standard practice. This is unfortunate because the objections to the use of plane co-ordinates are numerous, and increase with the distance from the origin. In addition to the fact that it is fundamentally wrong to use plane co-ordinates in surveying areas on the spherical surface of the earth as if it were a plane, they are also confusing to the surveyor who has always used the meridian as his line of reference. True azimuths must be corrected when using plane co-ordinates, the correction depending on the position of the point with reference to the origin of co-ordinates. Errors are certain to occur where two co-ordinate systems join.

---

[3] For reference to figures in parentheses, see "Bibliography", in Appendix.

SIMPLICITY OF HORIZONTAL GEODETIC CONTROL MUST BE EMPHASIZED

In order that the engineer may be encouraged to use this geodetic control in his every-day work (and it would be an aid to every engineer having any kind of survey work to do), its simplicity must be emphasized. A comparable example is in the use of geodetic levels. Their advantages are instantly admitted and they are used whenever possible, even where profile levels must be run for miles to base some project on the common sea-level datum. If the horizontal geodetic system were made as simple to understand as the vertical system, it would be used by all engineers.

Horizontal Geodetic Control Is Easy to Understand.—Surveyors and engineers have generally understood and used the fundamental principles of geodesy; that is, that the earth is an approximate sphere, that north is always to the pole, that the meridians of longitude converge, and that parallels of latitude are curved lines when run on the earth's surface. Children are taught in the elementary grade schools that the earth is a sphere and that points are located on it by measuring from the equator and the meridian through Greenwich, in terms of degrees and minutes of latitude and longitude. Therefore, it is easy for any layman to understand that the corners of his lot or farm are at a certain latitude and longitude, based on these well known references.

When engineering students are taught in college that they are to ignore all that they have previously learned about the shape of the earth; and that they are to consider it a plane surface for surveying purposes, because the solutions of geodetic problems are too difficult, they are led a step backward; a step that is entirely unnecessary. They should be told instead that: (1) All points located by the U. S. Coast and Geodetic Survey are tied to the equator and to the Greenwich meridians by an average of many observations; (2) it is their duty as surveyors to tie their surveys to such points, wherever possible; and (3) the computations to do this are no more difficult than those involved in ordinary surveying.

Information to Beginners.—For those who have never made any study of geodetic control methods the following simple facts will be an aid.

The computation of geodetic positions is a distinct and separate operation from adjustment of any kind; that is, no least squares computations are involved in the simple computation of geodetic positions. Having the geodetic position of one point and the geodetic azimuth and the distance from that point to another, the geodetic position of the second point and the geodetic back azimuth are computed in the standard printed forms.

The computations for difference in latitude are made by multiplying the length of the line between the points by the cosine of the azimuth times a factor taken from tables. The purpose of this factor is to convert the meters of length into seconds of arc, at the latitude of the initial station. This latitude difference is then corrected by three other values all of which vary, in some degree, with the sine of the azimuth (that is, they depend on the difference in longitude). The computation for difference in longitude is made by multiplying the length of the line by the sine of the azimuth times the secant of the latitude, and by a factor, taken from tables at the latitude of the new station. This factor converts the meters into seconds. No corrections are made to the difference in longitude.

Although the standard forms for geodetic computations of both the Coast and Geodetic Surveys and the Geological Survey are well arranged for the work as done by those Bureaus, they are not a good guide to the beginner. The computations are done in steps as follows: (*a*) Having the geodetic azimuth from one known point to another known point by a previous computation, the geodetic azimuth to the unknown point is computed by a simple addition or subtraction of the angles at the known point (spherical excess corrections are necessary in the case of very large triangles); (*b*) the difference in latitude is then computed by the steps and corrections shown on the standard form, and is followed by the computation for the difference in longitude; and (*c*) the difference in azimuth is computed last. On short lines it is not necessary to apply all the corrections to the difference in latitude as the values found will be negligible. The entire operation requires only a knowledge of logarithms and simple trigonometry.

Astronomic azimuths and positions are those that are determined by observations on the sun, moon, or stars. Geodetic azimuths and positions are those that are computed and carried forward by geodetic computations. Astronomic azimuths and positions should check with the geodetic azimuths and positions, except for small corrections.

CONTROL SYSTEM OF PANAMA CANAL ZONE

Origin.—Since 1911, the Section of Surveys of the Panama Canal Zone has used a system of geodetic control as the base for all surveys. It has been found to be of great value in avoiding confusion, as all surveys are reported with positions of latitude and longitude. No special study is necessary by those using the system. In the vicinity of the Canal surveys are made by five different Canal or other Government organizations as well as by some private engineers. It is possible for each of these agencies to use the work done by any or all the others because all surveys are tied to the one common Panama-Colon Datum.

At the beginning of the construction of the American Canal, and for the several years of the preliminary work, a situation existed on the Isthmus, with respect to survey control, that was much worse than that in the United States prior to the establishment of the Standard North American Datum. There were many different systems of surveys that joined and overlapped each other without a common base. On the Atlantic side of the Isthmus there was a base line and a triangulation system which were based on an astronomical determination of a point on the Colon Light-House. On the Pacific side, there was another system of triangulation based on an astronomical determination of the south tower of the Panama Cathedral. The two astronomical determinations were originally made by outside departments for coast surveys. There was no definite cross-tie between the two systems, although there were many survey lines covering the construction area, established by both the French and the American engineers. This situation led to much confusion especially where the work of two separate divisions met.

In 1910 and 1911 a base line, 3 785.454 m long, was surveyed on the Tavernilla Dump (now covered by Gatun Lake) and measured to a probable error of 1:700 000. A triangulation system, called the primary system for local purposes, consisting of twenty-three stations (including the ends of the base line and the stations of the old Atlantic and Pacific Systems) was carefully located and measured. The triangles of the primary system had an average closure of 1.98″ and a maximum closure of 5.12″. The computations and adjustments were made in Washington, D. C., by the U. S. Coast and Geodetic Survey, by which it was classed as secondary work. Serious discrepancies were found between the positions of the two systems on the opposite sides of the Isthmus. After having made all possible corrections to these positions, dual positions were computed through the primary system (using the initial astronomic value of each of the old systems) for the Balboa Station in the center of the Canal Zone. These two positions were then averaged and the mean position of the central point was adopted as the common datum, called the Panama-Colon Datum.

Approximately seventy supplementary triangulation points were established, and the angles observed, computed, and tied to the primary system; these angles were observed with lesser care than those of the primary system and the computations were made locally; they are considered the secondary system. These triangulation stations were the base for all surveying done on the construction after 1911 and since, in the maintenance and operation of the Panama Canal. They are also used for the control of that part of the military maps covering the vicinity of the canal, and as a base for extending triangulation surveys covering both coasts. Since the establishment of the main control system, it has been necessary to extend it for particular points, and to produce control to desired places. There are now (1937) about 250 triangulation points (most of which are second-order points) in the area around the Canal Zone; the controlled area averages about 4 sq miles per station. This complete system is comparable to the geodetic control net of the United States and all the supplementary work that has been done to extend it.

When this triangulation system was established it was intended to be used as a control on which a rectangular system of surveys would be based. The proposed plan was similar to that of the General Land Office surveys (although not in method), modified somewhat to resemble the systems of rectangular co-ordinates that were then being adapted to some of the large cities in the United States. Monuments for the 2-km intersections of the co-ordinate lines were to be located in the field. This plan failed when it was less than one-half completed, mostly because of the impossibility of locating or using the intersection points on the rough topography of the Canal Zone. Shortly afterward, it became necessary to do considerable surveying to settle land claims and to locate some of the topographical features in the outlying parts of the Zone. To complete this work, the surveyors, some of whom had previously worked on the triangulation system and were thus familiar with geodesy, adopted the present system as a practical substitute for the planned scheme.

Control of Maps and Municipal Surveys.—In working from the triangulation net in the Canal Zone the procedure varies with the class of surveying to be done. For most of the surveys in the occupied parts of the Canal Zone, at the terminals, and along the Panama Railroad, the Section of Surveys has placed control points on the curbs of the streets and in other accessible places. These points are located by ordinary transit and chain traverse with an accuracy of 1:5 000. Since there is no private ownership of property on the Canal Zone, there is no use in maintaining a higher accuracy than is necessary for the control of ordinary municipal work in a suburban district of an American city.

For work involving the boundaries between the Republic of Panama and the Canal Zone, or for the boundaries of the military and naval reservations, transit traverses are tied directly to the triangulation system. Such surveys are run with a varying accuracy, depending on the location and importance of the lines. For the computations of positions on all the transit traverse lines the procedure is as follows:

(1) All triangulation stations are recorded in a card index. The card for each station gives the position of the station and the azimuths and distances to the observed stations (see Table 1).

TABLE 1.—SAMPLE CARD FROM FILE OF TRIANGULATION STATIONS

	14 630.51	4.1652595	Iron

The positions are given with the seconds reduced to feet; this reduction is made very easily from tables which give the length, in feet, to three decimal places for the seconds of both latitude and longitude for every minute of latitude. As the variation between minutes is small, interpolation between minutes is satisfactory for most purposes. If a more accurate determination is required, the formula for any latitude is taken from *Special Publication No. 5* of the U. S. Coast and Geodetic Survey (6).

The surveyor consults this card index before beginning a survey from a station and uses the correct azimuth. On closing his survey on another station his azimuth will be in error (in addition to the errors made in running the line) an angle equal to the difference in geodetic azimuth because of the difference in longitude of the two stations. No lines are run locally that are closed on the same station; that is, closed circuits. In computing the traverse this error, with all the field azimuth errors, is balanced evenly over the angles to close on the two triangulation stations. Thus, the azimuths in the computations are approximately correct, depending on the evenness of the course lengths; if some lines are much shorter than others, or if a series of short lines is followed by a series of long lines, errors will be introduced. For most of the work the errors in running the line are far greater than those that develop from this difference in azimuth between stations. It is scarcely realized by the men doing the work that there is any difference.

After the angles are balanced the line is then computed in the ordinary manner by converting the azimuths into bearings and using the sine and cosine to obtain the latitudes and departures. The line is then adjusted to close on the triangulation stations by distributing the error of closure by any method that is justified by the accuracy of the field work.

For the computation of lines using this system it is necessary to have a table giving the value, in feet, to the nearest hundredths of feet, of the minutes of latitude and longitude, for each minute of latitude. Such a table, a section of which is shown in Table 2, covering the two degrees of latitude of local interest, consists of one sheet slightly larger than letter size; the table, mounted on cardboard, is easily consulted by computers. When, in summing up the feet of latitude or longitude, the values go above those for 1′, the proper value taken from Table 2(*a*) is subtracted or added to the sums and the next minute placed in the minute column.

Table 2(*a*) can be prepared in several ways. The method that gives the more accurate value in feet is, to make an inverse geodetic calculation to obtain the distance, in meters, between two points on the meridian or on the parallel 60″ apart, at the latitude desired. In the case of a line with an azimuth of 0°, or 180°, the computation for obtaining the distance in latitude reduces to the simple division of the distance between the stations, in seconds, by the factor taken from the tables, as all the corrections contain a multiple of the sine of the azimuth, which is zero in this case, and the other term is divided by the cosine which is unity. The value found by the inverse calculation is in meters and is converted to feet to be included in Table 2(*a*). The computation for the distance in longitude is made in the same manner; the operation of making the inverse calculation requires only one multiplication and one division in this case, in addition to the reduction of meters to feet. These two tables (Tables 2(*a*) and 2 (*b*)) can also be prepared by the use of tables that can be found in *Special Publication No. 5* (6), which give the lengths of the seconds of both latitude and longitude for each minute of latitude in meters. This latter method does not give accurate values in the last decimal place because of a lack of sufficient significant figures in the values given in *Special Publication No. 5* of the U. S. Coast and Geodetic Survey (6).

Methods Used for More Accurate Surveys.—Triangulation is used for locating points with a higher degree of accuracy than by the transit traverse method, or for determining the positions in a truly geodetic manner. Quadrilaterals, using the stations of the existing system, are observed and adjusted. The observations are made with a repeating theodolite, reading to 10″, six complete sets of angles, both direct and reversed, and horizon closures, are turned. The standards of secondary triangulation are obtained without difficulty. The geodetic positions are computed by the use of a standard form (No. 9–902) prepared by the U. S. Geological Survey (4). Values for the corrections can be found in *Bulletin 650* (4), or in *Special Publication No. 8* (5).

ANALYSIS OF ERRORS

Errors in the Computations of Traverses.—The foregoing system of computation for traverse positions does not give exact geodetic positions, but it does give positions that are nearer to the truly geodetic than can be determined with the survey methods used. The line that would yield the nearest to the true geodetic positions of the points would be one with many equal courses. The balanced azimuths would then make the line follow the curve of the earth and the computed positions, to be nearly geodetic. The line creating the worst condition would be that containing one long straight course. The direction of the line also affects the difference between the positions as computed by this system and the true geodetic positions. Lines running north or south are affected very little by the geodetic corrections, being only concerned with the difference between the spheroid of reference and a true sphere, whereas lines running east or west must be corrected for convergence of meridians. For these reasons the computations for errors were made on the basis of a line running due west consisting of one single course.

Table 3(*a*) was prepared by taking an even degree of latitude and longitude as a base and computing geodetic positions of points at varying distances on a straight line beginning at the base, with an azimuth of 90 degrees. These positions are placed in Columns (2) and (4). They would represent triangulation stations at the various distances apart. The difference in azimuth is placed in Column (6), Table 3(*a*), and shows the maximum difference that would appear in the azimuths of lines run between stations at the same distances apart as those in Column (1). The positions of the same points on the same straight line are then computed by the use of the sine, cosine, and table method (see Column (7)). The difference between these positions and the true geodetic positions is shown in Column (8), Table 3(*a*). It will be noted that the errors in longitude are very small. The proportional error is shown in Column (9).

* Latitude, by cosine and table, equals 9° 00′ 00″. † 9° 0′. ‡ 40° 0′. § 39° 59′. ¶ Latitude by cosine and table, equals 40° 00′ 00″.

Table 3(*a*) shows the maximum errors that will be introduced in any line run between triangulation stations which are the distances apart shown in Column (1). It is clear that this maximum error will not be reached in practice as it would require running one straight course between triangulation stations. If this were done the balanced azimuths would be the average of the forth and back azimuths of the line and, if this were used in the sine, cosine, and table method, the line would check exactly. To show a more practical determination of the errors it was assumed that the ends of the aforementioned line were to be triangulation stations 100 000 ft apart, and that a traverse was run between them with points as shown in Column (1), Table 4(*a*). The angles were then balanced over these courses and the traverse was computed in the usual way, using the sine, cosine, and Table 2. The unbalanced traverse is compared with the true geodetic positions and these errors are shown in Columns (7) and (8), Table 4(*a*). The line was then corrected to close on the triangulation point by a simple distribution of the error of closure according to the lengths of the courses, thereby lessening the errors to the values, as shown in Columns (10) and (11). Table 4(*a*) shows the errors in this particular traverse; it would be possible to arrange a traverse that would give any closures and errors desired, but this was considered to be an example of the worst condition ever likely to be encountered in the field. Most of the traverses run will have a better distribution of length than this, and will have errors that will be much less than those given in Table 4(*a*).

Use of This Same System in the United States.—The personnel of the Section of Surveys is hired locally or is requisitioned from the United States from young men with some college training and with general field experience. No attempt is made to find men trained for geodetic work. These men work satisfactorily with this system after a short period of instruction. They soon become familiar with the common geodetic operations and understand the principles on which their surveys are based. The superiority of the system is such that these new men soon wonder why a similar system is not used generally in the United States.

One of the reasons for the adoption and the success of this system of surveys on the Canal Zone is the fact that, being near the equator (the Canal Zone is between Latitudes 8° 55′ and 9° 25′), the effects of geodetic corrections are much less than they are 30° or 40° farther north. Tables 2(*b*), 3(*b*), and 4(*b*), similar to Tables 2(*a*), 3(*a*), and 4(*a*) for the Ninth Parallel of Latitude, were prepared to show the errors that would be developed in using the same system at the Fortieth Parallel of Latitude.

CONCLUSIONS

The conclusions that can be made from the arguments given in this paper are:

(1) Plane surveying is out of date, and any mention of it should be avoided. Any system of surveying that does not fit in with the positions of the National Geodetic Net is doomed to eventual failure.

(2) If it were clearly understood by the engineers of the United States that the computation of geodetic positions had nothing to do with least squares adjustments of any kind, and that these computations were very easy to make, geodetic control would come into common use.

(3) A system such as that described herein is a valuable aid in performing all kinds of field engineering work.

(4) For the greater part of engineering work the lines can be run between the triangulation stations, ignoring the geodetic corrections, because the errors of the measurements in the field are more than those introduced by ignoring the geodetic corrections.

(5) For the few occasions when it is necessary to determine positions that require the use of trangulation and the computation of geodetic positions these positions can be determined by the average engineering organization without special training or instruction.

ACKNOWLEDGMENTS

The Canal Zone system of triangulation was begun under the direction of C. M. Saville, M. Am. Soc. C. E., then Assistant Engineer in charge of the Third Division of the Office of the Chief Engineer of the Isthmian Canal Commission. The method of using the system was begun under his direction and has been continued by the Section of Surveys of The Panama Canal, under the direction of Mr. O. E. Malsbury, from 1913 to 1926, and Mr. R. Z. Kirkpatrick, from 1926 to 1936, as Chiefs of Surveys. Various extensions of triangulation and improvements of tables were made by the Fortifications Division of The Panama Canal, under the direction of Assistant Engineer R. C. Jones, and by the Dredging Division of the Panama Canal, under the direction of the Superintendent, J. G. Claybourn, M. Am. Soc. C. E.

APPENDIX

DISCUSSION

PHILIP KISSAM,[3] ASSOC. M. AM. SOC. C. E. (by letter).—A most important and basic conception has been presented by Mr. Sheldon. He has indicated the prime necessity of establishing the position of all horizontal survey points in relation to a single fundamental datum. This principle cannot be emphasized too strongly, and its general adoption at some time in the future is inevitable. All surveys will become in fact parts of one great survey and the inter-relationship between all survey points will be capable of quick determination. Although the advantages of such a condition are too many to enumerate herein, a moment's thought will convince the reader that every effort should be made to attain this aim. As Mr. Sheldon states: "A comparable example is in the use of geodetic levels. Their advantages are instantly admitted and they are used whenever possible, even where profile levels must be run for miles to base some project on the common sea-level datum." A common vertical datum co-ordinates only one dimension, a common horizontal datum co-ordinates the other two. It appears to be obvious that far greater utility of a similar nature will be found in the use of a horizontal datum.

Moreover, two indirect benefits will obtain when a survey is placed on a horizontal datum. It will be usually necessary to connect it with two or more known control points. With such a connection a check on accuracy will be obtained and the precision of results can be raised by adjustment. Furthermore, the permanent marking of surveys will be encouraged, as it will be at once apparent to the engineer in charge that points of such a survey will have a lasting value and it will be well worth while to place monuments at the stations and to record the descriptions and data relating to these monuments. The cumulative effect of monumenting surveys on a standard datum will further advance the acceptance of the system.

Mr. Sheldon's description of the surveying methods in use in the Canal Zone illustrate pointedly the rapid adoption and the utility of such a system when it is known and available. He states that it has been used as a base for all surveying on canal construction since 1911, for control of part of the military maps, as a base for extending triangulation, for municipal construction, and for the boundaries of the Canal Zone and military and naval reservations.

Without question, the standard datum that should be adopted is the North American Datum of 1927, as advocated by Mr. Sheldon; but the method of expressing positions appears to be open to question. Thus far, only two methods have been developed which offer the requisite characteristics; both have sufficient advantages in their favor to merit careful consideration. Mr. Sheldon advocates the use of geographic positions. The U. S. Coast and Geodetic Survey advocates State plane co-ordinate systems based on definite projections especially adapted for the purpose. Such projections have already been designed by that Bureau for every State and in many States they are already in use.

---

[3] Associate Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

Geographic positions must be computed in either case for the fundamental first and second-order triangulation; but with the adoption of standard plane co-ordinate systems, the plane co-ordinates of any geographic position can be computed according to the plane system existing in the area. Likewise, the plane or "grid" azimuth can be computed from the geodetic azimuth at any known position.

Although Mr. Sheldon's arguments advocating the use of geographic positions are sound, the arguments he has chosen against plane co-ordinate systems seem to the writer to be valid only when local co-ordinate systems are considered. State-wide systems have not been carefully weighed; in fact, they have been only mentioned by reference to *Special Publication No. 193,* of the U. S. Coast and Geodetic Survey (11).[2] In most areas, these State systems will produce a higher degree of accuracy than the method proposed. Does not the proposed system require reduction from geographic positions to plane co-ordinates, computation by plane co-ordinates, and, finally, reduction back to geographic positions with accompanying loss of accuracy?

It may be stated justly that in many commercial surveys a high degree of accuracy is frequently not of major importance; but lack of precision is not the basic objection to the system proposed. There is a certain fact which has not been given sufficient consideration in Mr. Sheldon's paper. It is a fact not susceptible of mathematical deduction nor scientific demonstration. It was the reason which caused the U. S. Coast and Geodetic Survey, finally, to adopt plane co-ordinates after a long and careful study of the question. It was the basic argument that influenced the Federal Board of Surveys and Maps to recommend the use of plane co-ordinates to its twenty-four member Federal mapping agencies. The fact is that engineers making surveys over a limited area or of low precision refuse to use geographic positions, and are entirely justified in so doing.

To the writer it appears that the cause for this stand is not the lack of a simple geodetic manual, nor the lack of training received by engineers as students, nor any other cause that can be remedied. If a remedy were available, the writer would recommend plane co-ordinates for the present and geographic co-ordinates for the future, because it would take so many years to change the thought in the engineering schools and in the profession that the general adoption of a common datum might be endangered. Mr. Sheldon describes in especially clear and forceful paragraphs, and carefully prepared tables, the simplicity of a certain system of geodetic reduction for small surveys or for surveys of the usual commercial precision. The recommended system can be criticized only for its lack of accuracy. His suggestions could not be better chosen as guides to develop the proper attitude toward geodetic reduction. If the writer could convince himself that geographic positions should be used for the type of surveys under discussion (very large precise surveys must usually be reduced by geodetic methods), he would still recommend the use of plane co-ordinates if only as a stepping stone to the later adoption of geographic positions.

Unfortunately, however, the increase in cost necessitated by the use of geographic positions precludes their adoption for commercial purposes. If the engineer can be shown that he will receive concrete advantages by using a standard datum, he may be persuaded to extend his survey to control monuments; but the extra advantages to him of expressing the stations of his survey in terms of geographic positions instead of plane co-ordinates are so limited, if existing at all, that it is impossible to justify any of the necessary increase in computing costs.

The State plane co-ordinate systems advocated are considerably better than the local systems mentioned by Mr. Sheldon. The State systems are based on carefully devised projections; in general they have a minimum dimension of about 180 miles, a maximum dimension frequently equal to the largest dimension of the State, and a maximum scale correction of one part in ten thousand. It appears that only a small percentage of engineers making ordinary surveys would be required to work in an area where such systems adjoined, and those few who might have to do so could utilize one of the systems throughout their survey. One of the great uses for a standard datum will be for the description of property. In fact it is the writer's hope that the demand for control for property surveys will be so great that it will ensure sufficient control for all surveys. It will be only the greatest exception when a property survey will cross from one State system to another. The boundaries of the systems have been especially arranged to reduce further the possibilities of this occurrence.

In conclusion, it is well to emphasize the fact that Mr. Sheldon has presented an important and timely paper, worthy of the careful study of all civil engineers. He shows the importance of a universal horizontal datum and directs attention to the simplicity of geodetic reduction for ordinary surveys. However, in spite of offense to the mathematical sense that plane co-ordinates invariably produce and also in spite of the difficulties encountered when two such systems join, the accuracy and practical advantages they offer make them invaluable as a means of establishing the use of a universal horizontal datum and are probably the best method of utilizing such a datum in any case.

The question at issue could be stated as follows: Is the increased cost to the private surveyor, of computing geodetic positions for "run-of-the-mill" surveys, justified by the elimination of the errors and difficulties which may occur at the infrequent boundaries of adjoining plane co-ordinate systems? The writer believes that the cost is not justified.

Ralph Z. Kirkpatrick,[4] Esq. (by letter).—After having had an initiatory part in its development, the writer inherited, administratively, the horizontal geodetic control system in the Canal Zone, which is described accurately in Mr. Sheldon's paper.

---

[4] Chf. of Surveys, Panama Canal, Balboa Heights, Canal Zone.

In any work of sufficient importance the method is likely to warrant the expense of the requisite secondary and tertiary triangulation and traverses. An interesting application was in the 1911–12 rectangular Canal Zone Land Survey, a sectionalization of lands into 2-km squares. Unfortunately, when 40% of the intersections had been determined in the field, the project was abandoned due to the adoption of the then new military policy of nationalizing all lands and expropriating by purchase all settlers' lands, crops, and improvements.

The flexibility of the system has caused its use in the Canal Zone in virtually all city, cadastral, and topographical surveying (such as the Madden Road and Dam project), whether in the jungle or elsewhere, by the Army, Navy, and the Canal Administration. An interesting and early adaptation was in determining the errors in boundaries of certain Colombian rectangular land grants owned by the Panama Railroad Company. The lines had been run by magnetic bearings and measured inaccurately. Studies of the old documents were made and certain long-time accepted boundary points were tied into the geodetic control, and new controlled traverses were run through the accepted points. Eventually, a position was found for "Point A" (the initial point of beginning in the descriptions of the 1855 grants), for which all conditions were met. It was then learned that a mile-post (mentioned in the description), had been moved many years before. Comparison of the true azimuths through certain of these points revealed a compass variation of 7° 14′ east, virtually checking the variation (7° 15′) on the 1855 map; with that checked, the steps in correcting the boundaries in the field became mere routine.

E. B. Roberts,[5] M. Am. Soc. C. E. (by letter).—A problem is treated in this paper which is vital to surveying and mapping programs—a problem, therefore, the economic importance of which can scarcely be over-emphasized. The author is heartily endorsed in his plea for general use of geodetic control in the co-ordination of surveys. It is thought that this principle has the support of most informed engineers, and that the problem, therefore, is one of means to its end. The means advocated in this paper are open to strong criticism.

Because of its scope, the national geodetic datum is computed and defined in terms of geodetic co-ordinates. The reference surface being a spheroid, the azimuthal and distance relations of points on the surface cannot be determined by plane geometry. Geodetic computation of positions is necessary, as well as other special treatment. Triangulation of any magnitude does not achieve full value unless adjusted by least squares. The checking of geodetic and astronomic determinations in horizontal control surveys involves highly technical problems, and the differences are not always small, as stated by Mr. Sheldon.

---

[5] Hydrographic and Geodetic Engr., U. S. Coast and Geodetic Survey, Washington, D. C.

These considerations are not pertinent to the problem, however, because the establishment of the national datum, and the performance of control surveys on a scope demanding geodetic treatment, are provided for by competent Federal and State organizations. The problem is how practicably to handle local surveys, mainly traverses, so they may be defined in terms of, or relative to, the national datum, a sufficient number of control points on that datum being presupposed to be available. Three possible methods are:

(1) Use of geodetic co-ordinates and pure geodetic computations;
(2) Use of geodetic co-ordinates and plane survey computations; and
(3) Use of rectangular co-ordinates on an arbitrary reference plane related to the national geodetic datum.

Method (1).—This method appeals to the geodesist because of its technical perfection. It is true that geodetic position computation in itself is simple enough to be understood by competent surveyors. It is the only form of geodetic computation that would be indicated in general for local surveys. Its use, however, for the computation of points through the mass of traverses comprising ordinary surveying would be laborious and generally unwarranted in view of the development of Method (3). For this reason Method (1) is difficult to popularize.

Method (2).—After stressing the technical unsoundness of plane co-ordinate surveys and the simplicity of geodetic position computation, the author tacitly acknowledges the laboriousness of geodetic position computations for traverse work, and proceeds to advocate Method (2). Its advantages are the use of the geodetic datum, and simplicity, with no laborious computations, and no artifice, such as a plane co-ordinate grid. Its shortcomings in the matter of accuracy are serious.

It involves linear adjustment of azimuth discrepancies and position closure errors in traverses between geodetic control points. Geodetic corrections are grouped with accidental errors for adjustment. This is illogical, because the geodetic corrections have no linear characteristics; that is, they have no accidental distribution.

Table 4 is an inadequate criterion of proportional errors, because it deals only with the special case of straight traverses. It is not an example of the worst condition ever likely to be encountered. Although it is true that most traverses would have better length distribution than this extreme example, it is also true that they would have poorer distribution of relative directions. In the straight traverse used as an example the linear distribution of closure errors tends to approximate the distribution of geodetic corrections. In a meandering or circuitous traverse this is not so. In the case of a traverse closing on its own starting point the algebraic sum of the geodetic corrections is zero, resulting in their complete disregard by the linear adjustment. A moment's consideration makes it clear that Table 4 has no meaning for other than straight traverses.

It is unnecessary to develop this reasoning further. Even if the proportional errors shown by Table 4 were critical, they would still be too large for acceptance for common use in the United States; in fact, they are greatly in excess of those found in modern plane co-ordinate projections.

Method (3).—In plane co-ordinates, linear traverse adjustments concern only accidental errors and, in this case, are logical. Position computational methods are technically rigorous. The source of error lies in the impossibility of correctly representing a spheroidal surface on a plane surface. The error, however, is definitely known, and can be kept small.

The Lambert and Transverse Mercator grids established for the various States by the U. S. Coast and Geodetic Survey make geodetic control available for use on plane rectangular co-ordinate projections the maximum scale errors of which are kept within satisfactory limits. As an example, the entire State of North Carolina was covered by a single projection, only at the very extremities of which did the scale error become slightly greater than 1:10 000. Obviously, throughout the greater part of the State the errors are much smaller. Even so, the scale error, everywhere, is known and readily corrected if necessary.

Admittedly an artifice, and an indirect approach to the problem, such a projection nevertheless is finding ready acceptance. It leaves to competent organizations the performance and computation of necessary geodetic surveys, and the definition of the control points in terms of the projection. The local surveyor has nothing new, either to learn or to do, but to accept a ready-made grid instead of a local, unrelated grid of his own. All the control points will eventually be on it, and his work will be that of plane survey computation in its simplest form. Nevertheless, it will be on the national datum.

From the foregoing it is argued that plane surveying is definitely not "out of date." It is, in fact, finding wider use in connection with the projections described, and bringing the use of geodetic control more and more "into the picture."

H. W. HEMPLE,[6] M. AM. SOC. C. E. (by letter).—Geodetic control expressed on a geographic base has no superior when accurate methods of measurement, and exact methods of computation, are used. Mr. Sheldon is to be commended for endorsing it for local surveying purposes. However, he uses an approximate method of computing whereby plane surveying methods are applied to a geographical base, and the resulting data are expressed in terms of geographical positions. His field of activity is in the vicinity of the equator, and, therefore, he is able to do this without undue violence, because of the small rate of convergence of meridians, and because the area covered by his surveys is of limited extent. Since he can do this, the author immediately assumes the premise that such a method should be generally adopted throughout the United States, and concludes that there is no need for the adoption of the plane co-ordinate systems such as have been devised recently by the U. S. Coast and Geodetic Survey for each of the States.

---

[6] Hydrographic and Geodetic Engr., U. S. Coast and Geodetic Survey, Washington, D. C.

The term, "errors," is used rather loosely in the paper. To develop the spheroid representing the earth's surface on a plane it is necessary to apply certain mathematical corrections which are definitely known. These corrections can be applied to measurements made on the earth's surface, in order to relate them to the plane, and they are not errors in the sense of mistakes, blunders, or personal peculiarities of the observer, which apply to surveying observations. Mr. Sheldon considers these corrections, which are mathematically determined, in the same sense as errors of observation.

Table 3, entitled "Maximum Error Possible," purports to show the greatest possible errors which would occur for traverses computed by his method. Table 3 is misleading, however, because traverses do not usually extend in a straight line, but consist of a number of broken courses. He applies a correction for azimuth closures equally to all such courses. In this correction is included the effect of convergence of the meridians. This effect is a variable quantity, depending for any given latitude upon the length of line and its direction. In any given latitude, and for lines of equal length, it should be applied as a maximum to lines in an east-and-west direction, and as a minimum of no correction to lines extending north and south. On a line which bears eastward the convergence should be positive, and on a line which bears westward, it should be negative. Mr. Sheldon, on the other hand, distributes this effect, which is included in the azimuth closure, equally on all lines, even to those running in a north-and-south direction and to those lying in different quadrants. These effects of the convergence of meridians are not always small, and for traverses covering some distance the discrepancy due to their non-consideration, is likely to be considerable. A little study shows that to adopt such a system with its attendant discrepancies generally throughout the United States will lead to endless confusion.

To state that no consideration should be given to the convergence of meridians, because these effects are far overshadowed by the type of surveying accomplished and the accuracy obtained, is to take a rather limited viewpoint. Surveys of an accuracy of 1 part in 10 000, or better, are being executed by engineers and surveyors constantly, and work of this order of accuracy is not exceptional. Instrument manufacturers report that their greatest demand is now for 20″ and 30″ instruments, whereas several years ago the minute transit was most generally sold. This means that the Engineering Profession is becoming alive to the utility and ease of execution of accurate surveys. Certainly as the land becomes more thickly populated, more accurate surveys will be a necessity, and this being the case, the surveying system accepted should be adapted to such needs.

In advocating the method of computing advanced in this paper, Mr. Sheldon states that loop closures should be avoided, and that the courses should be of equal length. Why adopt a system of computation where restrictions such as these are placed upon the field work? Any computing system recommended should be adapted to the various conditions to be encountered in ordinary field operations. The terrain is not always such that courses of equal length can be obtained. It is not always possible to have triangulation stations conveniently located at the ends of a traverse, and it is frequently necessary to make a loop and close on the same station. Certainly, if the conditions of the field work are such as these, the work should not be hampered unnecessarily by restrictions imposed by the method of computation.

The writer has computed three actual traverses: (1) By the method advocated by Mr. Sheldon; (2) by the method of the State plane co-ordinate system; and (3), by geodetic methods (see Table 5).

TABLE 5.—COMPARATIVE ACCURACY OF SURVEYING COMPUTING METHODS.

Traverse No.	State	Length of traverse, in feet	Criteria	(1) Method advocated by Mr. Sheldon	(2) State plane co-ordinate system	(3) Geodetic method
1	Nebraska	80 700	Azimuth difference	9′–48″.3	0′–59″.0	0′–64″.4
			Error of closure	1 to 4 000	1 to 11 700	1 to 11 700
2	New Jersey	27 600	Azimuth difference	2′–14″.4	0′–47″.1	0′–49″.4
			Error of closure	1 to 7 220	1 to 12 800	1 to 12 800
3	Nebraska	69 000	Azimuth difference	7′–55″.2	0′–05″.7	0′–10″.3
			Error of closure	1 to 11 300	1 to 30 200	1 to 30 200

These traverses were chosen at random. The field work was done in accordance with instructions for second-order surveys specifying an error of closure of 1 to 10 000, or better. These results show that the State plane-co-ordinate systems and the geodetic methods of computing are rigid, and that the same field observations give the same closures. If third-order specifications for field work had been adopted, the results from the method advocated by Mr. Sheldon would give closures of less than 1 to 5 000 and the work would not conform to third-order accuracy. For this method, also, it is impossible to determine, for any given traverse, what proportion of error is introduced by the method of computation, and what is due to the field observations. If this method were adopted universally, and closures such as those illustrated were obtained for traverses between fixed triangulation stations, then lines run between stations established on different traverses, would be subject to large discrepancies, and the resulting confusion would be intolerable for any rigid control system.

If an extensive system of triangulation is required, the geodetic methods of computation should be used. These computations are not especially difficult or involved, and should be readily understood by any graduate of an engineering school, who has pursued the usual mathematical courses. The resulting data are expressed in terms of latitude and longitude. These terms can be readily converted to the plane co-ordinate system adopted for the State, and on that projection any traverse can be computed with greater ease to any required degree of accuracy than would pertain to computations of traverse by geodetic methods or by the method advocated by Mr. Sheldon.

These State systems of plane co-ordinates were adopted at the urgent request of practical engineers who wished to make use of the advantages accruing to their surveys through connection to the national net of geodetic control, but wished the mathematics of relating their surveys to such points to be as simple as possible, consistent with attaining the accuracy desired.

In devising the plane co-ordinate systems for the various States, two general forms of projection were used. For those States the greatest extent of which is in an east-and-west direction, the Lambert conformal projection was adopted, and for those States lying mostly in a north-and-south direction, the transverse Mercator projection was used. The earth's spheroid at sea level was developed on these projections for areas the extent of which was determined by the limiting scale factor necessary to bring the sea-level surface to that of the plane. In most cases this limiting correction, or scale factor, was kept less than 1 part in 10 000. This limitation necessitated more than one zone in most of the States. These scale factors vary according to the distance from lines of exact scale which, in the Lambert projection, consist of two standard parallels of latitude, and in the transverse Mercator projection of two lines on either side of the central meridian and parallel to it. For an area 158 miles in width, the maximum scale factor is less than 1 part in 10 000. The scale factor varies as the distance from a line, and not from a point of origin, as stated by Mr. Sheldon.

For any surveys within these zones which are connected to the national control net, and are expressed in terms of State plane co-ordinates, the distortion due to placing the surveys on the projection is, in most cases, less than 1 part in 10 000. If the scale factors are applied to the linear measurements, which is not a difficult matter, then the limit of accuracy is dependent almost solely upon the standards of the field measurements.

It is true that at the junctions of the plane co-ordinate systems, there is a jump from one zone to the other. To obviate any difficulties due to traverse lines extending from one zone to another, a sufficient overlap is provided at the junctions, so that any traverse may be placed on either one zone or the other. It is a simple matter to convert the co-ordinates of one zone to those of the other at the point of overlap.

In making use of plane co-ordinate systems for the computation of traverse surveys, a connection is made at each end of the line to triangulation or traverse stations previously located on the national system of control surveys; or the traverse may be a loop and tie to the same initial point at the end of the survey. The positions of the stations to which connections are made are expressed in terms of x and y-co-ordinates with a grid azimuth to a definite point near-by, all on the plane co-ordinate system adopted for the State. The grid azimuth is carried through the traverse from the starting point to a closure at the station at the end of the traverse. The azimuth closure is then distributed equally among the angles of the traverse. The linear measurements are reduced to the horizontal, and if they are above about Elevation 500 they should also include the correction to reduce to sea level. If the maximum of accuracy is desired, the scale correction should also be applied. As previously stated, in most cases, this scale correction is less than 1 part in 10 000 and may be ignored if the accuracy desired does not exceed that criterion. The survey is then adjusted by the method of "latitude and departure" which is so generally known to surveyors and engineers.

The United States is not alone in the adoption of the plane co-ordinate systems for general surveying purposes. Such projections have long been in use in many European countries. Most of these countries are thickly settled and land values are high. Methods of a high degree of accuracy are required for property surveys. These countries have found a plane co-ordinate base adequate for their needs. Should not this country benefit by the experience of others? As the population of the United States becomes greater and land prices increase, surveying standards pertaining to property must be on a higher plane than has generally prevailed to this time. Plane co-ordinate systems, mathematically determined and related to the spheroid, to which field surveys can be referred by utilization of the simple methods of plane surveying, are entirely logical and consistent, and furnish a simple and readily understood method to which engineers and surveyors may turn with confidence that the accuracy desired will be obtained.

These systems are finding ready acceptance among engineers and surveyors. Two States—New Jersey and Pennsylvania—have already adopted laws legalizing the use of the State plane co-ordinate system for property description purposes. Several other States are also considering similar laws.

As to Mr. Sheldon's conclusion that plane surveying is out of date, if by this statement he means relating surveys to a State plane co-ordinate system, the writer takes issue with him. These systems are mathematically logical, and the surveying data expressed thereon are consistent among themselves. Surveyors need have no hesitancy in relating their surveys to such systems with assurance that, if the recommended methods of computing are followed, the accuracy of their data will be limited only by the standards of the field measurements.

J. C. CARPENTER,[7] M. AM. SOC. C. E. (by letter).—Any argument for the universal use of horizontal geodetic control should receive the unanimous endorsement and active support of the entire Engineering Profession. This basic scheme for reference of surveys is the only satisfactory method, and its general adoption seems so logical that it is difficult to understand the indifference displayed by the majority of civil engineers. Before engineers can attain the objective of the universal use of horizontal geodetic control they must enlist, not only engineers, but administrators, executives, and legislators, in a campaign to promote the use of this extremely valuable datum of reference. Engineers are the only members of society who can be brought to realize the value of horizontal control, and the responsibility for this educational work will fall on the shoulders of a small group who are enthusiastically determined to carry the campaign to its logical conclusion. Papers of the type presented by Mr. Sheldon are necessary to bring the subject to the attention of engineers throughout the country.

---

[7] Senior Highway Engr., U. S. Bureau of Public Roads, Fort Worth, Tex.

Perhaps the "wish was father to the thought" in Mr. Sheldon's statements that the main triangulation net of the U. S. Coast and Geodetic Survey is nearing completion. About 65 000 miles have been completed in the field and partly computed and published. The final spacing of 25 miles between arcs, will require 117 000 miles. Hence, the actual work is scarcely half finished. True, the projection of the remaining cross-traverses will be easier and less expensive, but there will be some work necessary on the older nets and a large volume of computation and adjustment required so that a conservative estimate places the project now (1937) at about 50% complete. The only way to complete the remainder of the work is an educational campaign among engineers, first of all, and an insistent demand from members of the profession for the completion of the net to a 25-mile spacing.

Similarly, Mr. Sheldon's optimistic statement that some States have begun to tie their extensive highway surveys to the national net is questioned. A large mileage in North Carolina has been tied to the network. Texas made a start on one survey but has never finished that one project and seems indifferent to the entire method. If the chief engineers of the forty-eight State Highway Departments of this country would spend enough time on a study of the possibilities contingent upon the use of geodetic control for highway surveys, and then give the scheme a fair trial in the field, they would leave a permanent legacy of basic control for all planning operations, all mapping procedure, cadastral surveys, and engineering surveys of every character which would be as valuable as the transportation facilities they provide, and, undoubtedly, its permanency would be equal to, or in excess of, the surfaces now being constructed. Geodetic coordinates tied in to the equator and to Greenwich meridian, converted to x and y-co-ordinates for ready use by the most imcompetent land surveyor, spaced along the highways, monumented, and the co-ordinates stenciled in the monuments, will bring the use of this system to a practicable possibility.

Mr. Sheldon has correctly stated the reasons engineers fail to use the network as a control, even if they find a monument within usable distance of their survey, but there is no excuse for the modern engineer to avoid the use of the control, for the Coast and Geodetic Survey has developed a simple and practical method of conversion from spherical to plane coordinates and when the x and y-values are known, it becomes a matter of the use of familiar latitude and departure surveying. O. S. Adams[8] has written a clear and convincing description of the procedure that has been developed by the Coast and Geodetic Survey for the engineers of the United States to use in making their surveys of permanent value. Mr. Sheldon has listed publications that may be consulted by interested surveyors. There are two very important publications of the Coast and Geodetic Survey, which are not mentioned, namely, *Special Publication No. 194*,

---

[8] "State-Wide Systems of Plane Co-Ordinates," *Civil Engineering*, January, 1937, p. 33.

"Manual of Traverse Computation on the Lambert Grid," and *Special Publication No. 195*, "Manual of Traverse Computation on the Transverse Mercator Grid." These excellent publications outline in clear and concise form the procedure to be followed in using plane co-ordinates. Every detail is covered and each possible problem is illustrated by examples. Plane co-ordinate tables for the State may be obtained from the Coast and Geodetic Survey and any engineer who may decide to use the Geodetic network can obtain complete information and detailed instructions from that agency.

Mr. Sheldon has described the system in use on the Canal Zone and his description admirably illustrates the difficulties, probabilities of error, and complications in closure that may be expected when an isolated area is to be covered by a system of control. This is the best possible argument for the adoption of the plane co-ordinate control adopted by the Coast and Geodetic Survey for all surveys in the United States. This Canal Zone system of control is not suitable for general use in the United States. Without doubt, the national geodetic net will ultimately be used as a control for all surveys, but the realization of this condition will be brought about through the use of the plane co-ordinate systems developed by the U. S. Coast and Geodetic Survey for all the States of the Union. Conformal conic projections flattened to a plane will provide simple, easily used surfaces and allow engineers to use ordinary surveying methods and the co-ordinates will be right-angle x and y-distances, in feet. When the procedure is so simple and easy to apply there is no excuse for any engineer to become frightened and fail to take advantage of the control survey. With the completion of the triangulation system and publication of the positions, together with the plane co-ordinates based on these new State systems, the adaptation of this system for all surveys will be very much facilitated.

Air-mapping has developed rapidly during the twenty years, 1917–37. No doubt many important improvements in methods and technique are just "in the offing." There are numerous agencies operating throughout the United States and the pictures being obtained are undoubtedly superior to any existing maps; but the horizontal control that is necessary to make these pictures display, accurately, the correct and true position of the topography is not in existence and there is some question as to the value of these pictures in the permanent mapping method for the entire country. It is a case of "the cart before the horse" and, in this instance, the cart may be found to be of limited value.

The geodetic network must be completed by the agencies of the National Government. Its completion is the first important step in the development of a logical plan for mapping, planning, construction, and maintenance of public and private works. Engineers are competent to explain the immense value and vital necessity of this work and, therefore, the "Practical Use of Horizontal Geodetic Control" warrants the attention of all members of the profession, and its application should be actively encouraged for all surveys.

George D. Whitmore,[9] M. Am. Soc. C. E. (by letter).—The proposition set forth by Mr. Sheldon, to compute all horizontal surveys on the spherical co-ordinate base, unquestionably has considerable merit. He convincingly urges engineers to use the ideal spherical co-ordinate basis for preserving survey results, and for rendering such results universally usable. It is believed, however, that the procedure he proposes is too far ahead of the times. Perhaps the end result which he describes could be better accomplished by getting to it more gradually—by easy stages or steps.

Many surveyors and engineers of the present time, for example, although understanding generally the mathematics and theoretical value of rectangular co-ordinate systems as computing and plotting bases for survey results, nevertheless do not clearly realize all the every-day practical advantages to be gained by using even this simple type of co-ordinate system. Hence, a majority of engineering surveys to-day are executed and used without benefit of any kind of a co-ordinate base—spherical or plane. From the standpoint of the engineers' education, therefore, it might be preferable to stress, for a few years at least, the importance and advantages of any system of co-ordinates, rather than to try to plunge at once into full use of geographic co-ordinates. After all, the use of co-ordinates, whether they are spherical or rectangular, is only a means to an end. The primary purpose of any co-ordinate system is to show by a simple mathematical expression the relationship of each point to all other points of the system. The units of measure used, whether feet, meters, or degrees of arc, are only a means of writing this expression.

Most engineers appreciate the necessity for some kind of co-ordinate basis in constructing maps covering large areas, especially if several map sheets are involved. If the maps cover extremely large areas, such as a State, the necessity of spherical co-ordinates is not questioned. If the maps cover smaller areas, such as a city or county, the chances were, until quite recently, that the maps would have been based on some kind of a local plane co-ordinate system. Thus, in strictly mapping operations, the need for a co-ordinate basis is not questioned. Either through inertia or lack of complete understanding, however, engineers have not as a body carried this same reasoning into their engineering surveys. It seems apparent to the writer that what is good practice for mapping is also good practice for surveying.

Perhaps the principal reason why engineers have been slow in using co-ordinate systems in surveys is their realization of the shortcomings of local plane co-ordinate systems, so well explained by Mr. Sheldon. It so happens that there is now available, however, a type of plane co-ordinate system which overcomes many of the disadvantages of such local systems, but which retains many of their advantages. This is the State Plane Co-Ordinate System developed and published for each State by the U. S. Coast and Geodetic Survey in 1934. So much has already been written regarding these State-wide plane co-ordinate systems that there is no need to repeat the descriptions herein. It might be stated in summary, however, that these systems extend over large areas without serious distortion in either distances or positions. Such distortion as does exist in distances or co-ordinates is exactly known from the relation between the spheroid and plane, and, hence, can be determined instantly in case more precise distances or positions are reqired. These systems, on the other hand, have all the advantages of local plane co-ordinate systems in simple, easy computations. They have also the principal advantage of spherical co-ordinates in that they are related directly to all the basic control surveys of the country; it is a matter of only a few moments of computing to convert plane co-ordinates to geographic, and *vice versa.*

[9] Chf., Surveys Section, Eng. Service Div., TVA, Chattanooga, Tenn.

Thus, it seems apparent that the State-wide plane co-ordinate systems, representing a nice compromise between the universal geographic and the local plane systems, will be the basis, if any, used by engineers in the computation of their surveys during the next several years. Regardless of the real merit of getting all surveys on the universal spherical base, it will take several years and much more propaganda than a few papers in the technical journals to convert engineers to the actual practice.

The experience of the surveying organization of the Tennessee Valley Authority, which adopted the State-wide plane co-ordinate systems soon after their publication, is gratifying. Until that time, all routine reservoir surveys were computed on local plane co-ordinate bases. All valley-wide projects (usually extending over parts of seven States), such as basic planimetric maps, topographic maps, and regional maps, were plotted on the geographic co-ordinate base. Extensive mapping projects similar to these latter are still plotted on the geographic co-ordinate system, with the principal control surveys being computed in terms of spherical co-ordinates. The traverses serving as detailed control for such maps are computed either on the State plane system or the spherical system, whichever happens to be most convenient. Since such map sheets show the projection lines for both systems, either basis may be used in plotting.

All reservoir maps and surveys, however, since they extend over smaller areas (each reservoir being usually entirely within one State), are now computed on the State plane co-ordinate bases. Such surveys include traverse control; large-scale topographic maps of dam sites, camp sites, and town sites; cadastral surveys and maps for land acquisition; transit-tape traverse of the final reservoir property boundary; ranges for measuring future silt deposits; transmission line surveys, and many other types. In the computing unit, where a large volume of computations are handled, using both geographic and plane systems, there is practically unanimous opinion that the State-wide plane systems fulfill a long-felt need, that they must displace local plane co-ordinate systems, and inevitably will be used by practical engineers rather than the more cumbersome and difficult spherical system.

R. M. Wilson,[10] M. Am. Soc. C. E. (by letter).—Many questions that arise in the use of horizontal-control surveys are included in this interesting paper. One of the most important of these is: In what form should the results of control surveys be expressed to meet the requirements of the many kinds and classes of dependent surveys? The basic net of first- and second-order triangulation, reaching into all parts of the United States, provides a rigid framework by which to determine the correct horizontal position on the earth's surface of all other surveys that are connected with it.

---

[10] Chf., Section of Computing, U. S. Geological Survey, Washington, D. C.

It is well understood that the geographic co-ordinates of a triangulation station identify, exactly, the position of that station on the surface of the earth. It is true that the rectangular co-ordinates of that station also identify its position exactly, provided the rectangular co-ordinate system is based on a formal plane projection of the geodetic reference system.

The standard rectangular co-ordinate systems for the various States developed by the U. S. Coast and Geodetic Survey are based on mathematically accurate principles. They provide the means to transform geographic co-ordinates into rectangular co-ordinates, and *vice versa,* for any particular point in a survey, without in the least jeopardizing the identity of the position to which the co-ordinates refer. It is apparent, therefore, that co-ordinates in either form represent equally well the position of a point as determined by geodetic surveys. One form is merely a translation of the other. It should be noted that the results of first- and second-order triangulation contained in the more recent *Special Publications* of the Coast and Geodetic Survey give the co-ordinates in terms of latitude and longitude and also in terms of x and y referred to the standard State systems.

It is left to the discretion of the user, therefore, to decide which form of co-ordinates will best suit his particular requirements. It is not at all necessary, however, that an engineer must accept one form for all surveys to the total exclusion of the other. In general, geographic co-ordinates are desirable in projects that are geographic in scope, that is, those that involve large parts of the earth's surface. Rectangular co-ordinates are the natural form in which to express detailed and intensive surveys within small areas, and surveys made in connection with the development of local engineering projects.

Mr. Sheldon mentions the U. S. Geological Survey as one of the organizations using geodetic co-ordinates. The topographic "quadrangle" maps issued by the Survey are integral parts of the topographic map of the United States, and it is logical that the map should be subdivided according to uniformly spaced meridians of longitude and parallels of latitude. The units are thus arranged in an orderly and systematic manner throughout the country from Maine to California and from Florida to Minnesota. There is no discontinuity in arrangement because of State lines. It is obvious, therefore, that geographic co-ordinates are the best form in which to express the positions of control-survey stations used in the standard mapping operations of the Geological Survey, because this mapping is geographic in scope. The system just described was selected by the Geological Survey before 1880. Even if the State rectangular co-ordinate systems had been available for use at that time, any system based on them could not have been considered as comparable in usefulness to the one actually chosen and in use to-day for subdividing the topographic map of the United States.

The Geological Survey recognizes the value of the State rectangular co-ordinate systems, however, and is now publishing many of its standard topographic maps with marginal marks to show where the grid lines of these systems may be drawn. Any engineer can then draw the grid lines, and so plot upon the map, or scale from it, any positions expressed in rectangular co-ordinates in which he may be interested.

The kind of transit traverse described by Mr. Sheldon, with its results computed in terms of geographic co-ordinates, is not new. The Geological Survey began using it for the control of topographic mapping as early as 1893. During the 20 yr since 1916 a total of about 100 000 lin miles has been done, and in 1935 alone the Geological Survey executed 9 204 lin miles of transit traverse. The field and computing methods have become more accurate and efficient with the passing of time, so that these control surveys have remained consistent with the increasing accuracy of the mapping based on them. Frequent azimuth observations are made by the simple astronomic methods familiar to surveyors to avoid any appreciable accumulation of azimuth error in the traverse.

The conversion factors given by Mr. Sheldon in Table 2 are the reciprocals of the M and P factors used by the Geological Survey to express the results of its traverse in the form of geographic co-ordinates. The proved usefulness of these surveys justifies the attention that Mr. Sheldon has given them.

The standard co-ordinate systems developed by the Coast and Geodetic Survey are designed to be State-wide in application. Nevertheless, any individual engineering project or survey that involves an entire State is extensive enough to be considered geographic in scope, so that geographic co-ordinates ordinarily would be appropriate to use for it.

In surveys extending over an entire county, or over a compact group of several counties, rectangular co-ordinates are convenient to use. Then, because the systems are continuous throughout large zones in each State, any county survey usually will be consistent and continuous with surveys made in adjacent counties. Discontinuity exists only along State boundary lines and along the lines separating the large zones; but the systems provide an overlap, so that no ordinary survey need be separated into parts because it lies across a State or zone line.

Many county surveys, and nearly all city surveys, are already referred to some rectangular co-ordinate system. Most surveys for general engineering projects, for mining or other local projects in which accurate and intensive work is required, use rectangular co-ordinates. The State systems provide the means to express the results of these surveys in common terms, so that they may blend harmoniously and so that each may have the benefit of the results of others adjacent to it. To use these systems no real change is needed in the methods already employed in plane surveying beyond accepting the co-ordinates for the origin and the azimuth of an initial line as given by the basic control surveys. Of course, the same object—harmony—could be attained by using geographic co-ordinates, but these may not be convenient to use in local projects. The State systems provide for harmony without losing the advantages of plane-surveying methods.

It would be ridiculous to use figures expressing latitude and longitude in setting column foundations for structures or for calculating volumes in earth-work. It would be equally ridiculous to struggle with plane rectangular co-ordinates, referred to the State systems, in plotting a map of a continent or in computing a far-reaching arc of triangulation. Nevertheless, the standard State co-ordinate systems can hold, in rigid relationship with one another, surveys that differ in extent and scope even as widely as these.

JULIUS L. SPEERT,[11] JUN. AM. SOC. C. E. (by letter).—The author gives voice to a complaint that undoubtedly has been felt by many engineers, but has seldom been mentioned. It is unfortunate that the relative simplicity of many kinds of surveying computations should be masked by complicated explanations or instructions. This condition is probably due to the fact that, as far as the writer knows, the theory of surveying computations is to be found, in general, in only two types of publications; namely, college textbooks, and Government publications. By its very nature, a college textbook must approach its subject gradually, emphasizing the method of approach rather than the ultimate conclusion. The voluminous explanation necessary in this type of treatment makes the book unsuitable as a practical working manual. Similarly, Government publications on surveying, as a rule, are scholarly treatises, written by, and of value to, scholars and mathematicians, but too frequently unintelligible to the average surveyor, whose knowledge of higher mathematics is somewhat limited and who has little desire to become involved in its ramifications.

If there were available a concise manual of instructions in which the method of performing the computations was clearly explained and the significance of each step was briefly stated, there would be less tendency for the young engineer and the practical surveyor to shun precise methods of computing and recording surveys in favor of the simpler methods of plane surveying. The mathematical justification for the various steps should be included in the appendix to this manual, where it would be available to the mathematically minded but would not confuse and bewilder those less gifted.

The author's proposed remedy is to simplify the use of geodetic control by substituting for the more rigorous computations what amounts almost to the methods used in plane co-ordinate computation. For the Canal Zone, where the maximum convergence of meridians amounts to not more than 5′, this method appears to be satisfactory. However, examination of Table

---

[11] Asst. Engr., Water Resources Branch, U. S. Geological Survey, Washington, D. C.

3(*b*) and Table 4(*b*) shows that for latitudes in the United States excessive errors might readily be introduced into surveys of any appreciable extent. The author offers no simple method for evaluating these errors.

There can be little doubt that the development of the State plane co-ordinate systems, published by the U. S. Coast and Geodetic Survey in *Special Publication No. 193* (11)[2] constitutes the greatest advance in recent years in the simplification of surveying computations. These systems permit computations as simple as those of plane surveying and yet make it possible to tie any located point rigidly to the national geodetic-control net as well as to every other point tied thereto. Although a true, undistorted representation of the earth's surface is impossible on a plane, the State systems permit a precise evaluation of the error involved in the computed position of any point, thereby, in effect, eliminating that error by making possible a compensation for it.

To make the geodetic-control net more readily available for the use of plane co-ordinates, the U. S. Geological Survey has recently published, in pamphlet form, a set of formulas and tables by means of which the conversion of geodetic co-ordinates to plane co-ordinates on the State systems may be greatly simplified.[12] These formulas and tables are designed to be used with a computing machine and natural functions, thereby dispensing with cumbersome logarithms, and greatly reducing the labor and time required for the conversion. Complete detailed instructions are included in the pamphlet and, for those interested in the theory, the derivation of the formulas is explained in a short appendix.

With all the facilities now available for tying any survey to the national geodetic control net, there should be little excuse for an isolated, uncontrolled survey, and there is no longer any need for a part-way compromise between geodetic control and its practical application.

R. C. SHELDON,[13] ASSOC. M. AM. SOC. C. E. (by letter).—Although he was pleased with the several interesting and instructive discussions that were presented, the writer would have been more pleased if the opinions of those engineers interested in small local surveys had been presented.

Several of the discussers have stated that the system of survey computations as presented can be criticized for its lack of accuracy. The system is a combination of geodetic and plane computations and is used in such a manner that the accuracy of the reported position of any point is only limited by the accuracy of the survey methods, or by the accuracy of the basic control system. This is accomplished by the following steps:

(1) Geodetic positions are obtained for scattered points covering the area. This is the base control system, comparable to the control net, both primary and secondary, of the U. S. Coast and Geodetic Survey.

(2) Surveys run between these scattered points are usually computed by plane methods. The computed positions are reported as geodetic positions,

[12] "Formulas and Tables for the Transformation of Geodetic to Plane Co-Ordinates on the Lambert and Transverse Mercator Projections," by J. L. Speert, U. S. Dept. of the Interior, Geological Survey, 13 pp.

[13] Asst. Engr., Section of Surveys, The Panama Canal, Balboa Heights, Canal Zone.

the residuals beyond any minute line being carried in feet. This plane calculation gives positions which are not the same as those that would be obtained by a geodetic computation of the same traverse. This discrepancy was called an error in the paper. Table 3(*a*) and (*b*) gives the maximum possible discrepancy. Table 4 shows that this maximum is greatly reduced in practice.

(3) In cases where the points of the base system are so far apart that the error, as shown by Table 3 (the rigid use of which is modified by Table 4), approaches that of the specified error of the survey, additional triangulation points are put in and geodetic computations are made to obtain their positions. It is seldom necessary, locally, to place any of these additional points.

Mr. Hemple states that Table 3(*a*) and (*b*) is misleading because traverses do not usually extend in a straight line, but consist of a number of broken courses. The discrepancy between positions determined by geodetic computations and those found by plane computations, as well as the convergence of meridians, is caused by the fact that straight lines run on the surface of the earth by transit or other means are curved lines when referred to the sphere as a whole. With the standard assumption that the meridians of longitude all converge at the pole and the parallels of latitude are all parallel to the equator, the effect of this curvature of straight lines varies with their direction, being nothing for lines running due north or due south and a maximum for lines running due east or due west. The degree of this curvature also varies with the latitude, being nothing at the equator and a maximum at the pole. This latter variation would be small over the extent of latitude covered by the type of surveys under discussion, and can be ignored.

To present a clear picture of the relation between convergence of meridians, azimuth discrepancies, geodetic computations, and plane computations, it can be stated that a geodetic computation is the plane computation of a line that has been corrected for convergence of meridians in sections of equal length, those sections being of infinitesimal length.

From the foregoing and from an examination of the formula for computation of geodetic positions given in *Special Publication No. 8* (5)[2] of the Coast and Geodetic Survey, it is apparent that the discrepancies between plane and geodetic computations as well as the effect of convergence of meridians are almost entirely dependent on the difference in longitude of the ends of the line concerned. It is impossible to find any group of lines, running in any direction, that will have a difference in longitude greater than that of a line of equal length running due west.

Table 3(*a*) and (*b*) gives the maximum difference between positions determined by plane computation and positions found by geodetic computation, at the various distances from the point of origin. Table 3(*b*) would be entirely too rigid to use as a criterion for spacing points of the primary or secondary system on the Fortieth Parallel of latitude. The writer prepared Table 4 to show that this maximum difference was greatly reduced in practice by balancing the angular difference, due to convergence of meridians, and the error of traverse closure, due to neglect of geodetic corrections. Table 4 shows that for a straight-line traverse of 100 000 ft, the maximum error, from Table 3(*b*), would be 1:500, the unbalanced error of closure would be 1:1 100, and the position error of the worst point would be 1:2 300. Thus, the proportional errors shown by Table 4 were roughly one-half those of Table 3 for unbalanced traverses and one-fourth those of Table 3 for balanced positions. Mr. Hemple has submitted Table 5 showing the results of calculations of three separate traverses. The writer has prepared Table 6 to show the errors that would have been expected in these traverses if Tables 3 and 4 had been used as a guide. It would appear that Table 4 was a conservative estimate of the worst condition ever likely to be encountered in practice.

TABLE 6.—COMPARISON OF EXPECTED TO ACTUAL ERRORS

Traverse No.	Length, in feet	Maximum error expected (Table 3(*b*))	Unbalanced error expected (Table 4(*b*))	Unbalanced error obtained (Table 5)
1	80 700	1 : 750	1 : 1 500	1 : 4 000
2	27 600	1 : 1 500	1 : 3 000	1 : 7 220
3	69 000	1 : 900	1 : 1 800	1 : 11 300

It is unfortunate that Mr. Hemple did not extend Table 5 one place farther and show the discrepancy between the final positions as computed by the geodetic methods and as determined by the writer's method. This final position is the ultimate object of any survey. The writer feels certain that the discrepancy of this final position, in all three cases, would be less than the specified accuracy of the survey.

In the three examples given, even if the plane method of calculation suggested by the writer were satisfactory, he would not advocate its use on traverses of the type shown; that is, on traverses of sufficient importance to justify:

(1) The measurement of horizontal angles over these distances with sufficient accuracy to obtain closures consistently of less than 1′;

(2) Chaining with the accuracy and care necessary to secure 1:10 000 closures;

(3) Observing and computing the temperature corrections necessary; and,

(4) The reduction of the calculations to sea level.

The percentage of the total cost of the survey of computing either all or several sections of the traverse by a geodetic computation will be very small.

It is to be clearly understood that the methods presented in the paper are used as an extension of an existing system of primary and secondary control and are not used to obtain that control.

Both Mr. Roberts and Mr. Hemple gave the fact that loop traverses were not permitted in the proposed system as one of its disadvantages. This writer agrees with Professor Kissam that the fact that it does prohibit loop traverses is one of its advantages. Loop traverses have so many of the same qualities of loose ended lines that they are prohibited on any survey that is based on any general control system. On any survey unimportant enough to be based on one tie to the base net, or to the supplementary net, the error taken from Table 3 without any correction for angle balancing would not be large. For example, from Table 3(*b*), a line running for a distance of 10 000 ft from its origin must be at least 20 000 ft long and would be in error at its extremity less than 2 ft—an error of 1 part in 10 000 ft of line and an error of position of 1: 5 000.

Mr. Roberts criticizes the linear adjustment of azimuth discrepancies and position closure errors in traverses between geodetic control points. There would be many ways of correcting these azimuth discrepancies and geodetic corrections. The one chosen by the writer was the least accurate but was used because it was far simpler than any other. It requires no extra effort, the geodetic corrections and azimuth corrections being combined with the accidental errors for adjustment. Since these discrepancies and azimuth corrections are kept well below the specified accuracy of the survey the exact balancing of these small corrections is not important.

Traverses that are tied to any base net must originate at one of the points on this net and terminate at, or tie to, another unless they are the objectionable loops previously mentioned. In order to do this they must have a general direction, which is that of the line between the stations, although there may be courses in the traverse that will run exactly opposite this general direction. In this manner all traverses between points on the base system take on generally the characteristics of a straight line between the points. Any adjustment that corrects the closing error has a tendency to bring the positions of the several points nearer the geodetic positions. The fact that, in cases where the individual course runs opposite to the general direction of the traverse, the correction is applied in the opposite sign from the true correction is not as damaging as it would seem, because the corrections applied to the predominant number of courses in the traverse are applied in the right direction and tend to correct the discrepancies of all the positions.

As Mr. Wilson states, the method of transit traverse and computation given in the paper is not new and has been used by many organizations for years. The U. S. Geological Survey uses astronomical observations for azimuth to keep the effect of convergence of meridians at a minimum whereas, in the Canal Zone system, more frequent ties to the base system are used to accomplish the same result.

Professor Kissam asks the question, "Does not the proposed system require reduction from geographic positions to plane co-ordinates, computation by plane co-ordinates, and, finally, reduction back to geographic positions with accompanying loss of accuracy?" The system can best be explained as a plane co-ordinate system in which the spaces between successive minute lines of latitude and longitude are made the planes. The small plane areas that are enclosed by the minute lines are thus made to join at the lines, and there is no distortion of discrepancy when crossing from one to another. The only reduction that is necessary is the one that is required on any plane co-ordinate system; that is, the positions of the points on the base geodetic system must be converted to the plane co-ordinate system used. In the proposed system this reduction is made very simple, only the conversion of the seconds of latitude and longitude to feet being necessary. All points are used with that residual beyond any minute being given in feet.

Many of the discussers have advocated the State-wide plane co-ordinate systems that have been devised by the Coast and Geodetic Survey. These systems have met with much success in the years since the writer began preparing the paper under discussion. Their use is now advocated by many important organizations. They are, as Mr. Hemple points out, the law in at least two States, all of which is part of the reason why the writer feels some hesitancy in presenting the criticism of these State-wide plane co-ordinate systems that should have been made years ago. A greater part of this hesitancy is due to the fact that where they have been adopted and are in use, they will give surveyors and engineers a method of tying their surveys, that will be entirely satisfactory for most uses.

There are some points to these plane co-ordinate systems, however, that should be given full consideration before they are adopted in any State and required by law for land boundary description.

The use of the State-wide plane co-ordinate systems, or any other system that does not use the parallels of latitude or the meridians of longitude as a key, requires the introduction of the *X* and *Y*-designation, which is an added factor that engineers, surveyors, but more especially laymen, must learn to understand.

The State-wide systems still have the same objectional feature that is inherent in any plane co-ordinate system, in which the planes are continued for any distance; that is, a grid azimuth must be used. This is certain to cause considerable confusion especially in counties that already have grid azimuths for their own local plane system that will be different from the new State-wide grid. For many years to come, it will be necessary in those places, to mark every azimuth with some identification to show whether it is on the old grid, the new grid, or true azimuth. The Engineering Profession, which is just beginning to understand that there is a true and constant north, is to be now taught, that north is not north, but something else at right angles to the grid system. Although it is a relatively easy problem to identify the system on which any point may be recorded, as the figures will usually be much different, the identification of an unmarked azimuth will be difficult.

One of the advantages of any control system is that any point on a large project is identified and compared to any other point in the system by its co-ordinate positions. In intrastate work the plane system of co-ordinates covering that State does this very well. The tendency now is to forget political boundaries, however, and to base projects and surveys on natural features. Mr. Whitmore mentions that the TVA covers parts of seven

States. Seven different State systems of co-ordinates are used and then the geodetic system is used to correlate them all. If a system as advocated by the writer had been adopted, the same amount of field and office work would have placed the entire project on the one system.

The projections of the State-wide plane co-ordinate systems have been arranged so that the curved surface of the earth covering entire States has been squeezed in at the centers and spread out at the edges to form a plane. The degree of distortion caused by this squeezing has been kept below the ratio of 1: 10 000. For all surveying work for which it is desired to have an accuracy finer than this, certain corrections must be made. This fact will tend to place a restriction on the more accurate surveys. Surveys that on an unrestricted basis would be run to finer accuracies than 1: 10 000 will be run on this standard because of the inclination on the part of engineers not to use any more corrections than necessary. In this manner, progress in more accurate surveying will be retarded.

The use of State-wide plane co-ordinate systems has been mentioned by both Professor Kissam and Mr. Whitmore as a possible approach to the eventual universal use of geodetic control. The writer believes that, rather than being a stepping stone, the use of the State-wide plane co-ordinate systems will act as a wall stopping any future approach to that universal use. Plane surveyors will be content to follow the systems that are given them, and will become, if possible, a lower ranking branch of the profession than they are at present; and the knowledge and practice of geodesy will be confined to the employees of the U. S. Coast and Geodetic Survey.

The basic criticism of the writer to the State-wide systems of plane co-ordinates, or any other system of co-ordinates except geodetic, is that they are unnecessary. When the control system of the U. S. Coast and Geodetic Survey is completed, giving points of which the geodetic co-ordinates are known, at intervals of not more than 25 miles, it will be necessary for some organization, either local, State, or national, to place a number of supplementary points between these basic control points, for the use of local surveyors and engineers. In Pennsylvania, this spacing of supplementary control has been placed at a maximum of 5 miles.[14] These supplementary points will have to be established regardless of the system of computations used. In order to be of unquestioned authority they will have to be located with sufficient accuracy to justify their computation on a geodetic basis. If they are to be placed close enough to be useful to the local surveyor without prohibitive expense they will be close enough so that the maximum error introduced in any line run between them (computed by a plane computation as described in the paper and shown in Table 3(*b*)) will be less than the specified error of the surveys desired. For example, in Pennsylvania, with the maximum spacing of secondary control at 5 miles, the maximum error for the worst case would be the unbalanced, or loop, traverse run for 2.5 miles from the point of origin and returned. From Table 3(*b*) this would give a maximum error of 1: 3 500, approximately, which would be the worst case possible and would seldom be encountered. Most lines would be run so that the errors caused by neglect of geodetic corrections would be negligible.

---

[14] **"A Standard System of Plane Coordinates for Pennsylvania," by the Pennsylvania State Planning Board, Harrisburg, Pa.**

Professor Kissam has revealed the fact that the cost of computing surveys on a truly geodetic basis would be prohibitive for any commercial survey. However, the cost of computations on the system as presented by the writer would be very little. The first and second-order control will have geodetic computations in any case. The spacing of the secondary control will be governed by practical reasons so that it will be used. The cost of running and computing the third order, or traverses for use, will be the same in any case, for the writer's system, for plane co-ordinates, or for uncontrolled surveys.

Mr. Carpenter has revealed the fact that the main control net of the U. S. Coast and Geodetic Survey is not nearing completion, but is, in fact, little more than half finished (1938). It would be probably more important at this time to find ways and means of completing this important work and the enormous amount of supplementary control that will be necessary before it can be properly used on any system, than it is to find ways to use it after it is completed. Private engineers and small political units cannot be expected to spend very much money on any type of control other than local. A small part of the money wasted on inaccurately controlled and duplicated surveys would have completed this control system many years ago.

Laws have been passed in two States legalizing the use of State-wide systems of plane co-ordinates for land boundary descriptions. These laws were passed after considerable effort on the part of those interested, and will undoubtedly be legal for a long time. These laws would have been of more permanent value if they had been drawn in a more general manner, so that the primary requirement had been a survey based on geodetic control, leaving the method of making the connection between the geodetic control and the survey to the engineers and surveyors.

PRESSURES BENEATH A SPREAD FOUNDATION

By D. P. KRYNINE[1], M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. O. K. FRÖHLICH, DONALD W. TAYLOR, JACOB FELD, G. P. TSCHEBOTAREFF, A. HRENNIKOFF, ROBERT G. HENNES, T. A. MIDDLEBROOKS, A. A. EREMIN, M. M. BUISSON, FREDERICK J. CONVERSE, AND D. P. KRYNINE.

SYNOPSIS

An attempt has been made to confine the scope of this paper as nearly as possible to the limits defined by the title. Hence, discussion of tangential stresses (shears) and of pile foundations has been omitted entirely. In the "Introduction" an outline of stress distribution formulas is given, with special emphasis on the use of the "concentration factor," a conception applied to soil mechanics only since 1934.

Part I contains a description of a method of determining pressures under both uniformly and non-uniformly loaded foundations, except the case in which unit pressures on a part of the loaded area are infinite. This graphical process, termed the "reduced area method," may be applied in the case of a structure of arbitrary shape, and of an earth mass with an arbitrary concentration factor. Part II deals with the rigidity of structures and earth masses principally from the standpoint of their interaction.

Each of the two parts of the paper can be read independently. Only elementary mathematics, including trigonometry, has been used, the proofs of statements that require the application of calculus being presented in Appendices I and II.

Notation.—The letter symbols introduced in this paper are assembled for convenience of reference in Appendix III.

INTRODUCTION

Every theory of stress distribution within a body applies necessarily to an ideal material. Earth is not such a material, and theoretical formulas for semi-infinite isotropic bodies as used in this paper, may furnish data for an estimation of stresses within an earth mass, only if the latter is more or less homogeneous and isotropic to a considerable depth. Since stresses within an earth mass cannot be computed accurately, but can only be estimated,

---

NOTE.—Published in April, 1937, *Proceedings*.

[1] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

quick graphical methods are advanced in this paper to replace cumbersome analytical procedures.

Stress Distribution Formulas.—Consider the infinitely large mass in Fig. 1. A concentrated vertical force, P, is applied to its horizontal surface at Point A, thus creating unit stresses, s, within the mass, which decrease in intensity at a rate proportional to the square of the distance from the origin (Point A). At any point of the mass (O, in Fig. 1), the unit stress produced by the force, P, at Point A, will be:

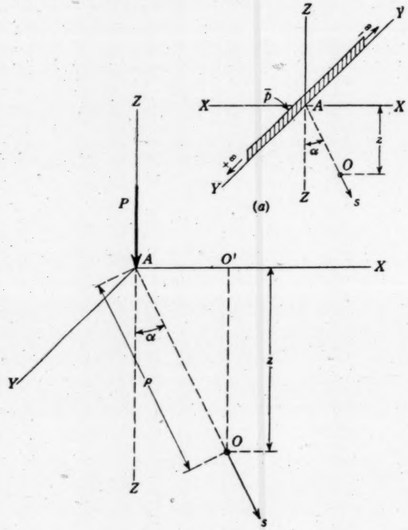

FIG. 1.

$$s = \frac{n\,P}{2\,\pi\,\rho^2} \cos^{n-2} \alpha \;\ldots\ldots (1)$$

Equation (1) has been proposed by John H. Griffith, M. Am. Soc. C. E.[2], and Dr. O. K. Fröhlich,[3] of Holland. Full credit for the development of a comprehensive theory of the concentration factor should be given to Dr. Fröhlich. The "concentration factor," n, is somewhat greater than 3 in the case of clays, and 6 or 7 in the case of coarse sands. It equals exactly 3 in the ideal case in which the mass under consideration follows Hooke's law, and is isotropic and incompressible, so that it may change its shape but not its volume. In such a case:

$$s = \frac{3\,P}{2\,\pi\,\rho^2} \cos \alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Equation (2) may be obtained from the formulas developed by Boussinesq.[4] If the mass is loaded at its horizontal surface with an infinitely long unit load, expressed as $\overline{p}$ units of weight per unit of length, and acting along the axis, Y-Y (Fig. 1(a)), the stress distribution in the plane, XAZ, and in every vertical plane parallel to it, will be the same. The stress, s, at Point O, will be:

$$s = \frac{2\overline{p}}{\pi\,\rho} \cos \alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Equation (3) represents the two-dimensional (plane) analogue of Equation (2). This is the so-called "Michell's radial distribution."[5] It shows that, in the case of a plane stress distribution within an elastic isotropic body, the stress intensities are inversely proportional to the distances from the origin of stresses, A.

Since α is the angle formed by the stress, with the vertical, the vertical pressure, p_z, at Point O (Fig. 1), is:

$$p_z = s \cos^2 \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

To find the two-dimensional analogue of the general formula, Equation (1), the vertical pressure at Point O caused by the action of a straight line (Axis Y-Y, Fig. 1), with a load, $\bar{p}$, per unit of length, bearing on the boundary, must be considered. A proposed method is developed in Appendix I. The value of the vertical pressure at Point O (Fig. 1) would be:

$$p_z = \frac{n_1 \bar{p}}{\pi \rho} \cos^n \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

From Equation (5) the value of the plane stress in a general case is:

$$s = \frac{n_1 \bar{p}}{\pi \rho} \cos^{n-2} \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

For the sake of brevity and for the purposes of this paper only, the coefficient, $n_1 = f(n)$, may be termed the "plane concentration factor," with values corresponding to n, as shown in Table 1. When $n = 3$, the value of n_1 equals 2, and Equation (6) becomes identical with Equation (3). Equations (1) and (6) can be applied in the case of any mass regardless of whether or not it follows Hooke's law. Since in this paper stresses are not determined from strains, the resultant of stresses coming to a point from two or more different sources may be determined by superposition.

PART I.—THE "REDUCED AREA" METHOD OF DETERMINING PRESSURES UNDER STRUCTURES

Pressures under uniformly loaded structures (vertical unit load, p) will be first determined; and for the purposes of Part I it will be assumed that the unit soil reaction, p, is also uniformly distributed throughout the foundation, and that it is vertical. Non-uniform loading, except the case of infinite unit loads, will also be discussed; and the corresponding soil reaction at a point of the earth's surface will be assumed vertical and equal to the unit load at that point.

THREE-DIMENSIONAL PROBLEM

Referring to Fig. 2, the problem is to determine the vertical pressure, p_z, at Point O. The horizontal projection, O', of this point on the boundary plane is selected as a center, and the loaded area, M' N', is subdivided into zones by concentric circles, as shown in the plan view. The radii of these circles, although arbitrary, should be chosen so as to make the division curves pass through marked breaks in the perimeter of the loaded

areas. Credit should be given to Messrs. Kögler and Scheidig[6] who first proposed subdividing a loaded area into circular rings, and not into rectangles, as is usually the practice. The area of an elementary zone, dA, practically equals the length of the curve, STU, times the width of that zone. The length of the curves is measured simply by "stepping off" small openings of a compass. Plotting the vertical ordinates, $T' T'' = S\,T\,U$, a figure, $M\,T''\,N$, shown in the vertical projection (Fig. 2), would be obtained. The area, $M\,T''\,N$ (Fig. 2) evidently equals the original loaded area. To take advantage of this "transformed" area the following graphical construction is proposed: The stressed condition at Point O would not change if the horizontal loaded area, A, weighing p units per square unit of area, is replaced by the transformed area; also if A of the same unit weight, p, is concentrated as a vertical line load between Points M and N. Actually, a hypothetical load acting at a point of an arc (Fig. 2), can be moved to any other point of the same arc without influencing, in any way, the value of the vertical pressure at Point O. This is because the values of ρ and α to be used in Equations (1) and (4) for computing the vertical pressure, are the same at all points of that arc. Hence, for computing the vertical pressure at Point O, all the loads acting on an arc (Fig. 2) may be concentrated at an arbitrary point along that arc. This is precisely what is done in constructing the "transformed area" by bringing all the loads of different arcs (Fig. 2) to their respective points of intersection with an arbitrary line, $M'\,N'$. An elementary strip, dA, of that vertical figure, produces an elementary vertical pressure, dp_z, at Point O, which can be determined using Equations (1) and (4):

$$dp_z = \frac{n\,[p\,dA]}{2\,\pi\,\rho^2} \cos^n \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

or, taking into consideration the fact that $\rho = \overline{O\,T'} = \dfrac{z}{\cos \alpha}$:

$$dp_z = \frac{n\,p\,dA}{2\,\pi\,z^2} \cos^{n+2} \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

The vertical pressure, p_z, at Point O, would be obtained from Equation (8) by summation, thus:

$$p_z = p\,\frac{n}{2\,\pi}\,\frac{1}{z^2}\,\Sigma\,dA \cos^{n+2} \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

The area, $\Sigma\,dA\ \cos^{n+2}\alpha$, which will be termed the "reduced" area, A_r, may be determined as follows: An arbitrary vertical distance, O-O' is taken as a unit, and a graph of $\cos^{n+2}\alpha$ plotted. For doing so, radii vectors emanating from Point O and making different angles, α, with the vertical are drawn, and distances equal to $\cos^{n+2}\alpha$ are plotted along each radius vector. The ends of the radii vectors would then form a smooth curve which is the graph in question. For extensive use a table of values of

---

[6] *Die Bautechnik*, Vol. 6, No. 17, p. 231 (1928).

$\cos^{n+2}\alpha$ will be found helpful. The following tabulation shows, for example, values of $\cos^{n+2}\alpha$ for the case in which the Boussinesq formula holds ($n = 3$):

in degrees	$\cos^5 \alpha$	α in degrees	$\cos^5 \alpha$
10	0.927	50	0.110
20	0.735	60	0.031
30	0.487	70	0.005
40	0.264		

In Fig. 2 the unit vertical distance referred to, accidentally equals the depth, z. The point of intersection, X, of a radius vector, OT', is joined with the top of the graph, $\cos^{n+2}\alpha$ (Line $O'X$). An ordinate, such as $T'T''$, is then reduced, tracing $T''x$ parallel to $O'X$ to intersect the continuation of the radius vector, OT', at Point x. Plotting $T'y = T'x$ and repeating this operation for all points of the line, MN, the "reduced area," A_r, is obtained and measured by a planimeter. This value is then introduced into Equation (9) to replace $\Sigma\, dA \cos^{n+2}\alpha$:

$$p_z = p\,\frac{n}{2\,\pi}\,\frac{A_r}{z^2} \quad \text{.......................}(10)$$

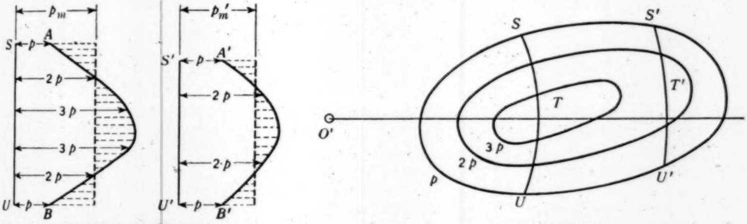
FIG. 3.—CONSTRUCTION OF THE TRANSFORMED AREA.

Since the ratio, $\frac{A_r}{z^2}$, is an abstract number, the scale of the drawing (see Fig. 2) has no bearing on the result. The value, $\frac{n}{2\,\pi}$, may be taken from Table 1. If there is infinite pressure at a part of the loaded area (for instance, at its perimeter), the "reduced area" would also have infinite ordinates. In such a case it is difficult to measure the "reduced area" graphically, and the proposed method does not work.

In a particular case when the horizontal projection, O', of Point O, falls within the loaded area (Area $A\ B\ C\ D\ E$, Fig. 3), the largest possible complete circle is drawn within the area, from Point O' as a center. The ordinate, $P\,P'$, of the transformed area equals the length of the circumference of this circle; and $O'P$ is a straight line. The remainder of the procedure is as explained previously herein. As shown in Fig. 3, the construction may be confined to one side of Point O', plotting the ordinates of the "transformed" area as total lengths of the arcs of equal diameters (shown in solid lines in the plan, Fig. 3). Ordinates of the transformed area may be plotted on a reduced scale. In such a case the resultant vertical pressure, p_z, should be increased accordingly.

If the structure is non-uniformly loaded, for instance, as shown with isolines in Fig. 4(*b*) the problem may be easily reduced to the case of uniform loading with a given unit load, p. For doing so, first all arcs of the loaded area, such as $S\ T\ U$, are rectified, and pressures at each point plotted as ordinates. This procedure, as shown in Fig. 4(*a*), is analogous to the construction of a profile from a set of contour lines as in surveying. Let p_m be the average pressure acting at the arc, $S\ T\ U$; and if the latter is imagined in the form of a circular ring one unit wide, the total load carried by the arc in question would be $S\,T\,U \times p_m \times 1$. Since the vertical pressure p_z, at Point O caused by the arc, $S\ T\ U$, does not depend on the way in which pressures are distributed along that arc, but solely on the value of the total load carried, an arc of unknown length, x, loaded uniformly with an intensity, p, would cause the same pressure, p_z, at Point O, in which case the following condition is fulfilled: $S\,T\,U \times p_m \times 1 = x \times p \times 1$, from which $x = S\,T\,U \dfrac{p_m}{p}$. This means that all ordinates of the transformed area, are to be modified (increased in the case of Fig. 4) in the proportion, $\dfrac{p_m}{p}$, the value of p_m being individual for each ordinate.



(*a*) CROSS SECTIONS (*b*) PLAN

FIG. 4.—PRELIMINARY GRAPHIC OPERATIONS IN THE CASE OF NON-UNIFORM LOADING.

Two-Dimensional Problem

In Fig. 5 a two-dimensional problem is solved for the general case of a non-uniformly distributed load, all the pressures being finite. At each point of the loaded area, *M N*, there is a vertical unit load, p_1, and the values of the ratio, $\frac{p_1}{p}$, are plotted as ordinates, such as *T′ T″*. In this manner an area, $M\,T''\,N = A$, is obtained which is analogous to the "transformed" area in the three-dimensional problem. The total load acting along *M N*, equals $p\,A$; and the elementary vertical, $p\;dA$, applied at Point *T′*, produces, according to Equation (5), an elementary vertical pressure, dp_z, at Point *O*, equal to:

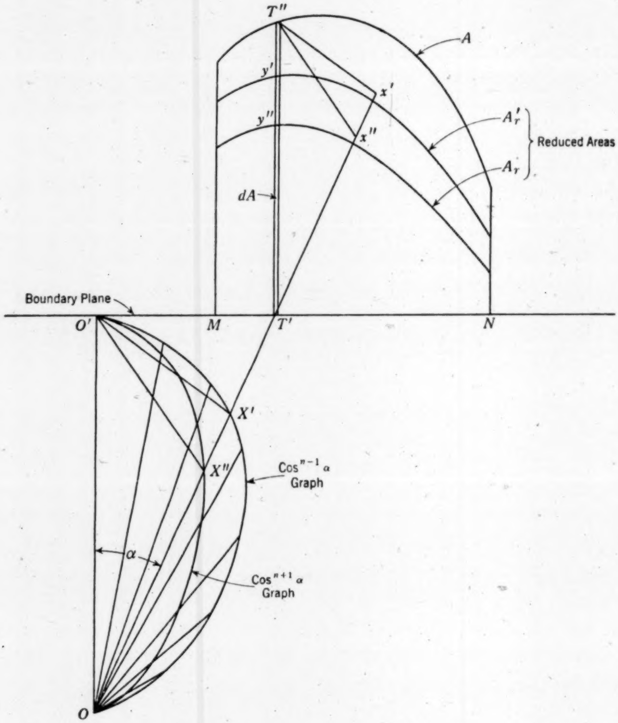


Fig. 5.—Vertical Pressure at a Point Determined by the Reduced Area Method (the Two-Dimensional Problem).

$$dp_z = \frac{n_1\,[p\,dA]}{\pi\,\rho}\cos^n\alpha = p\,\frac{n_1}{\pi}\,\frac{1}{z}\,[dA\,\cos^{n+1}\alpha]\;\ldots\ldots\ldots\ldots(11)$$

Equation (11) is derived directly from Equation (5). Following a procedure analogous to that used when discussing the three-dimensional problem:

$$p_z = p \, \frac{n_1}{\pi} \, \frac{A_r}{z} \quad \text{.......................(12)}$$

in which A_r is the "reduced" area. To construct the reduced area, A_r, it is necessary to use the graph of $\cos^{n+1} \alpha$. For instance, if the Boussinesq formula holds, the equation would be $\cos^4 \alpha$. The values of $\frac{n_1}{\pi}$ may be taken from Table 1. If Point O is located somewhere under the loaded strip, MN, a vertical line passing through O (Fig. 5) would divide the drawing in two parts. A graph, $\cos^{n+1} \alpha$, is constructed separately for each part, the vertical line passing through O being the axis of symmetry of this double graph. The remainder of the procedure is as explained previously.

To determine the horizontal pressure, p_h, at Point O (Fig. 5), the sum of the principal stresses, s, should be found first, and then the vertical pressure p_z, subtracted from it. Substituting $p \, dA$ for p in Equation (6) and remembering that $\rho = \frac{z}{\cos \alpha}$, the elementary stress at Point O would be:

$$ds = p \, \frac{n_1}{\pi} \, \frac{1}{z} \, dA \, \cos^{n-1} \alpha \quad \text{...................(13)}$$

Hence, the sum of the principal stresses, obtained from Equation (13) by summation, is:

$$s = p \, \frac{n_1}{\pi} \, \frac{A'_r}{z} \quad \text{.......................(14)}$$

in which A'_r is the "reduced" area, constructed by using the graph, $\cos^{n+1} \alpha$. If the Boussinesq formula holds, the graph of $\cos^2 \alpha$ is to be used. Finally:

$$p_h = s - p_z = p \, \frac{n_1}{\pi} \, \frac{(A'_r - A_r)}{z} \quad \text{................(15)}$$

Since both ratios, $\frac{A'_r}{z}$ and $\frac{A_r}{z}$, are abstract numbers, the scale of the drawing (Fig. 5) has no bearing on the results. To make this fact clearer, it is necessary to recall that Area A is the sum of the products of dimensionless ratios, $\frac{p_1}{p}$, multiplied by certain widths; hence, A is a length, dimensionally.

The problem of finding the horizontal pressure, p_h, in the case of a three-dimensional stress distribution is more complicated than that solved in Fig. 5 for the case of a plane stress distribution and will not be discussed herein.

Normal stresses under non-rigid structures can also be determined by using the properties of the "angle of visibility" of the foundation. Application of this method to the study of plane stress distribution within an elastic isotropic mass has been discussed by the writer elsewhere.[7]

Example.—Fig. 6 illustrates the determination of the vertical pressure, p_z, at a depth, $z = 100$ ft, under the entering angle, X, of a structure uniformly loaded with 2.5 tons per sq ft. The value of the reduced area, A_r, constructed under the assumption that the Boussinesq formula holds, is 6 560 sq ft, and the vertical pressure: $p_z = p \, \frac{n}{2\,\pi} \, \frac{A_r}{z^2} = 2.5 \times 0.477 \times \frac{6\,560}{100 \times 100}$ $= 0.78$ ton per sq ft. Note that the vertical scale used to construct both the transformed and reduced areas in Fig. 6 is one-half the horizontal.

FIG. 6.—APPLICATION OF THE REDUCED AREA METHOD.

PART II.—PRESSURES UNDER RIGID FOUNDATIONS

In the case of an actual structure, soil reactions are in equilibrium, not with unit loads acting at the loaded surface as assumed in Part I, but with stresses within the structure close to the surface of contact with the earth. It follows that for finding stress intensities within the earth mass beneath a foundation, it is first necessary to establish the manner in which stresses are distributed at the base of the given structure and to consider the surface of contact of the structure with the earth as being loaded with those stresses acting as unit loads. The method which has been discussed in Part I, will be then fully applicable. Unfortunately, the problem of stress distribution at the base of a structure has not yet been solved definitely. Therefore, in presenting Part II of this paper, the writer limits his task to the review of available information in this field, both theoretical and experimental, and advances several ideas of his own. This discussion will be limited to uniformly loaded foundations only.

---

[7] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1288.

RIGIDITY OF STRUCTURES AND EARTH MASSES

A structure will be termed "absolutely rigid" if it can be visualized as consisting of thin vertical slices so strongly bound together that they act as a unit. An opposite case would be a "non-rigid structure," which can be visualized as consisting of thin vertical slices with no lateral bonds so that each of them can settle down individually. The degree of rigidity in actual engineering structures is some value between these two limits. To form an accurate idea of the rigidity of the entire structure one should know how to express this rigidity numerically. At the present time this cannot be done in all cases.

Earth masses may also possess varying degrees of rigidity which could be expressed by a number as, for instance, the coefficient of pressure at rest, K, or the concentration factor, n. A mass that develops considerable horizontal stress under vertical load at rest (such as clays) may be considered as non-rigid. Compact sands, on the contrary, may be considered as rigid masses. If one knew how to express the rigidity of both the structure and the earth mass by comparable coefficients, one could attempt to attack the problem of the mutual rigidity of the two masses in contact, replacing the structure with an "equivalent mass." Because of the uncertainty of the manner of expressing the rigidity, however, both structures and earth masses will be identified in this paper, only as "rigid" and "non-rigid," the former approaching the state of absolute rigidity, as already defined.

If the earth mass supporting a structure is more or less homogeneous and isotropic to a considerable depth, the settlement of the structure is due to strains which gradually decrease with the depth. This is a case of "contact settlement" when the seat of settlement resides close to the base of the structure. If there is a soft layer at a certain depth, the structure may undergo an additional settlement owing to consolidation of that soft layer. It may be said that in this case the seat of settlement resides "in deeper strata."

When a deformable body moves through a medium offering resistance, its action is definable in two steps: (*a*) It moves as a non-deformable solid body; and (*b*) resistances of the medium produce deformations (or strains) in it. In a similar manner, a contact settlement is characterized by: (I) A downward movement of the structure; and (II) deformations of the structure due to interaction with the earth mass (Fig. 7). To understand the nature of these deformations the structure will first be assumed non-rigid; thus the phenomena at the surface of contact would occur practically as if the structure were replaced by a non-rigid earth mass. Afterward, rigidity will be restored to the structure, and corresponding changes in the stress distribution over the base of the foundation will be discussed. In a general way, stresses close to the surface of contact of two masses are the same in both masses, according to the well-known physical law of equality of action and reaction. Strains, however, are different because the less resistant of the two masses should yield. Hence, according to these considerations, a rigid mass under a non-rigid structure should bend the latter upward, as shown diagrammatically in Fig. 7(*c*). A case of settlement of this type was reported by Dr. Scheidig[8] when some strucures constructed on loose sand, settled at the edges. The writer understands that the buildings in question were erected rather hastily. Settlement I (Fig. 7(*c*)) occurred at once, owing to the compression of the loose sand; and probably when the latter became compact, the insufficiently rigid masonry was deflected upward. It should be noticed that if a loaded thin elastically isotropic layer is underlaid with rock or similar material, the formation of cupolas is also possible.[9] The writer understands, however,

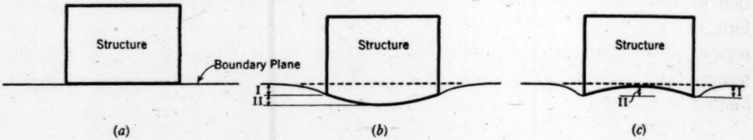

FIG. 7.—EXAMPLES OF CONTACT SETTLEMENT.

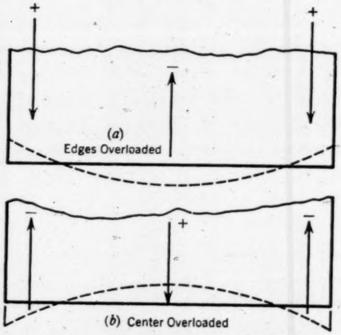

FIG. 8.—ACTION OF ABSOLUTELY RIGID STRUCTURE.

that there was no such underlying stratum in the case of Dr. Scheidig's observations, and that the edge settlement in this case should be explained by the inter-penetration of the masses in contact.

Although the problem shown in Fig. 7(c) cannot be solved using methods of the theory of elasticity, the latter furnishes all necessary data for the problem of settlement of a non-rigid structure of finite size, supported by an equally non-rigid mass (Fig. 7(b)). With Fig. 7(b) and Fig. 7(c) in mind it is now easy to determine the character of stress distribution at the base of a rigid structure, at least, qualitatively. In order to keep the base of the structure even, additional forces should be applied. Thus, an absolutely rigid structure may be over-loaded at the edges (Fig. 8(a)), or at the center (Fig. 8 (b)), according to the rigidity of the underlying mass (a non-rigid underlying mass in the former case and a rigid mass in the latter). Fig. 8 (b) furnishes an explanation as to why, in all loading experiments on sand masses, the maximum stress in the soil is shown under the center of the loading plate.

DISTRIBUTION OF NORMAL STRESSES UNDER AN ABSOLUTELY RIGID FOUNDATION

The problem of an absolutely rigid structure built on elastic isotropic soil has been solved by methods involving the theory of elasticity. Boussinesq[10] and later Schleicher[11] determined the stress distribution at the base of a rigid round disk placed on an elastic isotropic mass from displacements of its points. Boussinesq's basic assumptions are: (1) That there is no friction at the plane of contact; and (2) the plane of contact is horizontal. Professor Michael A. Sadowsky,[12] of the University of Minnesota, applied the potential theory to solve the three-dimensional problem. According to these investigators, if r is the radius of the disk in question, the pressure at a point distant, $c\,r$, from the center of the disk, would be:

$$p_z = p \frac{1}{2\sqrt{1 - c^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

The pressure, p_z, equals $0.5\,p$ at the center of the disk ($c = 0$) and becomes infinite at the edges ($c = 1$). Since there are no absolutely rigid structures, even the slightest settlement at the edge of the loaded disk relieves the strain considerably, so that practically all stresses at the base of the loaded disk are finite. The influence of rigidity of a circular foundation slab in the distribution of pressures on the contact surface, has been considered by H. Borowicka[13] who assumed that both the structure and the earth mass are elastically isotropic with different values of the modulus of elasticity and Poisson's ratio. To express the stress distribution in a case of an absolutely rigid round disk placed at the top of an earth mass, with a concentration factor, n, the writer proposes the following empirical formula (see Fig. 9):

[11] "Die Verteilung der Bodenpressungen unter starren Gründungskörpern", *Der Bauingenieur*, Vol. 14, Nos. 17–18, p. 242 *et seq.* (1933); also, *Zeitschrift für angewandte Mathematik und Mechanik*, Vol. 8 (1928).

[12] "Distribution of Pressure Concentrated on a Small Surface", *Transactions*, Am. Soc. M. E., Vol. 54, Paper APM 54–21, p. 221 (1934).

[13] *Proceedings*, International Conference for Soil Mechanics and Foundation Engineering. Vol. II, Paper E-8.

$$p_z = p\left(\frac{n}{2} - 1\right)\left(1 - c^2\right)^{\frac{n}{2}-2} \quad \ldots\ldots\ldots\ldots\ldots (17)$$

Substituting $n = 3$ in Equation (17), the resulting form is identical to Equation (16). The value, $n = 6$, results in a parabolic distribution very similar to that found in numerous loading experiments on sand masses as reviewed elsewhere:[14]

$$p_z = 2\,p\,(1 - c^2) \quad \ldots\ldots\ldots\ldots\ldots (18)$$

Should the concentration factor, n, of the constrained earth mass increase to 8, the stress distribution at the base of the experimental disk would be defined by the curve:

$$p_z = 3\,p\,(1 - c^2)^2 \quad \ldots\ldots\ldots\ldots\ldots (19)$$

and this creates a pressure at the center of the disk equal to 300% of the average pressure, p, which is quite close to the result obtained by M. L. Enger,[15] M. Am. Soc. C. E.

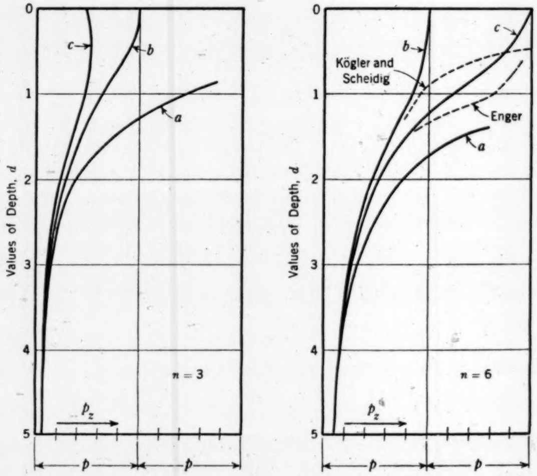

FIG. 10.—VERTICAL PRESSURES AT VARIOUS DEPTHS ALONG THE CENTER LINE OF A LOADED CIRCULAR DISK

Equation (17) has been designed on the assumption that the lower value of the concentration factor, n, equals 3. This is true of the isotropic masses for which the basic formulas given in the "Introduction," have been designed. Other geological conditions (for example, that of a hard layer underlaid by a soft one) are not covered by the formulas of this paper, and the solution of the corresponding problems should be sought elsewhere.

---

[14] "Distribution of Stresses Under a Foundation", by A. E. Cummings, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1077.

[15] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 372.

The problem of stress distribution under a rigid structure is complicated by the formation of the so-called "disturbed zone." It follows from the small-scale experiments that the cross-section of this zone under a circular disk is semi-circular or ellipsoidal with a top segment removed. These results cannot yet be generalized for the case of full-sized structures, however, because of the lack of corresponding observations. In order to investigate to what depth the rigidity of a loaded plate in a small-scale experiment affects the earth mass, Fig. 10 has been prepared. For two soils, with concentration factors, $n = 3$ and $n = 6$, respectively, curves representing the vertical pressure, p_z, at various depths along the center line of a round loaded disk, have been traced. Pressures p_z have been plotted horizontally. The load is the same in all cases, but distributed differently: Curves (*a*) correspond to a concentrated load acting directly at the surface of the soil; Curves (*b*) correspond to uniform distribution; and Curves (*c*) correspond to the case of an absolutely rigid plate, respectively. For the latter case, Equations (16) and (18) have been used (see Appendix II for mathematical details). At a depth of about twice the diameter of the loaded part ($z = 4r$ in Fig. 10), Curves (*a*), (*b*), and (*c*) practically coincide, which accounts for the well known statement that, at that depth, a loaded plate acts practically as a concentrated load. The average experimental curves of Kögler and Scheidig and Enger[16] (see Fig. 10), are located partly to the right of Curve (*c*); and this means that in the upper part of the experimental mass, approximately down to a depth, r, the concentration factor, n, exceeds 6 for which value the curve, *c*, in Fig. 10 has been traced. Afterward, the experimental curves swing rapidly to join Curve (*b*); and at a depth of about $2r$ there is no longer any influence of the rigidity of the loaded plate—at that depth the mass behaves as if the base of the experimental disk were uniformly loaded (Curve (*b*), Fig. 10).

Undoubtedly, the stress distribution at the base of an infinitely wide rigid structure should be uniform; it cannot be otherwise. To reconcile this simple logical statement with the results previously obtained, Fig. 11 has been prepared. The stress distribution at the base of a rigid narrow structure is represented in Fig. 11(*a*) and Fig. 11(*c*), for the cases of a non-rigid and a rigid earth mass, respectively. The stress distribution under a wide rigid structure is tentatively shown in Fig. 11(*b*) and Fig. 11(*d*), for the cases of a non-rigid mass and a rigid earth mass, respectively. It should be noticed that the curve in Fig. 11(*b*) is very close to that found theoretically by K. Wieghart[17] for the case of a beam supported by an elastically isotropic mass.

---

[16] The average values in question are those computed in the paper entitled "Distribution of Stresses Under a Foundation", by A. E. Cummings, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1078.

[17] Handbuch der Physik, Edited by R. Grammel, Vol. 6, pp. 180–181 (1928); for original work by K. Wieghart, see *Zeitschrift f. angew. Mathematik und Mechanik*, Vol. 2 (1922).

Pressures Under Actual Engineering Structures

To check theoretical considerations, pressure at the base of actual structures should be measured. This can be done by embedding pressure-measuring cells at the base of the structure during its construction. There are only a few published examples of such measurement, although such embedments have been reported from many places. From the three cases known to the writer one refers particularly to sewers[18] and two others will be discussed subsequently.

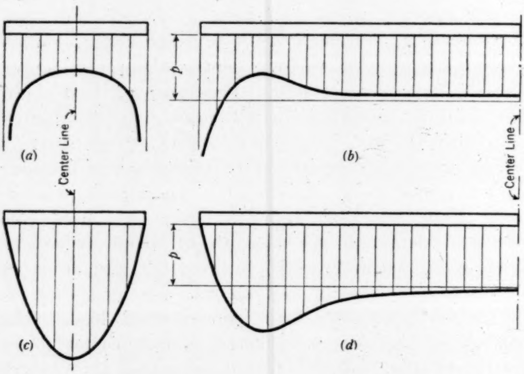

FIG. 11.—STRESS DISTRIBUTION AT BASE OF RIGID FOOTINGS, BOTH NARROW AND WIDE (A TENTATIVE SKETCH).

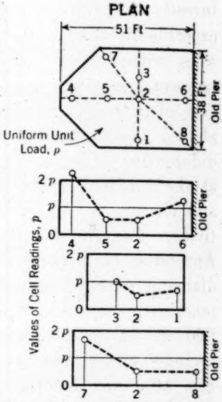

FIG. 12.—PRESSURES BENEATH A BRIDGE OVER THE RHINE RIVER IN GERMANY.

During the construction of the new bridge over the Rhine River, connecting Mannheim and Ludwigshafen, Germany, eight Goldbeck cells were placed beneath a pier,[11] and it was discovered that the foundation was overloaded at the edges (see Fig. 12). The foundation material was gravelly, and since European engineering thought had been accustomed to the idea that in the case of similar foundations the maximum pressure should be at the middle, there was an interesting discussion of the case.[19] The uncertainty was emphasized by the fact that the new pier was constructed close to the old one, which could have a certain influence on the stress distribution. In the case under consideration, the pier was founded on a caisson. Soil reaction could not lift the heavily loaded edges of the caisson, and, apparently, the foundation material was forced somewhat, into the concrete fill of the chamber. Consequently, the stress at the middle of the structure was relieved (see Fig. 7(*c*)). The writer believes that a similar condition may occur in other cases of caisson foundations if the latter may be considered as non-homogeneous structures consisting of a rigid shell containing a less resistant mass.

[18] "Observed Soil Pressures on the Deep Sewers of the North Toronto System", by C. R. Young, M. Am. Soc. C. E., and W. B. Dunbar, *Bulletin No. 145*, Univ. of Toronto (1935).

[19] "Sohldruckverteilung unter Pfeilern", by F. Kögler, *Der Bauingenieur*, Vol. 14, Nos. 37–38, p. 473 *et seq* (1933); also discussions by Messrs. Scheidig and Schleicher, pp. 482 and 483.

About 1933 a building was constructed by the Agricultural and Mechanical College of Texas.[20] Six Goldbeck cells were embedded under a footing as shown in Fig. 13. The soil beneath the building is clay with small varying quantities of sand and coarse material. The maximum pressure during the construction was at the center of the footing (Cell No. 4), but this shifted gradually during a period of about seven months to Cell No. 3. It might be concluded, at first, that the concentration of stresses near the middle of this structure, as shown by Fig. 13, is in disagreement with the hypothesis advanced, as, for instance, with the stress distribution shown in Fig. 11(*a*). Apparently, Fig. 11(*a*) predicts an overloaded edge under the given soil conditions. The confusion is clarified, however, if one realizes that the footing action is not included in the scope of this paper, which discusses only cases of the interaction between two masses. In the case under consideration, however, there is an interaction between three masses: A column, a base, and an earth mass (see

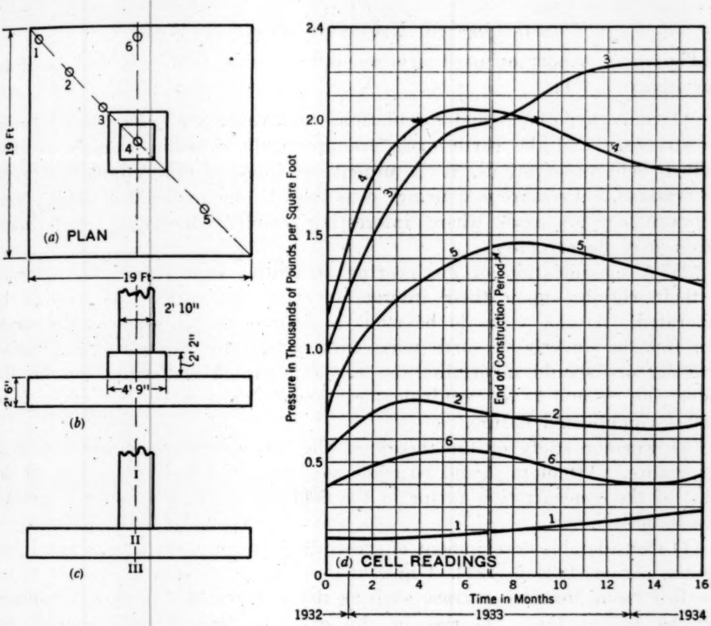

FIG. 13.—PRESSURES BENEATH A FOOTING OF A BUILDING AT TEXAS AGRICULTURAL AND MECHANICAL COLLEGE.

---

[20] "The Distribution of Soil Pressure Beneath a Footing," by F. E. Giesecke, M. Am. Soc. C. E., and others, *Bulletin No. 43*, Texas Eng. Experiment Station, 1933.

Fig. 13(*c*)). Should the rigid mass, I, Fig. 13(*c*), act directly at the surface of the mass, III, the edges probably would become overloaded; but the inclusion of the intermediate mass, II, apparently changes the situation. A very important conclusion from the Texas experiment is the possibility of pressure fluctuation at the base of a structure, which is probably due to a progressive change in the physical properties of the earth mass.

Outline of the Necessary Research Work

The most important necessary research in this field may be stated in four items:

(1) Since hypotheses and speculations concerning the interaction between the structure and the earth mass are practically worthless unless checked against field observations, it is urgent to increase the number of such observations. Pressure-measuring cells should be embedded under new structures in all cases where interesting results concerning such interaction may be expected.

(2) A classification of engineering structures concerning the influence of their rigidity upon their interaction with the earth mass, should be elaborated. Attempts should be made to express the rigidity of the structure and the underlying earth mass with comparable numerical coefficients. Investigators should determine the cases in which structures act on the underlying ground as an "equivalent earth mass" and when this action is of a more complicated nature.

(3) Further study of the theory of the "concentration factor," n, is of importance. Attempts should be made to develop methods of measuring the value of the concentration factor in the field before (and not after) a structure is built.

(4) Considerable development of stress distribution theories was noted during the period, 1934 to 1936. Unfortunately, these theories refer only to the so-called "semi-infinite" masses, such as those shown in Fig. 1. It is necessary to extend these theories in the case of "finite" masses, such, for example, as embankments. Some progress in this field has been made since the introduction of photo-elastic analysis. Data analogous to those obtained in the study of the properties of elastic bodies in contact should be obtained for "finite masses" of all kinds.

Most of the research outlined in Items (1) to (4) cannot be done by soil mechanics investigators alone. It requires, also, the most intensive co-operation of structural engineers.

Some Remarks on the Design of Foundations

Bending Moment.—When a structure is designed under the assumption of uniformly distributed soil reaction (as generally done in practice) there is no bending in the loading plate except in cantilever units; but if the "picture," afforded by Fig. 11(*b*) and Fig. 11(*d*), is correct, only the central part of a wide structure can be designed under that approximate assumption. According to Fig. 11(*b*) and Fig. 11(*d*) there should be bending moment, positive or negative, near the perimeter of a bearing surface, the sign of the bending moment depending on the physical properties of the local soil.

Settlement of a Structure Due to Consolidation in Deeper Strata.—To design a structure so that it will not fail by settlement, the designer should be aware of the geological condition of the earth mass to a considerable depth, say, about twice the width of the structure. This is because a possible consolidation of a deep soft layer may cause a serious settlement. Consolidation in deeper strata, however, has no effect on the interaction of the structure and the earth mass. In this case the entire situation is controlled by the same physical law which permits, for instance, the playing of games of ball or cricket on a moving steamship without disturbance. In an analogous sense, when consolidation in deeper strata begins, the entire mass, including the structure, would settle, and there is no reason whatever to believe that the stressed condition at the base of the structure would be disturbed. Settlement in such a case is assumed to be uniform. A similar idea, however, in a somewhat different form, has been advanced by Professor A. Casagrande.[21]

Interrelation of Stresses.—Serious thought should be given to the question of whether the actual method of designing a structure without taking into consideration the influence of the foundation on the stress distribution in the structure itself should be discontinued. Undoubtedly, the structure and the earth mass underlying it form a single statically indeterminate system; and the stress distribution in the mass influences that in the structure, at least at its lower part. This principle has been realized by dam builders; and it is to be hoped that an analogous procedure will be adopted for other branches of structural engineering.

CONCLUSIONS

1.—Stresses within a semi-infinite isotropic mass (see Fig. 1), caused by a concentrated force acting at the boundary, can be determined by using Equation (1). In the case of a two-dimensional (plane) stress distribution, Equation (6) should be used.

2.—Stresses caused by loads distributed at the boundary of an isotropic mass may be determined by superposition.

3.—The "reduced area method" supplies a means of determining pressures in an isotropic mass beneath uniformly loaded foundations. It consists in subdividing the loaded area into circular zones, rectifying them, to obtain the "transformed area" and reducing the latter graphically, according to the position of the load with respect to the point where pressures are to be determined.

4.—The "reduced area method" can also be applied in the case of non-uniformly loaded isotropic masses, if all unit loads are finite. Otherwise, the graphical measurement of the "reduced area" is difficult.

5.—The degree of "contact settlement" that may be expected of a structure built at the top of an earth mass is chiefly controlled by the mutual rigidity of both masses in contact and perhaps by other factors, such as the size and the shape of the structure.

---

[21] *Journal*, Boston Soc. of Civ. Engrs., Vol. 23 (1936), p. 15.

6.—The phenomenon of "contact settlement" of a non-rigid structure supported by a rigid earth mass consists in a downward movement, and in an upward deflection, of the structure.

7.—In the case of a narrow, absolutely rigid, structure, there is: (*a*) An overloading at the edges in the case of a non-rigid (for instance, a clay) foundation; or (*b*) an over-loading at the center in the case of a rigid (for instance, a sand) foundation.

8.—An empirical formula, Equation (17), concerning the stress distribution at the base of a narrow rigid structure, has been proposed.

9.—In the case of a wide engineering structure, there should be a certain tendency toward a uniform stress distribution at the center of the foundation. Apparently, the edges of a rigid structure are always overloaded, and there is always bending along its perimeter. Such moment will be positive or negative, depending on the physical properties of the soil beneath the foundation.

10.—There is a "disturbed zone" under a rigid structure apparently possessing a higher concentration factor than the remainder of the mass. The state of constraint along the center line of a round loaded plate in small-scale experiments goes only to a depth equal to one-half the width of the loaded area. Between this depth and that equal to twice the width of the loaded area, the stresses in the mass act as if the load were uniformly distributed through the foundation. At, and beyond, a depth twice the width of the loaded area the loading plate acts as a concentrated load.

11.—The stressed condition at the surface of contact of the structure with the earth mass does not depend on the consolidation in deeper strata.

12.—Field observations available concerning the stress distribution at the base of a structure, are insufficient. Hence, statements advanced in Part II of this paper (except those based on firm physical laws) are rather of a hypothetical nature. Further research is needed before they can be generalized and adopted unconditionally.

APPENDIX I

Determination of the Value of the "Plane Concentration Factor," n_1

The given force, P, and another unknown force, X, acting along the direction of the radius vector, $A\ O$, in Fig. 14, would produce the same stress at Point O, if Equation (20) is satisfied:

$$\frac{n\ P}{2\ \pi\ \rho^2} \cos^{n-2} \alpha = \frac{n\ X}{2\ \pi\ \rho^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(2)0}$$

from which,

$$X = P \cos^{n-2} \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Equation (21) holds also if a line load, $\overline{p}$, is substituted for the concentrated force, P. Hence, the value of the plane stress, s, at Point O, caused by the action of a line load, $\overline{p}$, at A (Fig. 14(a)) equals the vertical pressure at Point O' (Fig. 14(b)), distant vertically ρ from Point A, and subject to the action of a line load, $\overline{p}\cos^{n-2}\alpha$, at the boundary. In Fig. 14(b) the distance, $A\,M = \rho\tan\phi$, and $M\,M'$ is its differential. Hence, the value of this stress, s (see Equations (1) and (6)) is:

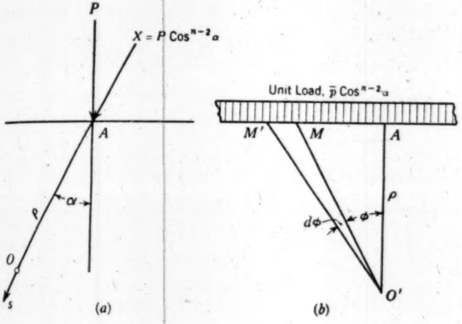

FIG. 14.

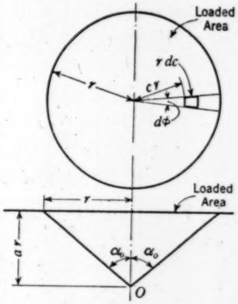

FIG. 15.

$$s = 2\int_0^{\frac{\pi}{2}} \frac{n\left[\overline{p}\cos^{n-2}\alpha\right]\left[\dfrac{\rho}{\cos^2\phi}\,d\phi\right]}{2\,\pi\left(\dfrac{\rho}{\cos\phi}\right)^2}\cos^n\phi = \frac{n_1\,\overline{p}}{\pi\,\rho}\cos^{n-2}\alpha$$

in which:

$$n_1 = n\int_0^{\frac{\pi}{2}}\cos^n\phi\,d\phi \text{ ....(22)}$$

In turn, the integral in Equation (22) equals:

$$\int_0^{\frac{\pi}{2}}\cos^n\phi\,d\phi = \frac{\sqrt{\pi}}{2}\,\frac{\Gamma\left(\dfrac{n+1}{2}\right)}{\Gamma\left(\dfrac{n}{2}+1\right)} \text{ ....(23)}$$

in which Γ is the gamma function. If the concentration factor, n, is not an integer, the value, n_1, is determined by using Equation (23). Otherwise, it is better to compute that value as follows: When n is an odd number, Equation (22) becomes:

$$n_1 = \frac{2\times4\times6\ldots(n-1)}{1\times3\times5\ldots(n-2)} \text{ ....(24a)}$$

and, when n is an even number:

$$n_1 = \frac{1 \times 3 \times 5 \ldots . (n-1)}{2 \times 4 \times 6 \ldots . (n-2)} \frac{\pi}{2} \qquad \text{(24b)}$$

Equations 24(a) and 24(b) check with formulas of plane stress distribution developed by Dr. O. K. Fröhlich.[22]

APPENDIX II

FORMULAS FOR TRACING CURVES IN FIG. 10

Equation (1) was used in plotting Curves (a), Fig. 10. Making $\alpha = 0$ and $\rho = a\, r$;

$$p_z = \frac{n\,[\pi\, r^2\, p]}{2\,\pi\,[a\ r]^2} = p\, \frac{n}{2}\, \frac{1}{a^2} \qquad \text{(25)}$$

in which a is a coeffcient $= \frac{\rho}{r}$.

The well-known formula[23] for the case of a uniformly loaded circular area was used in plotting Curves (b), Fig. 10; thus:

$$p_z = p\,(1 - \cos^n \alpha_0) \qquad \text{(26)}$$

in which α_0 is the angle formed with the vertical by the radii vectors joining the given point, O, with the perimeter of the loaded area (see Fig. 15).

Referring to Fig. 15 the area of the loaded element at the boundary is:

$$dA_c = [c\ r\ d\phi]\,[r\ dc] = r^2\, c\ dc\ d\phi \qquad \text{(27)}$$

The vertical pressure in the case of constraint is to be determined: (a) Using Equation (16) in the case of $n = 3$; and (b), using Equation (18), when $n = 6$. Thus, if $n = 3$:

$$p_z = \int_0^{2\pi}\int_0^1 \frac{\dfrac{3\,p}{2\,(1-c^2)^{\frac{1}{2}}}\,[r^2\, c\ dc\ d\phi]}{2\,\pi\,(a^2\, r^2 + c^2\, r^2)} \times \frac{a^3\, r^3}{(a^2\, r^2 + c^2\, r^2)^{\frac{3}{2}}}$$

$$= \frac{3}{2}\, p\ a^3 \int_0^1 \frac{c\ dc}{(1-c^2)^{\frac{1}{2}}\,(a^2 + c^2)^{\frac{5}{2}}} \qquad \text{(28)}$$

Substituting t^2 for $(1 - c^2)$ and remembering that the limits of t are 1 and 0, when $c = 0$ and $c = 1$, respectively:

$$p_z = -\frac{3}{2}\, p\ a^3 \int_0^1 \frac{dt}{(a^2 + 1 - t^2)^{\frac{5}{2}}} = p\, \frac{1 + 3\,a^2}{2\,(a^2 + 1)^2} \qquad \text{(29)}$$

---

[22] "Druckverteilung im Baugrunde", p. 28 (1934).

[23] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), Equation (23), p. 1090.

and if $n = 6$;

$$p_z = \int_0^{2\pi}\int_0^{1} \frac{6\,[2\,p\,(1 - c^2)]\,[r^2\,c\,dc\,d\phi]}{2\,\pi\,[a^2\,r^2 + c^2\,r^2]} \times \frac{a^6\,r^6}{(a^2\,r^2 + c^2\,r^2)^3}$$

$$= p\left\{2 - a^2 + \frac{a^6}{(a^2 + 1)^2}\right\} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

To obtain this result, a new variable has been substituted for c^2.

APPENDIX III

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials,[24] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = loaded area; $d\,A$ = a small element of a loaded area; A_r = reduced area as applied to vertical pressure; A'_r = reduced area as applied to horizontal pressure; A_c = area of a circle;

a = a coefficient $= \dfrac{\rho}{r}$;

c = a coefficient to express the distance from the center of a circular loaded plate, in terms of its radius;

K = coefficient of pressure at rest, or the ratio of principal stresses in a non-loaded semi-infinite earth mass;

n = a concentration factor; n_1 = a plane concentration factor, n_1 being a function of n;

P = a concentrated vertical force acting at the boundary of an earth mass (see, also $\bar{p}$);

p = pressure per unit area; a uniformly distributed load; p_m = average pressure acting along an arc of the loaded area; p_n = non-uniformly distributed load; p_z = vertical unit pressure at any point; p_h = horizontal unit pressure at a point; $\bar{p}$ = a unit line load.

r = radius of a circular loaded plate, or disk; as a subscript, r, denotes "reduced";

s = unit stress, or sum of principal stresses;

t = a substitution factor $= (1 - c^2)$;

z = depth of a point below the ground surface;

α = angle of a force, or of a stress with the vertical; α_0 = one-half the angle at the vertex of a regular cone;

Γ = gamma function;

ρ = radius vector of a point (distance from the origin);

ϕ = auxiliary angles in Figs. 14 and 15.

---

[24] A. S. A.—Z10a—1932.

DISCUSSION

DR. ING. O. K. FRÖHLICH[25] (by letter).—The practical significance of Part II of Professor Krynine's valuable paper consists in the emphasis placed upon the influence of the rigidity of structures on the distribution of soil pressures in the contact surface. Equation (16) represents the result of the treatment of the "classical" case of the stress distribution at the base of a circular and absolutely rigid disk, with a symmetrical load, placed on the horizontal surface of a semi-infinite, elastically isotropic mass. Boussinesq[10] has given this result in a very intuitive manner, which, in the writer's opinion, is worth mentioning here for two reasons: First, because it represents, for the practical engineer, a mnemo-technical means of reproducing Equation (16); and second, because it may be used to compute the stress distribution in the two-dimensional case. According to Boussinesq the unit stress at the base of the rigid circular disk (of radius, r) at any point, $c\,r$, of the contact surface is obtained by distributing the total load, $P = p\,r^2\,\pi$, equally over a hemisphere ($2\,r^2\,\pi$), which is assumed to be erected over the base circle of the disk, and by taking that part of this load, which is cut from the hemisphere by a vertical cylinder, having the unit surface at the given point as the base. It is easily seen that, in the center, where $c = 0$, the stress is $0.5\,p$; at the edge where $c = r$, it becomes infinitely great and at any point, $c\,r$, Equation (16) is satisfied.

In the case of a rigid strip (width, $2\,b$) of infinite length (the case of plane stress), a hemi-cylinder, having a diameter, $2\,b$, must be introduced instead of the hemisphere. The total load, $\bar{P}$, per unit of length equals $2\,b\,p$ and the load per unit of the cylinder surface is then $\dfrac{2}{\pi}\,p$. In a manner similar to the three-dimensional case, the formula for the pressure, p_z, at a distance, cb, of the axis of the loaded strip, becomes,

$$p_z = p\,\frac{2}{\pi\sqrt{1 - c^2}} \qquad \text{(31)}$$

which is analogous to Equation (16).

H. Borowicka[26] and A. Habel[27] have dealt with the influence of the rigidity of foundation slabs and strips on the distribution of the soil pressures in the contact surface. One of the characteristic results of these investigations is that, under equally distributed loads of slabs and strips for any degree of rigidity, the pressures under the edges are infinitely great, which is a consequence of the assumption, made in these theoretical computations, that Hooke's law remains valid beyond any limit. In this respect, the practical question arises as to the value that the pressure may attain under the edge of a foundation.

---

[25] Cons. Engr., The Hague, Holland.

[26] "Druckverteilung unter einem gleichmässig belasteten, elastischen Plattenstreifen, welcher auf der Oberfläche des elastisch-isotropen Halbraumes liegt," von H. Borowicka, International Assoc. for Bridge and Structural Eng., Second Congress, Final Rept., 1937.

[27] "Die auf dem elastisch-isotropen Halbraum aufruhende, zentral symmetrisch belastete elastische Kreisplatte," von A. Habel, *Der Bauingenieur,* 1937, H. 15–16.

An attempt to answer this question of the magnitude of the critical stress under the edge of a foundation was presented by the writer in 1934.[28] All the aforementioned theoretical computations of the distribution of the soil pressures under loaded plates or strips, having a certain degree of rigidity, relate to very simple cases which, in practice, are very seldom encountered.

To show how the practical problem of determining the influence of the rigidity of a given structure on the distribution of the soil pressures may be attacked, the following example will be considered: In Fig. 16 the four foundations, symmetrical about a center line, consist of infinitely long strips, supporting a rather rigid structure. The loads, P_1, P_2, may be determined as usual under the assumptions applying to unyielding foundations. This is a problem of pure statics, the solution of which is well known. The assumption that the structure is infinitely long simplifies the computation inasmuch as it reduces the three-dimensional, to a plane-stress, problem. The equations, given in the paper and in the monograph mentioned[28] enables the designer to determine the settlements, z_1 and z_2, if the concentration factor and the compressibility of the soil are known.

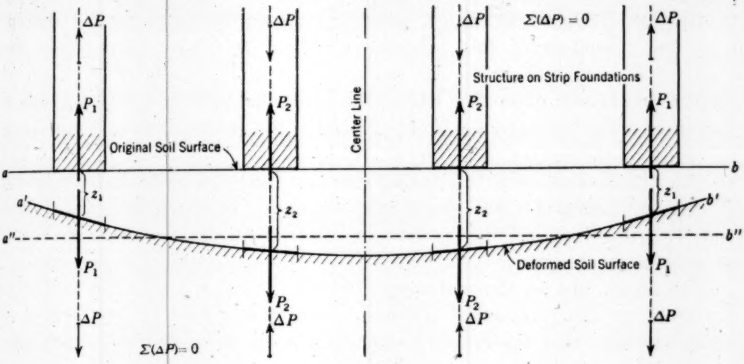

FIG. 16.

As the originally straight surface line, ab, of the soil changes into the curve, $a'\,b'$, it is evident that the distribution of the total load, ΣP, which originally was P_1-P_2-P_2-P_1, is changed by the interaction of structure and underground. How the supplementary system of forces, $\Sigma(\Delta P) = 0$, acts on the structure and on the ground, is shown in Fig. 16. The unknown value of ΔP must satisfy the condition that the deformation of the structure becomes identical with the deformation of the surface line of the soil. Especially, if the structure is absolutely rigid, the supplementary system of forces, $\Sigma(\Delta P) = 0$, must flatten the curve, $a'\,b'$, into a horizontal straight line, $a''\,b''$ (dotted in Fig. 16). As the settlements, due to the action of the supplementary forces, vary directly with ΔP, the numerical work involved is not so tedious as one would suppose at first glance. The last step of this procedure is to compute the so-called secondary stresses in the structure, caused by the four supplementary forces, ΔP, which is again a problem of pure statics.

---

[28] "Druckverteilung im Baugrunde," Equation (5), p. 84.

Donald W. Taylor,[29] Assoc. M. Am. Soc. C. E. (by letter).—The author is to be commended for advancing the question of stress distribution under rigid footings and rigid mat foundations, and for emphasizing the fact that the common practice of assuming uniform distribution of pressure is not logical and may be unsafe in some cases. Most engineers will agree with his recommendation that extensive use should be made of pressure-measuring cells under new structures to furnish data on actual distributions.

Professor Krynine has made free use of the concentration factor, a parameter which should be adopted only when the extent to which it is applicable is held clearly in mind. The same point may be said to apply to Dr. Fröhlich's work[3] which, however, contains many valuable conceptions for a student of this subject. Fröhlich has shown that under the edges of a rigid footing on the surface of a sand deposit a condition of plastic flow must exist for which the concentration factor will have a maximum value of perhaps 6 or 8. Under the footing, progressing from the edge to the center, this factor will decrease from point to point and also it will decrease with increasing depth. Thus, the concentration factor at different points for the given case may vary as much as from 8 to 4 and with this in mind it may be seen that diagrams such as Fig. 9 may be very misleading.

The author makes the statement that consolidation of deeper strata has no effect on the interaction between a structure and the earth mass on which it rests; that the entire system may be assumed to settle uniformly. This can no more be possible than that the middle support of a rigid continuous beam can settle without increasing the load which the outer supports must carry. In Fig. 17(*a*) consider the loaded area to be the surface of a sand deposit where there is a complete lack of rigidity, and for simplicity let it be loaded uniformly and let the load be applied instantaneously. Before the underlying layer has had time to compress appreciably the settlement, which will occur entirely within the sand, will be as shown; and the stress thrown to the buried layer, according to the usual conceptions of spreading out of stress, will be as indicated. From this distribution of pressure on the buried layer, it is evident that the

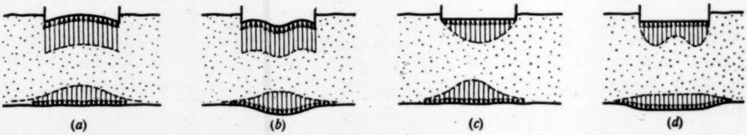

Fig. 17.

---

[29] Research Associate, Soil Mechanics, Dept. of Civ. and San. Eng., Mass. Inst. Tech., Cambridge, Mass.

compression in this layer will be greatest at the center. The loaded area must undergo a settlement approximately equal to this compression and after a period of time will have settled about as shown in Fig. 17(*b*). Since the surface stress distribution does not change, the stress at the compressible layer is probably not radically altered. For comparison, in Fig. 17(*c*), let the footing be rigid. When suddenly loaded the stress distribution under it and the stress transmitted to the clay will be as shown. It is evident that in this case there is a tendency toward greater settlements at the center of the loaded area, and yet the rigid footing requires that the settlement must be uniform. The only possible result is that as settlement proceeds there must be a readjustment of the two stress distributions of Fig. 17(*c*), since the stress distribution at the compressible layer is caused by the stress at the loaded area and also must be such as to give uniform settlement. Fig. 17(*d*) is a rough indication of probable distribution for the rigid footing after a period of time.

JACOB FELD,[30] M. AM. SOC. C. E. (by letter).—Because of the clarity of exposition as well as the completeness of the paper, the author's contribution to the study of soil mechanics is one of outstanding merit. The limitations of the results are carefully stated and no universal solution of a very important problem is claimed.

The broad application for Equations (1) and (6) is possibly open to criticism. The derivation of Equation (1) is based on a summation of stresses resulting from strains. As long as the summation of strains resulting from stresses does not exceed that at the elastic limit of the isotropic mass, methods of superposition are permissible. Conclusions 1 to 5 are worth careful study and attention.

It might be proper to point out that the stresses, s, are acting in the direction of the radius vector, joining the point of loading with the point at which the stress is being determined; also, that the graphical method described gives the stress at any one chosen point in the earth mass and must be repeated for each point at which knowledge of the stress is desired.

As a practical problem, the vertical intensity of loading is required. A continuation of the basic formulas of the paper, as is done later for the explanation of the graphical method gives: The vertical unit stress at any point in an earth mass due to a point load, P, at the surface is,

$$p_z = \frac{P}{z^2}\frac{n}{2\pi}\cos^{n+2}\alpha \qquad \text{(32)}$$

The vertical unit stress at any point in an earth mass due to a uniform linear load, $\overline{p}$, at the surface is,

$$p_z = \frac{\overline{p}}{z}\frac{n_1}{\pi}\cos^{n+1}\alpha \qquad \text{(33)}$$

Equations (32) and (33) are derived from Equations (1) and (6) of the paper. For various values of n and α, tables based on the values for n_1 listed in Table 1, can be prepared for ready use, as shown in Table 2. By the use of Table 2, upon an assumed value of n, and with a given loading, stress conditions at various depths along radial lines 15° apart can be computed and stress intensity contours plotted.

---

Except in unusual cases, or at shallow depths, there is seldom any necessity to go into great details such as are outlined in the example illustrated by Fig. 6. Taking the data of that example, a very rapid approximate computation, using a slide-rule only, can be made as follows: Divide the area into three areas by the horizontal and vertical lines through Point X, and locate the center of gravity of each area:

$A_1 = 79 \times 60$; the center of gravity is 39.5 right and 30.0 up; α is

$$\tan^{-1}\sqrt{\frac{39.5^2 + 30.0^2}{100^2}} = 26° \, 20'; \text{ and, } A_1 \cos^5\alpha = 2\,740.$$

$A_2 = 55.25 \times 60$; the center of gravity is 27.63 left and 29.0 down; α is

$$\tan^{-1}\sqrt{\frac{27.63^2 + 29.0^2}{100^2}} = 21° \, 50'; \text{ and, } A_2 \cos^5\alpha = 2\,280.$$

$A_3 = 65.75 \times 60$; the center of gravity is 32.96 left and 31.0 down; α is

$$\tan^{-1}\sqrt{\frac{32.96^2 + 31.0^2}{100^2}} = 24° \, 20'; \text{ and, } A_3 \cos^5\alpha = 2\,480.$$

(The foregoing values are obtained from the correct location of the centers of gravity of the two trapezoids. It is close enough even to assume the centers 30 ft up and 30 ft down from the axis.)

The summation of $A \cos^5\alpha$ is 7 500, and the vertical unit pressure 100 ft below Point X is 0.89 ton per sq ft. This may seem to be in considerable error, the author's value being 0.78, but at a depth of 100 ft, the weight of the soil is approximately 5 tons per sq ft, and the totals are, therefore, practically identical. Much closer approximations, of course, can be determined by further subdivision of the loaded area.

G. P. TSCHEBOTAREFF,[31] M. AM. SOC. C. E. (by letter).—An interesting review of the most important recent developments in the study of pressures beneath foundations, including a method for the graphical determination of pressures within a soil mass, is contained in this paper. Special attention is given to the so-called "concentration factor." One of the welcome features of the paper is a list of questions, related to pressure distribution studies, which define the problems in need of elucidation by further research work. Most of the branches of soil mechanics and foundation studies have reached a stage of complex development calling for closer co-operation between the various research centers and practicing engineers if further progress is to be made rapidly. Such co-operation might be advanced considerably by a clear formulation of the problems requiring solution in the various fields. The publication of detailed lists of such questions should help to co-ordinate the efforts of the individual investigators and to stimulate them.

---

[31] Asst. Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

The purpose of this discussion is to add a few more points to the outline of the necessary further research work, as given by Professor Krynine, and to offer some comments concerning the possible methods of approach to the solution of these problems.

Problem 1.—When Should the Laws of Pressure Distribution and When —Alternatively—Should the Probable Irregularities in the Compressibility of a Soil Be Adopted as a Basis for Foundation Design?—All estimations of pressure distribution are based on the assumption that the soil is a homogeneous material of uniform compressibility. Systematic investigation is required in different localities to ascertain what types of soil are, as a rule, uniform—at least horizontally—so that the foregoing assumption can be considered sufficiently valid for purposes of practical design. Very little data are available on this important point. In addition to pressure-measuring cells embedded in the foundations, this investigation could best be done by systematic settlement observations on numerous points of all new structures to be erected on compressible deposits. The necessity of such observations for all purposes of foundation research has been stressed repeatedly in technical publications by numerous authors, but little has been done actually. It becomes more and more evident that such full-scale observations require the participation of national or local governments, or of other public institutions, to allow their successful organization on a sufficiently large scale.

The writer's experience with settlement observations of fourteen structures in Egypt and some records from other localities to which he has had access, tend to show that there may be in some cases a relation between the geological history of the deposit and the horizontal uniformity of its compressibility. Of course, many more observations and their comparisons are required in different countries before anything definite may be said on the subject, but the following outline may be attempted at present.

Cohesive soils which had been precompressed in the past by previous alternate exposures to drying and flooding showed a fairly regular horizontal distribution of the observed settlements over the area of the structure. This indicated a similarly regular distribution of the pressures within the soil. They appeared to follow a definite law very closely, approaching the one derived from the Boussinesq formulas. Presumably, the previous higher shrinkage and swelling pressures had had a tendency to make these clays and silts more homogeneous in respect of the degree of their resistance to the later smaller pressures from the structures. This may be tentatively explained, as follows: The shrinkage limit, that is, the density down to which a soil is compressed by drying, is fairly low for all fully inorganic cohesive soils and varies over a comparatively small range. (For the Nile clays and silts of the cases referred to the water content at the shrinkage limit varied from about 14% to 28% of the weight of the solid substance.) The soil which has shrunk most will also tend to expand most when wetted again. In the early stages of the life of a deposit of the type considered, adjoining zones of unequal compressibility may exist in the same layer since its sedimentation. (The age of the deposits referred to varies from about 600 to more than 2 000 years.) In each cycle subsequent repeated drying and flooding would cause, first, the considerable shrinkage of all zones of any compressibility and the appearance of numerous vertical shrinkage cracks. Then, during flooding, these shrinkage cracks would be silted in and, simultaneously, the soil around these cracks would start swelling. After a few cycles of this kind the swelling would be partly prevented by the newly added soil which had filled these cracks. The zones most compacted by the shrinkage would have a tendency to swell most and, being prevented from doing so, would as a consequence exert a horizontal pressure on the adjoining less compact zones which would be greater than the counter-pressure caused by the lesser degree of swelling of the latter. The effect of this one-sided excess of pressure should be to cause a further compaction of the weaker zone and an expansion of the stiffer one until equilibrium would be reached gradually, corresponding to a uniform resistance of both zones to horizontal pressure. This repeated process should have a generally homogenizing influence on fairly large areas of a deposit. The degree of its resistance to further vertical compression should thereby be rendered also more uniform.

The only case of a horizontally irregular degree of compressibility, as evidenced by a measured tilting to one side of a uniformly loaded structure erected on a sedimentary cohesive deposit of the type cited, was recorded during this series of observations on a very recent formation (less than 150 yr of existence). Local hydraulic conditions made it appear very doubtful that it could have been subjected during this short period to the homogenizing process of repeated shrinkage and swelling as tentatively described.

Older and deeper lying but non-prestressed cohesive deposits of different origin in other countries exhibited a varying behavior. Some showed obviously irregular settlements, giving evidence that they were governed by the soil irregularities and not by the pressure distribution. Others exhibited a regularity of settlement distribution in plan which indicated a soil material of almost perfectly isotropic compressibility characteristics. The writer has not come into contact with a sufficient number of settlement records of such cases to allow him to make comparisons for the purpose of establishing the factors governing this difference of behavior. He would only like to stress once more the necessity of gathering numerous complete and detailed records on the subject and of making careful comparative studies of the relevant factors. All the achievements of theoretical investigations and small-scale experiments on isotropic materials will be of little use in the final analysis unless one knows when Nature permits the application of the results obtained to engineering practice. Only full-scale observations can give a reliable answer to this question.

It may be expected that both cohesive and non-cohesive soils pre-stressed by glacier loads would exhibit in many cases a horizontally uniform degree of compressibility. Whenever the great pressure of a glacier was applied to a large area of an underlying older deposit, in compressing such area the glacier would probably plane or squeeze out the stiffer zones first, producing thereby a homogenizing effect on the later compressibility of the whole layer. The writer has not come in contact with records of settlement observations on such deposits and, therefore, makes the suggestion as a tentative one.

Glacier loads would probably be the only homogenizing force that could act effectively on a granular deposit if it was originally sedimented in an irregularly loose condition. Drying would be of no effect on such soils. All the records known to the writer concerning settlements on non-prestressed loose granular deposits (that is non-compacted sandy loams, sands, and gravels of a type where appreciable settlements were measured) appeared to give evidence pointing toward a pronounced horizontal irregularity in the degree of their compressibility.

Further numerous field observations may possibly lead to the deduction of reliable criteria for the guidance of engineers—presumably of a geological nature—indicating the types of soil deposits for which designs may be based on laws of pressure distribution and on what deposits probable horizontal irregularities in the compressibility of a soil should be considered primarily. The practical importance of such criteria is obvious.

Problem 2.—The Depth of the Foundation Beneath the Soil Surface Should Have Considerable Influence on the Value of the "Concentration Factor," the Exact Extent of This Influence Requiring Experimental Investigation.—Several attempts have been made to express mathematically, by means of the so-called "concentration factor," the observed fact that stresses in sand are more concentrated beneath the center of the foundation resting on it than would have been the case if the laws of pressure distribution in an isotropic solid body were valid for sand. The difference in concentration of pressures appears to depend mainly on the nature and the state of the soil material beneath the edges of the foundation; that is, assuming that the foundation rests on the soil surface and that the soil consists of cohesionless sand, a lateral yielding, followed by loss of the supporting power of the soil, is known to occur near the sand surface beneath the edges of the foundation. This phenomenon, in turn, causes a greater concentration of pressures beneath the center of the foundation than is the case on a more cohesive type of soil.

The degree of cohesion of a soil appears to be taken by the investigators of the "concentration factor" as the essential criterion for the choice of its value. For the case of a foundation resting on the soil surface the value of the "concentration factor" is generally assumed to vary from $n = 3$ (clays) to $n = 6$ (sands).

However, the weight of the overlying layers may also be important. The resistance to lateral yielding of the soil at the edges of the foundation depends on its shearing resistance. This resistance, in turn, may be due to the cohesion of the soil, or to its frictional resistance, the latter depending on the weight of the overlying layers. One may assume that at a certain depth of foundation beneath the soil surface this frictional resistance to lateral yielding would become so great that a sand would behave like a solid material with a "concentration factor" of $n = 3$. This may be a probable explanation for the case of the bridge caisson on the Rhine, mentioned by Professor Krynine (see Fig. 12), where pressure cells embedded at its base indicated greater counter-pressures of the sand at the edges than at the center of the caisson, as this should be the case for solid materials where no lateral yielding around the edges is possible. In addition to the weight of the upper layers, pressures transmitted by friction from the external side walls of the caisson may have acted here as an extra surcharge on the area around its base.

Small-scale tests made by Dr. O. Faber, in England, on soil reactions against foundation plates, give interesting indirect evidence on this subject.[32] These tests showed that, for a surcharge of 1.46 tons per sq ft around a circular foundation plate 1 ft in diameter (this surcharge representing the equivalent of about 30 ft of overlying soil), the soil reactions against the edges of the foundation plate were equal to about 60% of the average pressure assumed to be distributed uniformly over the entire test-plate area. For the case of no surcharge, the value of the reactions at the edge reached only 20% of the average pressure.

This increase in the value of the soil reaction against the foundation edge from 20% to 60% of the average pressure, caused by the surcharge around the foundation edge, indicates a substantial increase of resistance against lateral yielding of the soil beneath the edges and, therefore, confirms the views expressed herein concerning the considerable influence on the "concentration factor" of the depth of the foundation below the soil surface. Further experimental investigation of the limit and intermediate values of this influence is desirable. Such investigations should take into account the degree of density of the sand, which is also likely to affect the "concentration factor."

Problem 3.—The "Concentration Factor" Formulas Should Express the Physical Fact That the Influence of the Foundation Boundary Conditions on the Pressure Distribution Decreases with Larger Loaded Areas.—The preceding discussion tends to show that the value of the "concentration factor" depends mainly on the extent of the lateral yielding of the soil around the foundation edges; that is, the "concentration factor" should be governed by the conditions at the foundation boundary. The influence of these boundary conditions on the general pressure distribution obviously decreases with an increase of the size of the loaded area. In respect to soil reactions this circumstance is well illustrated by Fig. 11 of the paper, but it does not seem to have been taken into account in any of the "concentration factor" formulas thus far proposed.

---

[32] *The Structural Engineer*, London, March, 1933, pp. 120 and 122, Figs. 3 and 5.

It appears to the writer that the value of the "concentration factor" for a stress component, caused by pressures transmitted to the soil by a foundation element near the center of the foundation area, should be different from the value for a stress component, depending on an element near the edges of the area. In other words, a "concentration factor" changing in value with the distance from the center of the foundation toward its edges, should be used when making the integration of the stress components transmitted from the various foundation elements. The graphical method of integration proposed by Professor Krynine might be adapted to provide the possibility for taking care of this further important variable.

Conclusion (a).—In some cases the study of the geological history of a deposit, combined with full-scale settlement observations of numerous structures, may supply a criterion concerning the probable horizontal uniformity of its compressibility and, therefore, also a criterion as to how far future foundation designs may be reasonably based on pressure distribution laws.

Conclusion (b).—The estimation by means of the "concentration factor" of the pressure distribution beneath a foundation is more complex than would appear from the formulas so far proposed for this purpose by several authors. These formulas do not take into account variables of which the "concentration factor" is a function and which should strongly affect its values. These additional variables; that is, the surcharge of the overlying soil layers around the foundation and the size of the loaded area itself, might possibly cause, in many practical cases, a pressure distribution in sand approaching closely that of fully cohesive soils ($n = 3$), for which numerous auxiliary tables, computation graphs, and other accessories have already been developed, greatly simplifying and accelerating pressure computations.

Conclusion (c).—Much experimental and theoretical research is still required on this important subject, and Professor Krynine is to be complimented on having furthered its investigation.

A. HRENNIKOFF,[33] ASSOC. M. AM. SOC. C. E. (by letter).—Another step in the development of soil mechanics is marked by this paper, which is a valuable contribution to engineering knowledge. The writer has no suggestions to make in connection with the clear presentation of the author's interesting method, and he will limit himself to the discussion of the assumptions of the theory of a stress concentration factor, on which Professor Krynine's method is based.

---

[33] Instructor, Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

It may seem peculiar that, although the new science of soil mechanics deals with the same material as the classical theory of earth pressure on retaining walls, its development has proceeded along quite different lines, and little use has been made of the findings of the old theory. In this discussion the writer will endeavor to correlate the old and the new theories and to examine in detail some of the principles underlying the latter.

The classical earth-pressure theory involves consideration of a material with mechanical qualities that are characterized by the coefficients of friction, $f = \tan \phi$, and of cohesion, c. According to this theory, if at any point in the earth mass a normal unit stress, s_n, exists on any plane, the shearing unit stress on this plane cannot exceed the value,

$$s_s = f\, s_n + c \quad \text{.......................} (34)$$

although it may be less. This formula, known as Coulomb's formula, represents merely a statement of the fact that the maximum value of the shearing unit stress, at all possible on any plane, at any point, in a granular material, may be considered as the sum of two parts, one of which, $f\, s_n$, is proportional to the normal unit stress on the same plane, and the other, c, is independent of it. Coulomb considered the coefficients, f and c, as constant throughout the entire mass of earth, but for this discussion such a limitation is unnecessary, and the coefficients, c and f, will be thought of as quantities constant for different planes at the given point, but varying, if necessary, from point to point. There can scarcely be any quarrel with Equation (34) when so interpreted, since one cannot conceive of any cause that would contribute to the shearing resistance in a manner such that it could not be included either in one or the other of the two parts of the binomial of the formula.

Equation (34) shows the fundamental distinction between a solid body and an accumulation of granular particles constituting the soil. Although in the solid body any value of the shearing stress below the breaking point, imposed by the conditions of continuity, is possible, in the granular material there is a definite limit, and as soon as the limiting value of the shear is reached sliding occurs.

As is shown in standard texts[34] this limitation of the shearing stress results in a limitation of the ratio of the principal stresses. In a cohesionless material (that is, in a material for which c is zero) the least ratio of principal stresses, consistent with Equation (34), is,

$$k = \left(\frac{s_2}{s_1}\right) = \tan^2\left(45^\circ - \frac{\phi}{2}\right) \quad \text{................} (35)$$

in which s_1 is the major principal stress, and s_2 is either of the two remaining principal stresses. In a cohesive material the limiting ratio, k, depends on c, and on the value of the major principal stress; it is less than Equation (35), and may be as low as zero.

---

[34] For example, "Earth Pressure, Retaining Walls, and Bins," by the late William Cain, M. Am. Soc. C. E., New York, John Wiley & Sons.

The writer wishes to emphasize the fact that Equation (35) and its counterpart for the cohesive earth are derived by application of the equations of statics to an infinitesimal wedge of earth, and that they are not influenced by the deformations of the material, elastic or otherwise, and by possible variation of the coefficients, f and c, from point to point.

It follows from the preceding discussion that a granular material may act as a solid body only as long as the ratio of principal stresses at any point, found by application of the theory of elasticity, proves to be larger than the least possible value of k; but as soon as the ratio, $\frac{s_2}{s_1}$, tends to fall below k, the particles slip, the stresses re-adjust themselves, retaining the least ratio, k, between them, and the earth mass ceases to act as one solid body. When that happens, the only equations of the theory of elasticity that hold are those based on statics, while the continuity equations become invalid. This phenomenon of slipping must not be overlooked when the equations of elasticity based on continuity, such as the Boussinesq solution, are applied to earth.

The major principal stress in earth under a foundation assumes a value governed by the load and the two other principal stresses—values governed by k. Thus, if a foundation produces a vertical uniform pressure, p, on the foundation bed (an assumption which is not always true), the major principal stress immediately under the foundation is vertical and equal to p; and the other two principal stresses acting horizontally are equal to $k\,p$, unless a larger value is required by the conditions of continuity. Minor principal stresses less than $k\,p$ are impossible because that would require the existence, on some planes, of a coefficient of friction greater than $f = \tan \phi$.

With these principles in mind the question of the admissibility of the Boussinesq solution will be considered. This will be done first in relation to the two-dimensional problem, and, subsequently, some remarks will be added concerning the three-dimensional problem.

The solution has been derived for a solid body obeying Hooke's law. According to this solution the major principal stress acts in a radial direction (see Equation (3)) and is equal to,

$$s_1 = \frac{2\,\bar{p}}{\pi\,\rho} \cos \alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

and the remaining principal stresses, s_2 and s_3, are equal to zero. Whether or not this solution is applicable to earth depends on the following two questions: (1) Does the earth obey Hooke's law; and (2) can the minor principal stresses be equal to zero? Only in a case of positive answers to these two questions can the Boussinesq solution be applied properly to earth.

As to the first of these conditions, the applicability of Hooke's law is conceded by most investigators. However, it must be remembered that only a part of the total deformation may be subjected to this law, namely, the part that occurs before any sliding takes place. The part of the deformation that accompanies sliding, and involves a change of shape without any change of volume, naturally bears no proportional relationship with the stress, since the stress may be considered constant during this phase.

The second condition required by the Boussinesq solution (that is, the vanishing of the minor principal stresses) will now be considered in detail. Three broad cases should be distinguished:

(*A*).—*Cohesionless Material.*—In cohesionless material the minor stresses cannot vanish unless the major stress is zero, as is evident from Equation (35); consequently, the Boussinesq solution is not applicable to such material.

(*B*).—*Dry Cohesive Material.*—It is possible for the minor stresses in dry cohesive earth to vanish, provided c is sufficiently high and the major stress is sufficiently low. The greatest value of the major stress for which the minor stresses may vanish, can be found from the relation[34],

$$s_1 = 2\,c\,\tan\left(45^\circ + \frac{\phi}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

Equation (37) is derived from statics without any special assumptions. A conclusion, then, may be drawn that once the major stress under the action of a line loading exceeds the limiting value (see Equation (37)) the solidity of the earth is broken, which, in turn, means that the Boussinesq solution does not hold. Taking an example of stiff clay with $\phi = 7^\circ$ and $c = 1\,500$ lb per sq ft,[34] the value of s_1 from Equation (37) equals 3 390 lb per sq ft, a value that is not very high. The writer does not insist on the accuracy of the assumed coefficients for clay in his numerical example, but simply wishes to emphasize the fact that in conditions encountered in practice the dry cohesive earth is not likely to behave as one solid body, at least for some depth below the foundation; but, at a greater depth, where the major principal stress decreases sufficiently, it may act as a solid body. This conclusion is corroborated by the testimony of several investigators, referring to the region immediately beneath the foundation as a disturbed zone. From the writer's point of view this zone is merely a part of the earth mass in which the particles have undergone some sliding, and in which, consequently, the theory of elasticity does not hold.

(*C*).—*Cohesive Earth Saturated with Capillary Water.*—If the foundation bed of a cohesive earth is situated between the levels of capillary and gravitational waters, a state of uniform pressure due to a capillary action is superimposed on the state of stress caused by the load, increasing by the same amount both the major and the minor principal stresses. This condition is favorable to a behavior of earth as a solid continuum, and obviates the necessity of forming a disturbed zone. However, in order that the capillary pressure may properly materialize, the earth must be nearly saturated with capillary water. The writer does not think that mere presence of moisture in a cohesive earth would make it behave in a manner essentially different from dry earth, although the coefficients, c and f, may be affected by moisture content. No capillary pressure is present below the level of gravitational water. Capillary action in sand and gravel is negligible.

Failure of the Boussinesq solution to agree with the experiments led the investigators to adjust it by an arbitrary introduction of a quantity, $(n-2)$, instead of unity in the power of the cosine in the expression (Equation (36)) for the radial stress. The coefficient, 2, also had to be changed into $n_1 = f(n)$ due to considerations of statics; thus, the author's Equation (6) was obtained. In this empirically modified Boussinesq solution all other results of the original theory are retained; the radial stress is still considered as the major principal stress, and the two other principal stresses are held equal to zero; the empirical constant, n, termed the concentration factor, varies in magnitude depending on the nature of soil material. It is this modified theory that has been used by the author in the development of his graphical solution.

The weakness of the modified theory lies in its failure to take proper account of the earth disturbance, a fact leading to several apparent inconsistencies:

1.—As has been demonstrated, the minor principal stresses, caused by the loading, may be equal to zero only in cohesive material when it is lightly loaded, or nearly saturated with capillary water. When such a material is nearly dry, or completely submerged below the gravitational water level and, at the same time, is fairly heavily loaded, the minor stresses do not vanish, and it does not seem justifiable to disregard them. In cohesionless material the minor stresses cannot be equal to zero under any circumstances. One might think that this criticism would not apply if several line loadings were superimposed; however, the objection would still hold, at least for the region near the boundary of the loaded area.

2.—It seems improbable that the same value of n should properly describe the state of stress both near the foundation where the soil is disturbed and outside the zone of disturbance. The writer feels that the stresses at a point depend not only on the geometric location, but also on whether the point in question lies inside or outside the disturbed zone. It also appears that the size and shape of such a zone should have an important bearing on the settlement of the foundation and on the law of distribution of pressure over the base.

3.—The use of the principle of superposition in conjunction with the modified Boussinesq theory seems incorrect. As has been stated, the introduction of the empirical exponent, $(n-2)$, was due to one of two causes: (*a*) The failure of the earth to obey Hooke's law; or (*b*) earth disturbance. Either one precludes the application of the principle of superposition. That the statement is true with respect to the first reason needs no explanation. The earth disturbance, however, has the same effect: First, because the boundary of the disturbed zone is not the same for the three loads—Loading 1, Loading 2, and Loading $1+2$; and second, because in the disturbed zone, the minor principal stresses do not combine vectorially, but keep a constant ratio, k, with the combined major stress.

It may be argued that superposition is an additional empirical assumption which is to be used with the empirical formulas of the modified Boussinesq theory, but such an assumption stands as a contradiction to the physical nature of the phenomenon which it purports to describe. Suppose, for a moment, that Equation (6), describes truly the state of stress in certain soil under a line loading, and that the value of the concentration factor is determined from experiments with such a loading. If then the same soil is subjected to several line loadings, and the state of stress is analyzed by the formulas derived by superposition which involve the same value of n, then a disagreement will be noticed between the observed and the computed values of stress. The disagreement may be removed by a proper modification of the value of n accompanied by an admission that the magnitude of the concentration factor depends not only on the character of the soil, but also on the character of the load and on the depth. Thus, the assumptions of the modified Boussinesq theory lead to a deduction of variability of the concentration factor, with its dependence on several variables besides the character of the soil. This complicates the matter considerably. The difficulty, of course, is the natural consequence of an attempt to describe a physical phenomenon by an uncongenial formula and an unsuitable assumption.

The writer feels that the criticism of the use of superposition in the modified theory strikes at its very root, and unless it is removed, the theory fails, since superposition is the very essence of its application.

4.—The reasons for the particular significance attached by most investigators to p_z, the normal unit stress on the horizontal plane, are not clear. The primary object of stress analysis in the earth under a foundation is the determination of the foundation settlement, caused by the earth deformation, but this deformation is manifestly a function of all three principal stresses, and not of p_z alone. Nor can p_z always be considered nearly equal to the major principal stress. The writer thinks that the pressure exerted by the actual foundation on a bed of cohesionless material may be inclined at an angle of friction with the normal. If that is true, the major principal stress over a large part of the foundation bed in sand and gravel must be far from vertical.

The foregoing criticisms have been made primarily as they apply to the two-dimensional problem. They also apply with minor qualifications to the three-dimensional problem, in regard to which the writer wishes to make the following additional comment:

5.—In the original Boussinesq solution the radial stress is not a principal stress, except for an incompressible elastic solid body, and none of the principal stresses is zero. In the empirically modified solution, Equations (1) and (4), the radial stress is treated as the major principal stress and the other principal stresses are considered as non-existent. Although the author does not make any use of this interpretation, if it is adopted the original Boussinesq solution ceases to be a special case of the modified theory, except for the aforementioned physically impossible material. From these considerations it follows that if a certain earth material exhibits, in its mechanical characteristics, a great similarity to an elastic solid body, such a material is not subject to analysis by the modified Boussinesq theory, a conclusion which is as unexpected as it is logical. The modified theory, therefore, must be supplemented by the list of soils to which it is applicable.

Conclusion.—The Boussinesq theory has been chosen as a starting point in soil mechanics by many investigators. After some adjustments, an apparent agreement with the experiments has been reached, and the investigators have been eager to proceed with further development, whereas the nature of underlying assumptions apparently has received only casual attention. This discussion, by emphasizing some seeming inconsistencies, is intended to bring forward the necessity for critical examination of the basic principles on which the theory rests. The writer appreciates the qualitative value of the original Boussinesq theory in describing the stress behavior of the earth mass, and is inclined to concede a limited field for its applicability in quantitative determination of stress when dealing with cohesive materials, but he feels unable to explain the numerous apparent contradictions inherent in the modified theory. If the writer's diagnosis is correct, and the contradictions indicated by him are irreconcilable, a further elaboration of the theory of the concentration factor is futile.

ROBERT G. HENNES,[35] ASSOC. M. AM. SOC. C. E. (by letter).—This contribution by Professor Krynine to the growing literature on soil mechanics is of more than usual interest, not only because of the excellence of material and presentation, but also because the division of his paper into two parts illustrates rather aptly an important gap in the existing knowledge of this branch of the subject. Part I deals with the determination of numerical stress values in an ideal material under given conditions of loading, which is assumed quite generally to apply with acceptable accuracy to the case of stress distribution in a deeply underlying soil stratum. Part II deals in a more general sense with stress distribution over the surface of contact of the structure with the earth. For the average structure the stress distribution in the intermediate "disturbed zone" is of at least equal importance, but this region constitutes also an "unexplored zone," which needs more investigation before a satisfactory theory is available to the profession. In the meantime, the engineer must resort to the statistical, as opposed to the scientific, approach in dealing with what Professor Krynine terms "contact settlement."

Those who frequently have occasion to determine stress distribution in the subsoil should welcome the graphical methods presented in Part I.

---

[35] Asst. Prof., Civ. Eng., Univ. of Washington, Seattle, Wash.

Others, who only seldom undertake this task, can profitably study at least that part of the author's method which presents Kögler and Scheidig's use of annular elements, especially when confronted with non-uniform loads, or with loaded areas of irregular shape.

It is natural, but unfortunate, that most valuable contributions to the science of soil mechanics seem to widen progressively the gap between the specialist and the average civil engineer. It is the impression of the writer that many engineers without formal education in soil mechanics would read this, and similar papers, more profitably if the fundamental assumptions were treated from the physical as well as from the mathematical viewpoint.

Consider, for example, the case of a uniform load placed on the horizontal surface of a large supporting body. If the load could be transmitted through this material without spread, the resulting situation would be as shown in the free body diagram of Fig. 18, the entire load, *W*, being carried by the prism *ABCD*, which would, consequently, be shortened. If the material possessed any shearing strength, however, this compression would set up shearing stresses along the surfaces, *AD* and *BC*, thus transmitting part of the load to the adjacent regions, in violation of the assumptions. If the material had no shearing strength, the underlying material would flow from under the load until the vertical stress across any horizontal plane became equalized, and the body would float, as in Fig. 19. If the material possessed some shearing strength, but less than the maximum stress imposed, there would be flow until the maximum shearing stresses were relieved to a point within the capacity of the material to withstand them. The quantity of flow depends, in part, upon the location of the over-stressed material. If it cannot move without displacing a considerable quantity of adjacent material, the flow may be limited to the relatively small amount required to compress the adjacent under-stressed soil sufficiently to transfer to it the excess load. Because this quantity depends upon the compressibility of the material, the computation of stress distribution is greatly simplified if it is first assumed that the stresses nowhere exceed the shearing strength of the material.

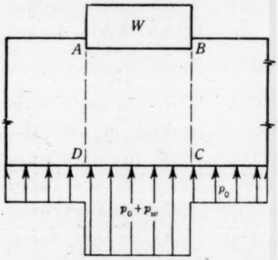

FIG. 18.

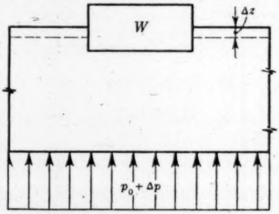

FIG. 19.

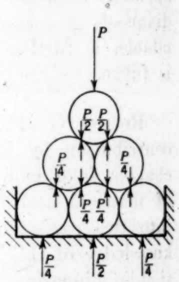

FIG. 20.

Next, consider a pile of incompressible rollers arranged as in Fig. 20. It is obvious that the load, P, would be divided equally between the two rollers in the second layer, and that in the third layer the middle roller would be subjected to a load of $0.5\,P$ while the two end rollers would each carry a load of $0.25\,P$, horizontal stress components being disregarded. If the same stress distribution were assumed to occur in a pile of elastic rollers, the application of the load, P, would result in a compression of each roller, and in the third layer the middle roller would experience twice the vertical compression of the end rollers, and hence lose contact with the overlying rollers which transmit the load. Since this is contradictory, it seems that for elastic materials the normal stress distribution on a horizontal plane will be more uniform than that represented by the example of the inelastic rollers. An intermediate case would be that of a material which, like soil, offered relatively more resistance to compression at higher temperatures. It should be noted further that, in the foregoing example, lateral forces have been neglected. As the end rollers experienced lateral displacements under stress, the middle roller would regain its proper share of the load, as the overlying rollers moved into more stable positions with equal bearing on their supports. Since vertical stress distribution is thus seen to be a function of lateral strain, it follows that divergence between the stress-strain relationships along horizontal and vertical axes would affect that nature of normal stress distribution. The general problem is further simplified, therefore, by assuming that the material has the same physical properties in all directions, and that it is a solid homogeneous mass.

In general, the foregoing assumptions are those of Boussinesq in determining the stress at a point in a semi-infinite, elastically isotropic solid, loaded by a single concentrated normal force applied at a point on the horizontal boundary plane.

With the foregoing concepts, and with a knowledge of Boussinesq's assumptions, one can visualize, in a general way, the application of this type of equation to lightly stressed soil strata, especially when the concentration factor is included. If those concepts are approximately correct, however, it is difficult to understand how the concentration factor can be made to cover the situation that arises when the shearing strength of the soil is exceeded at one or more points, involving such factors as the flow properties and the compressibility of the material. Yet this is the situation that commonly exists in the disturbed zone, at least under the edge of the footing where shearing stress is maximum. Even the lightest surface load, therefore, is likely to cause a trace of flow at the edge of the footing. If the footing is perfectly flexible, the flow continues until the edge of the footing has settled to such a depth that the weight of the adjacent earth has sufficiently served to relieve the intensity of the maximum shearing stress, or to increase the frictional resistance to flow. If the footing is perfectly rigid, the edges cannot settle independently; thus incipient failure of the soil at the edges is accompanied by transfer of some of the load to the central part of the footing, and the condition of uniform loading no longer holds. If this view is acceptable, Fig. 11(*a*) and Fig. 11(*b*) generally do not hold for surface loadings, whereas for footings at considerable depth, the effect of confinement might give even clay sufficient rigidity to correspond to Fig. 11(*c*) and Fig. 11(*d*). It would still be possible, of course, for the intensity of the soil reaction at the center of the footing to be relieved by the actual settlement of the soil, as in the case of consolidation of underlying clay strata.

T. A. MIDDLEBROOKS,[36] ASSOC. M. AM. SOC. C. E. (by letter).—The factors that influence the stresses in earth masses are treated most completely in this paper, which reveals clearly the fact that little is known about the true distribution of stresses in a foundation, especially where there is a wide difference between the rigidity of the structure and the foundation material. A quick realization of this fact by the Engineering Profession in general will be most helpful in speeding the accumulation of badly needed field data. The author's "reduced area" method of determining pressures under structures is a decided improvement over the usual procedure, and should meet with widespread usage.

Recognition of the influence of the rigidity of structures and earth masses on the stress distribution is of major importance. Professor Krynine has given a thorough presentation of the effect of this influence and he rightly states that the degree of rigidity in actual structures will be some value between the two extreme limits. The writer agrees with the statement that a clay can be considered as a non-rigid mass; but, on the other hand, he believes that a compact sand will act as a rigid mass only when it is supported by non-yielding strata. In the case of a footing resting on a compact sand stratum which, in turn, is supported by a non-rigid clay stratum, the sand, in this case, could not be correctly considered as a rigid mass. The same is true of a sand dam resting on a clay foundation. In cases where the clay is underlaid, as well as overlaid, with sand, the top sand should not be treated as a rigid mass, although the sand beneath it should be considered rigid. Working on this basis, the writer has been able to obtain some close checks on the stability of earth fills resting on clay in the foundation.

Interrelation of stresses in the structure and foundation are of utmost importance. The stresses in an earth fill have a marked effect upon the stress in the foundation. This fact has been ignored by numerous investigators in an attempt to devise a simple formula or method for analyzing the stress in a foundation. The writer has found that it is essential, in the design of earth embankments, that the fill and foundation be considered as a whole in determining the stresses in the foundation.

Considerable errors will occur in the computed foundation stresses if the stress in the structure is not taken into consideration, as would be the case if it is assumed to be perfectly rigid. It is evident that the greatest error in these stresses occurs when the actual rigidity of the structures and the foundations is approximately the same. Errors are also introduced if it is assumed that the vertical load on the upper boundary of the foundation material is equal to the weight of the material directly above it at every point, and that the shearing stress along this upper boundary is zero. It is only logical that "dam builders" should be first to recognize the importance of these principles, since the difference in the rigidity of the fill and foundation of a dam is much smaller than it would be for a footing on the same foundation.

---

[36] Senior Engr., Board of Engrs. for Rivers and Harbors, Washington, D. C.; Chf., Soil Eng. and Fill Control Div., Fort Peck Dam, Fort Peck, Mont.

In making use of computed foundation stresses, does the author consider satisfactory the generally accepted method of determining the probable settlement of a structure by computations based on the use of the vertical forces and the change in volume of the compressible strata directly beneath the loaded area only? In order to determine accurately the probable settlement beneath a footing, the volume change from consolidation throughout the entire pressure bulb should be used. Furthermore, the maximum principal stresses, rather than vertical stresses, should be used in computing the consolidation. This method will not be as simple to use as the generally accepted method, but too much simplification of a complex problem can easily lead to undesirable errors in the results. Therefore, since the engineer is attempting to determine the stresses more accurately, he is also justified in using a more nearly correct method of computing the consolidation.

A. A. EREMIN,[37] ASSOC. M. AM. SOC. C. E. (by letter).—A most interesting method of graphical computation of foundation stresses under spread footings is developed in this paper. It is simple and helps to visualize the distribution of foundation pressures. Professor Krynine's graphical construction may also be applied in the computation of foundation stresses with equations developed by Messrs. F. Kögler and A. Scheidig.[38] Using the author's notation, the vertical foundation pressure, p_z, at depth, z, as expressed by Messrs. Kögler and Scheidig is:

$$p_z = \frac{3\,P}{2\,\pi\,z^2}\,\frac{(\cos\alpha - \cot\phi\sin\alpha)\cos^4\alpha}{1 - \cos\phi} \quad\ldots\ldots\ldots\ldots (38)$$

in which ϕ is the angle of repose of the foundation material. Considering the principle of superposition of loads, the foundation pressures due to the load on an elementary area, dA, from Equation (38) are,

$$p_z = p\,\frac{3}{2\,\pi\,z^2}\sum\frac{dA(\cos\alpha - \cot\phi\sin\alpha)\cos^4\alpha}{1 - \cos\phi} \quad\ldots\ldots\ldots (39)$$

The summation of the last term in Equation (39) may be determined by a graphical construction similar to that shown in Fig. 2.

It is interesting to note that instead, of the term, n, used by the author in the equations for foundation stresses, Messrs. Kögler and Scheidig used the angle of repose, ϕ, to express the physical qualities of the foundation material.

M. M. BUISSON,[39] ESQ. (by letter).—The two quite distinct parts into which this paper is divided, are: (I) The description of a graphical method for computing the stresses in soils; and (II) a study of stresses that develop under a rigid foundation.

[39] Chef du Service CCI, Bureau Veritas, Paris, France.

Part I.—The Method.—In some cases, it has been possible to derive analytical formulas giving the values for horizontal and vertical normal pressures and for principal stresses at any point in a half space. By dividing the loaded area into rectangular, or square, elements, the vertical pressure can be computed easily, as, for instance, the method developed by Dr. Wilhelm Steinbrenner.[40] In some cases, Professor Krynine's method will be an easier one for the solution of similar problems, taking the value of the concentration factor, n, into account, with sufficient accuracy. This is an application of a graphic integration method which has been well known for many years, and which makes it easy to solve for the principal stress trajectories.

Moreover, since failure trajectories are isoclinic lines that meet the principal stress trajectories at an angle, $\frac{\pi}{4} - \frac{\phi}{2}$, one may draw easily such failure lines, and thus determine the failure conditions in cases where a purely analytical solution of the problem would not be possible.

In two-dimensional cases, if a semi-infinite plane is loaded and if $n = 3$, the failure lines are parabolas with their foci at the half-plane limit. The axis of the parabola is a straight line, inclined to the vertical by an angle equal to the friction angle.[41] In the case of an infinite loaded strip, it is known that the principal stress trajectories are hyperbolas with their foci at the edges of the loading strip. From this knowledge, failure trajectories can be drawn easily.

Failure would occur if the equilibrium of a certain part of the loaded body should become unstable. This condition will decide the position of extreme failure trajectories and also the loading conditions corresponding to an actual failure along these lines. When it is possible to determine the form of the plastic zones analytically—and, above all, to locate the point of intersection of the marginal plastic zone with the loaded surface—(the abscissa of this point is a function of the applied load)—one may locate the extreme failure trajectory also, in an analytical manner, since this line must necessarily meet the aforementioned point of intersection.[42]

In a particular case, a uniformly loaded strip would show, contrary to expectation, that the extreme plastic-zone lines are not in themselves failure lines; this indicates, incidentally, that the bases of Prandtl's computation are not exact.

Furthermore, if the stress distribution can be studied analytically, it is always possible, to choose from a set of possible failure trajectories, one along which actual failure conditions will be attained. This can be done graphically using a method similar to that applied in determining the slopes of earth dams. Without any difficulty, one may compute the load necessary to produce such a critical instability, whether the loading is rigid or semi-rigid.

[42] "Conditions de stabilite du sol," by M. M. Buisson, Travaux, Decembre, 1936.

Following the same general trend of thought, the writer would attach great importance to the systematic determination of failure conditions in most of the common loading cases. This can be done easily by means of Professor Krynine's graphical method.

On the other hand, actual tests have shown[43] that if an excessive load is applied to an earth mass, and both the earth mass and the superstructure fail, the failure trajectories in both bodies in contact are always prolongations of each other. They do not possess a common tangent at the boundary, however, but will meet at an angle, unless the angles of internal friction are the same in the soil and in the superstructure. It is worthy of note that, in cases where it was possible to trace lines for these failure trajectories, with sufficient accuracy, they were almost the same as the theoretical lines, corresponding to $n = 3$.

Part II.—The Stresses.—Concerning Part II of the paper, which relates to the study of the stresses that would develop under a rigid foundation, the writer would insist, urgently, on the great necessity of making actual tests and measurements on the foundations themselves.

Numerous important factors which are not yet completely understood are then in operation. First, the basic hypotheses must be checked. Only by actual testing or observation can one obtain reliable results. It is difficult indeed to determine, even approximately, the mutual reactions of both bodies in contact; that is, the superstructure and the supporting soil. Many results seem contradictory only because due attention has not been paid to an analysis of peculiar cases. Professor Fröhlich is credited with having studied the rare tests existing at the time and comparing them, case by case, with the theoretical results obtained by Boussinesq.

In this manner he arrived at the most interesting conception of the "concentration factor," n, thus providing a means of generalizing the formulas for the Boussinesq stress distribution.

Experimental tests and measures, however, are very difficult to carry to a successful conclusion, the principal reason being the presence of important, although secondary, phenomena. In general, pressures are measured by using Goldbeck cells. For small-scale models, it seems better to resort to small manometric capsules, closed in by a rubber diaphragm. It is necessary to conduct the tests in such a manner that the diaphragm cannot become displaced; otherwise, the readings will be affected. For instance, if the movable diaphragm had been pressed into the ground and if, subsequently, one wanted to return it to its original place, the necessary force is not at all in proportion with the actual pressure at the capsule point. Mr. Leo Rendulic[44] made use of a similar method for the measurement of hydrostatic pressures that are developed by various principal stresses in soil cylinder samples.

Actually, this force will be much greater than the pressure caused by any arching effect that may develop in the soil. If sufficient accuracy is to be attained, one must press the diaphragm beyond its definite stationary position and then release the force gradually, noting the pressure at the very moment when the initial position has been reached.

Nevertheless, even when such precautions are taken, errors can be made. The best way would be to mark a capillary zone on a tube, and then to make use of a tank filled with air under compression. The pressure could be exerted by water, for instance, as the measured pressures will be always low. If the air compression is kept constant, the meniscus will stay at the mark, and then the measured pressure will be the actual pressure in the soil.

With such apparatus in operation, one could detect such stress variations as those indicated by Professor Krynine. It is normal that such variations should occur because after loading the soil, its properties will be altered locally. If, previous to tests, the soil behaved as an isotropic and homogeneous body, it will no longer be so after the tests due, among other causes, to unequal settlements. It is obvious that factors for isotropic properties always express extreme conditions that are never absolutely obtained in actual soils.

Tests will show changes of two different types: (*a*) Rapid stress variations; and (*b*), slow changes in stress alterations.

The rapid variations will transform the curves (which appear continuous in Fig. 13 of the paper) into saw-toothed lines with maxima and minima. With the passage of time the difference between these maxima and minima will decrease. The curves in question reflect the process of re-grouping of soil particles. The slow changes are a result of the adjustment of the soil structure to the external load.

In testing some models of wharf retaining walls the writer used apparatus such as the aforementioned to extend the research to other tests more especially intended to study the form of failure curves, and to determine the conditions under which failure occurred. A certain number of capsules were placed in the soil, more or less at random, and only at the end of the tests could a satisfactory experimental procedure be devised. As new tests concerning this question are being conducted, the writer is not yet in a position to furnish definite results.

The original tests were performed in a large basin, 3.93 ft wide, 3.28 ft deep, and 11.5 ft long. Such a basin may be flooded or emptied, at will. A glass panel on one side permitted photographs to be taken which indicate, with the profile of the quay model, the particles in the soil.

By fixing the photographic apparatus in a definite steady position many pictures could be taken at various loading stages. By superposing such pictures taken at different times, one could easily trace (very approximately) the trajectories of movement in the soil particles as well as displacements of the wall itself; thus, the actual failure curves were derived in quite a satisfactory manner. Capsules were placed in the soil at different levels, as the soil was placed in the basin. Datum marks were fixed to measure vertical movements at the soil surface, as well as movements of the loading sheets, and of the quay model. These movements were measured by dials with an accuracy that could easily reveal 0.005 mm (= 0.002 in.).

Some test results were recorded during a loading test on a relatively long strip of homogeneous clay, 10 cm (3.94 in.) wide. The load was applied through rigid plates placed end to end along the entire width of the basin. A layer of fine sand, about $\frac{3}{8}$ in. thick, was laid between the plates and the clay, which provided for drainage through the soil immediately beneath the plates. Many difficulties had to be overcome:

(1) In some places, the pressure differences that were recorded during the application of the load were negative instead of positive as one would have expected. Such phenomena seem to be due to suction that occurs near the capsule, from the flowing clay. The capsules were practically fixed by seating them in the soil mass. It follows, therefore, that such readings cannot yield precise information as to stress distribution.

(2) To date (1937) test measurements have been made only at, or near, the critical loads, when the p_h-value (as recorded by a vertical capsule set 10 cm deep and 10 cm from the plates) is practically the compressive resistance of the same clay as that measured on cylinder samples. This value would be greater only if the material could consolidate.

(3) One may overload the soil beyond the critical loads obtained by rapid application, if the sample is permitted to consolidate after each partial loading. In a particular test, clay possessing a moisture content responding to the Atterberg liquid limit, offered a shearing resistance of 10 gram per sq cm (20.4 lb per sq ft). Failure under a rapid rate of loading took place under the action of a weight of 60 grams per sq cm (122.6 lb per sq ft). In a slow test process a load amounting to more than 120 grams per sq cm (245.3 lb per sq ft) would be required for the same purpose.

(4) Although the following statement bears only a distant relation to stress redistribution under rigid plates, it is useful to emphasize that, as the load approaches its critical value, one detects a considerable increase in the permeability. This is accompanied by a large and almost immediate settlement under the plate and, at the same time, a settlement occurs to the right and left of the plate. Thus, the extent of consolidation settlement beyond the plate, is much greater than the swelling that should have occurred as computed from the instantaneous settlement under the plate and from the constant-volume soil deformation.

Long before failure, however, one can note that instantaneous consolidation is occurring to a large extent, as the uplifted volume is practically nil, although the settlement under the plate is rather large; this is absolutely contrary to results derived from measurements of the permeability coefficient determined in the usual manner.

Observations on the movements of soil surfaces show that the flow influence varies with the distance to the plate; for instance, at a distance of 3 cm (1.18 in.) the maximum settlement was noted about 150 hr after the loading was completed, although at 20 cm and 30 cm (7.87 in. and 11.81 in.) such a maximum was recorded 70 hr after loading; the next swelling to occur was stabilized 200 hr after loading. One may conclude that the length of time necessary for flow stabilization in clay is almost equal to, or longer than, the time necessary for consolidation itself. Indeed, during the tests, the consolidation was not yet complete as the plate continued to settle.

The form of the settlement curve was readily adapted to logarithmic plotting, settlements being in proportion to logarithms of time. Thus, in this testing time, the settlements were due at once both to flowing and to consolidation processes, the effects being equal but opposite beyond the plate. After a certain time had elapsed the importance of the continuous flowing process eclipsed the consolidation noticeably.

The volume of soil raised on both sides of the plate was then equal to the product of the depth of settlement by the area of the plate. In this case, again, the settlement-to-time relationship was adaptable to logarithmic plotting. From the foregoing considerations, it seems that the logarithmic law, as given by Professor Buisman[45] for long-time settlements in eudiometric tests, would apply also to settlements from plastic flow.

Conclusions.—Research in the United States should be directed toward an extension of the ideas herein described, in order to obtain true information as to the behavior of the soil under foundations. This would not minimize, in the least, the merits of Professor Krynine's paper; but it is necessary in this connection to emphasize the urgent need of an experimental verification of theoretical results. At present, experimental data are much less available than theoretical research. It seems timely to minimize the importance of the latter and to strive for a rational balance with the importance of confirmatory tests.

FREDERICK J. CONVERSE,[46] ASSOC. M. AM. SOC. C. E. (by letter).—The method, described by Professor Krynine, for obtaining the pressure of any point within the soil below a loaded area, contains three important viewpoints which should be included in any method of pressure determination. In the first place, recognition of the fact that the soil cannot always be considered as an elastic isotropic medium is given by the use of such formulas as Equations (1) and (9), containing the "concentration factor," n. Secondly, the method can be easily adapted to non-uniformly distributed pressures at the surface. In the third place, the method can be used with equal facility for the case of single spread footings and for groups of foundations.

The work involved in the graphical solution presented by the author may be shortened somewhat by the following procedure: Consider a unit pressure to be applied at Point O', Fig. 2, and construct contours of equal vertical pressure in the soil below Point O', using Equation (8) with $\bar{p}\, dA$ equal to unity. Move the "transformed area," $M\ T'''\ N$, vertically downward until the horizontal through $M\ N$ passes through Point O, as shown in Fig. 21. The percentage of the unit pressure, indicated by the position of Point T' on the iso-pressure chart, multiplied by the height, $T'\ T'''$, gives the vertical component of the pressure at Point O due to a concentrated load, $T'\ T'''$, at the surface. This may be plotted vertically above Point T' and represents a point on the "pressure curve" (see Fig. 22). Its value corresponds to that of $T'\ y$ in Fig. 2, multiplied by $p \frac{n}{2\, \pi\, z^2}$. In a similar manner, other points on the "pressure curve" may

[45] "Results of Long Duration Settlement Tests," by A. S. Keverling Buisman, *Proceedings,* International Conference on Soil Mechanics and Foundation Engineering, Vol. I (1936), p. 103 (Paper F-7).

[46] Asst. Prof. of Civ. Eng., California Inst. of Technology, Pasadena, Calif.

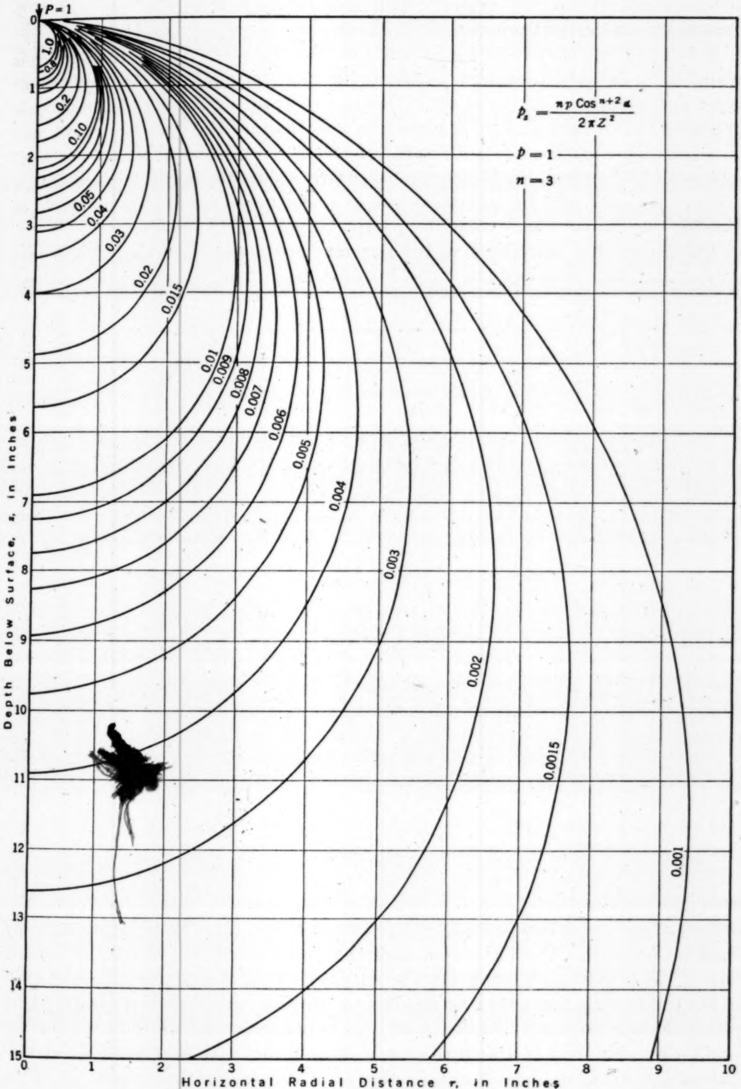

FIG. 21.—ISO-PRESSURE LINES OF VERTICAL COMPONENT OF PRESSURE WITHIN THE SOIL DUE TO A CONCENTRATED UNIT LOAD AT THE SURFACE

be found and the curve drawn. The area between this curve and $M\,T'\,N$ gives the total vertical pressure at Point O.

It is apparent that if an iso-pressure chart for a unit load at the surface is available, it is only necessary to draw the transformed area on transparent paper and place it over the chart at the desired position, using the same scale for depth that was used in the plan. In this manner the pressure curve may be readily constructed at any depth, once the "transformed area" has been obtained. If several iso-pressure charts are available, each representing a different value of n in Equation (8), the engineer may exercise his judgment in choosing the proper chart to fit the particular soil conditions.

Still more time may be saved if the data are presented in tabulated form without actually drawing the "transformed area" and the "pressure curve."

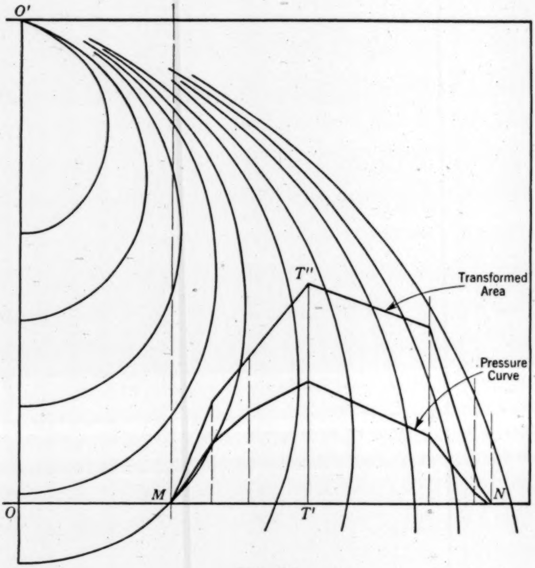

FIG. 22

In fact, even the circles used by the author to establish points on the "transformed area" need not actually be drawn if a transparent polar co-ordinate chart is at hand. With the center of the polar chart placed on the footing plan at the point below which the pressure is desired, the concentric circles will divide the footing areas into zones, and the number of degrees of arc swept by each zone may be read from the chart. It is not even necessary to redraw the foundation plan, if it is drawn to scale. Blue-prints may be used if the actual scale of the drawing is determined—that is, if the scale of the original drawing is corrected for shrinkage.

The author's example supported by Fig. 6 has been used as an illustration of the work involved when the graphical constructions are entirely eliminated.

The plan shown in Fig. 6 was used without redrawing, the scale being considered at 80 ft per in. Table 3 shows all the calculations for pressure at Point X at depths of 100 ft and 320 ft. The iso-pressure chart used was constructed from Equation (8) with $n = 3$. It is shown in Fig. 21.

TABLE 3.—CALCULATIONS FOR AUTHOR'S EXAMPLE, POINT X

There is an important advantage in being able to use an independent iso-pressure chart, aside from the simplification of calculations. At present, Boussinesq's formula, as modified by the "concentration factor," gives the best available information as to pressure distribution in soils. If the soil is stratified within the pressure range, still further modifications must be made. The iso-pressure chart may be modified to suit the particular conditions of the site, and to take advantage of advancing knowledge of stress distribution, without affecting the foregoing method of analysis in any manner.

D. P. KRYNINE,[47] M. AM. SOC. C. E. (by letter).—The discussion of this paper has brought to the attention of the profession several important ideas and has permitted the elucidation of several obscure facts in a more or less adequate manner.

Difference Between the Boussinesq and Fröhlich Stress Distribution.—The writer always has been of the opinion that there is no strain at a certain distance from the loaded area; and this opinion, although contrary to that held by most engineers is in accordance with that of Boussinesq who states:[48]

> "* * * besides it is evident that the sections of the body located at infinity, or rather beyond a certain distance from the loaded portion [contact area] keep their shape and their dimensions."

Thus, what conventionally is meant by "infinity" may be a rather short distance, according to the properties of the soil and the value of the load. Obviously, this statement should be checked experimentally. Furthermore, Boussinesq visualizes the semi-infinite body as a hemisphere of a radius, r, tending toward infinity;[49] but he states categorically that his analysis does not apply to the total loading of the horizontal plane bounding this body from above,[50] since in this case the settlement is infinite. To make this fact clearer, it should be remembered that according to a general belief the settlement of a loaded rigid or non-rigid circular disk, as measured at its center, is proportional to its diameter. Admittedly, the body upon which the disk is placed is assumed to be elastically isotropic. If the diameter of this disk becomes infinite, the settlement likewise will be infinite. Such a situation is not covered by the Boussinesq analysis as stated by Boussinesq himself; and this leads to an opinion that there should be a certain limit of loaded area to which this analysis (particularly the method of superposition) may be applied. Furthermore, according to one of the basic requirements of the theory of elasticity, strains under consideration must be small. In using the principle of superposition in the case of larger areas, this fundamental condition is not satisfied. In other words, application of the principle of superposition to larger areas does not seem to be justified; and, as far as earth masses are concerned, this statement may be proved by experience.

If a part of the horizontal surface of an earth mass is loaded, earth under a rigid structure is "disturbed," except when the unit load is very small. Experiments and some field observations prove this statement.

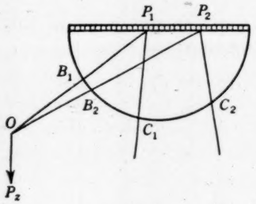

FIG. 23

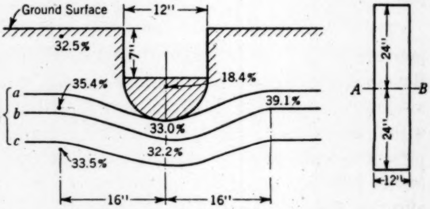

FIG. 24.—LOADING EXPERIMENT AT EAST HARTFORD, CONN. PERCENTAGES SHOW MOISTURE CONTENT AFTER EXPERIMENT

When the Boussinesq formula is applied (see Fig. 23), it is assumed that the "disturbed zone" has no influence on the value of the stresses at Points B_1 and B_2 and that pressures at Point O may be added by superposition. This procedure is not quite accurate. Dr. Fröhlich attempted to increase or to concentrate all the stresses that radiate rather vertically (as at Points C_1 and C_2) and to decrease those that radiate rather horizontally (see Fig. 23). Pressures at Point O are added by superposition.

Beyond question, the Boussinesq formula is the only scientific tool to use for computing stress distribution within a mass. Other formulas proposed are simply practical corrections of the Boussinesq formula which, however, does not fit small-scale loading experiments on sands. The Fröhlich-Griffith formula fits the latter experiments, but there are objections against its application to larger areas. These objections, as revealed in the discussion, are examined subsequently.

Formation of a "Disturbed Zone."—The "disturbed zone" possesses physical properties that are different from the earth mass. It is a kind of pedestal for the structure and moves down with it during the entire settlement period. Professor Hennes states that the "disturbed zone" needs more investigation. The writer welcomes this statement and believes, in addition, that this study should follow a certain order, beginning, for instance, with the observations of pressure at the base of full-sized structures as formulated in one of the writer's conclusions. It is generally assumed that the basic cause of the formation of the "disturbed zone," in dry cohesionless sands, is the lateral escape of particles. The edges thus become unloaded and the central part stressed. This is the opinion expressed by Professor Tschebotareff in his able discussion. Sometimes it is believed that in certain cases there is no "disturbed zone" at all. For instance, Mr. Hrennikoff thinks that such is the case when the foundation bed is situated between the levels of capillary and gravitational water; and, generally, that the formation of the "disturbed zone" is due to mutual sliding of particles.

To these two causes of the formation of a "disturbed zone" (lateral escape and mutual sliding) the writer wishes to add "packing in" of the particles if there is a more or less considerable settlement and if the structure is wide. It is obvious that if a foundation is 200 ft wide, particles at the center will not travel 100 ft in either direction to escape at the edges. They will stay where they are and will tend to penetrate downward, forming the "disturbed zone." The phenomenon of "packing in" may be observed even in the case of small loaded areas as may be seen from the following field experiments made by the writer.

A wooden platform, 4 ft by 1 ft in size, was loaded uniformly with 12 tons of pig iron that remained on the platform for more than two weeks. The experiment was made in East Hartford, Conn., the soil being fine, cohesive, silty sand.[51] An excavation through the middle of the loaded area, where the stress distribution could be considered plane, revealed a clear-cut, semi-circular "disturbed zone" (Fig. 24). Thin natural sand layers of a color different from the remainder of the mass were bent (but not broken) by the action of the load, and from their shape it could be concluded that the "disturbed zone" was formed by the packing in of soil particles from beneath the loaded platform. There was also some bulging around the load. Another experiment in Stratford, Conn.,[52] was made at the bottom of a rectangular excavation, 13 ft deep, the soil being fine sand with the water-table 1 ft below the bottom of the excavation. Two posts, *A* and *B* (Fig. 25), 1 sq ft in cross-section, were loaded to 5 tons each, and the settlement of the posts and of the adjacent area was observed. Post *A* was simply placed on a sand surface, whereas previous to placing Post *B*, the corresponding 1 sq ft area was enclosed in a coffer-dam of 1½-in. boards driven 3 ft deep. The earth from this coffer-dam was not excavated. There was bulging arount Post *A*, whereas the entire area surrounding Post *B* simply settled. Since in the latter case there was no bulging, and no possibility of the particles escaping laterally, it was concluded that the entire volume of soil corresponding to the settlement sank until it was packed both into the coffer-dam and into the "disturbed zone" in the same manner as in the East Hartford experiment.

[51] *Engineering News-Record*, Vol. 109 (1932), p. 782.

[52] Annual Rept., Connecticut Soc. of Civ. Engrs., 1934, pp. 70–81.

The writer believes, furthermore, that in the case of a wide structure the "disturbed zone" is not geometrically similar to that under a smaller model. Other opinions as to the formation of a "disturbed zone" below a rigid loading plate, are: (*a*) Fröhlich's "plastic" zone [53] with an elastic nucleus inside (Fig. 26) which, in the belief of the writer, may occur as an exception only when there is no settlement and the loading plate itself is non-rigid; (*b*) Terzaghi' rough mechanical model of the "disturbed zone," [54] composed of sand grains glued with asphalt, the bonds between asphalt and sand being broken as the increasing load reaches a certain limit (Fig. 27(*a*)); (*c*) A. Nádai's disturbed zone [55] in a metallic plate which is formed when a rigid metallic punch is applied to the plate and is revealed upon heating and re-crystallization (Fig. 27(*b*)). A "disturbed zone" under a rigid tool, working in metal, has been reported on several occasions. It follows that the main cause of the formation of a "disturbed zone" is not the lateral escape of particles (which is merely a possibility), but rather "packing in" as mentioned previously.

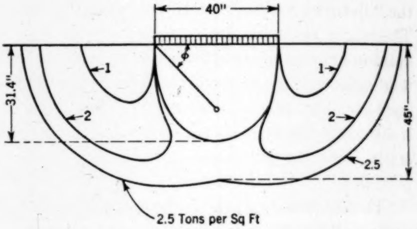

FIG. 26.—GRADUAL FORMATION OF A DISTURBED ZONE AFTER FRÖHLICH

Concentration Factor.—This item appears in almost every discussion. It is mentioned by Dr. Fröhlich, who is the original author of this theory. Mr. Taylor rightly states that the free use of the "concentration factor" is permitted only when the extent to which it is applicable is held clearly in mind. The writer wishes that such sound judgment might also be the guiding principle in applying the Boussinesq formula. "Under the footing," states Mr. Taylor, "progressing from the edge to the center, this factor will decrease from point to point and also it will decrease with increasing depth. Thus, the concentration factor at different points for the given case may vary as much as from 8 to 4 * * *." Mr. Feld indicates that the broad application of Equations (1) and (6) containing the "concentration factor" is possibly open to criticism.

[53] "Druckverteilung im Baugrunde," p. 76 (1934).

[54] "Theorie der Setzungen von Tonschichten," von Charles Terzaghi, M. Am. Soc. C. E., and O. K. Fröhlich, p. 13, Fig. 8 (1936).

[55] "Plasticity," by A. Nádai, p. 249, Fig. 312 (1931).

Professor Tschebotareff discusses the matter in a very comprehensive manner and comes to the conclusion that a "concentration factor" changes in value with the distance from the center to the foundation toward its edges. At a certain depth of foundation beneath the soil surface the resistance to the lateral yielding would become so great that a sand would behave like a solid material with a "concentration factor," $n = 3$. Mr. Hrennikoff states: "It seems improbable that the same value of n should properly describe the state of stress both near the foundation where the soil is disturbed and outside the zone of disturbance." Professor Hennes expresses an analogous opinion stating that it is difficult to understand how the "concentration factor" can be made to cover the situation which arises in the "disturbed zone."

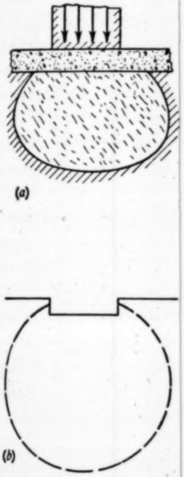

FIG. 27.—DISTURBED ZONE: (a) TERZAGHI; (b) NÁDAI

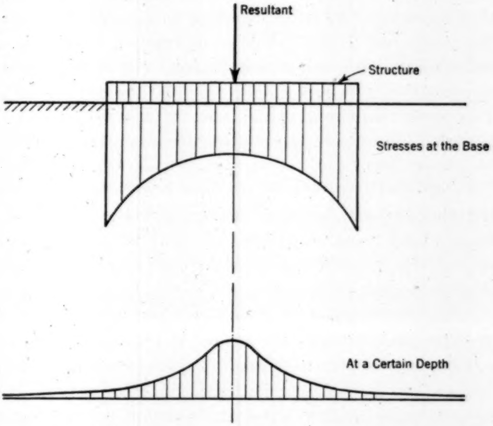

FIG. 28.—APPLICATION OF SAINT VENANT'S PRINCIPLE TO THE COMPUTATION OF STRESSES IN AN EARTH MASS

The writer wishes to make it clear that he never intended to suggest that stresses within the "disturbed zone" could be computed using Fröhlich's formulas. It is impossible to do so since these formulas have been designed for homogeneous and isotropic bodies as carefully specified in the paper, and the "disturbed zone" represents nothing but a foreign body within a relatively homogeneous and isotropic mass. As a rule, stresses never are computed close to sections where forces are applied. In textbooks on elasticity, points of application of forces are generally circled to show that at that section there is a zone that does not obey the formulas developed. In an analogous manner the progress report of the Committee of the Society on Earths and Foundations, leaves a blank space close to the ground surface when tracing a pattern of isobars.[56]

---

[56] *Proceedings*, Am. Soc. C. E., May, 1933, pp. 782–783.

As to the value of the "concentration factor" which changes from 8 at the edge of a foundation to 4 at its center, the writer would be very willing to examine this statement if he knew precisely what the center of a foundation is. To clarify this idea, consider Point X in Fig. 6. It practically coincides with the centroid of the plan of the structure; and the vertical pressure under this point, if computed according to the Boussinesq formula, is greater than under any other point of the structure. Hence, Point X is the center of the foundation shown in Fig. 6; on the other hand, it is located at the very edge. Is the "concentration factor" at that point a maximum or a minimum?

Undoubtedly, there is an "edge action" or "edge disturbance" along the perimeter of a round foundation; and this is shown by curves in Fig. 11(*b*) and 11(*d*). Owing to the phenomenon of "packing in," it is also very probable that there is stress concentration at the middle of such a foundation and Fig. 10 was prepared to show this phenomenon. It may be seen therefrom that the value of the "concentration factor" at the middle of a round experimental plate was more than 6 and not 4. Fig. 10 shows also that the "concentration factor" decreases with the depth. The writer was the first to establish this fact.[57] His general opinion concerning the "concentration factor" was published in 1936, as follows:[58] "The physical nature of this new conception is not very clear as yet; and perhaps this is simply a temporary tool which will be put aside when the theory has advanced in this province." In this paper the writer recommends field research as the only way to solve this problem. Apparently, mere speculation or mathematical formulas are of no help in clarifying the bases of such a theory.

In designing the "reduced area method" the writer carefully avoided recommending any numerical value of the "concentration factor," leaving its determination to the eventual field research as stipulated in the "Conclusions." The two values of the "concentration factor" given at the beginning of the paper have been secured in small-scale experiments and cannot be used in practice.

If field research shows that variable values of the "concentration factor" should be used in computations (and this is not certain as yet) the "reduced area method" will still hold. Mr. Feld rightly remarks that the graphical method described must be repeated for each point at which the knowledge of the stress is desired. It is equally easy to apply the method in question to different points either using the same value of the "concentration factor" or changing it from point to point. In any event, a single value of the "concentration factor" will suffice for smaller areas; and it should be noted that curves in Fig. 9, to which Mr. Taylor objects, have been traced for this case.

Summary.—It is premature to argue about the law that governs the distribution of the "concentration factor" around the base of a structure before the corresponding field research is done. Even the incomplete field evidence at the disposal of the writer does not agree in any respect with the speculations advanced by most of the discussers.

Test of Fröhlich's Formulas by Saint Venant's Principle.—Stresses and strains may be distributed arbitrarily within the disturbed zone without influencing the general trend of stress distribution in deeper strata which always shows overloading close to the center, if the foundation is uniformly loaded and round or rectangular in shape. Actually, according to Saint Venant's principle, stresses at a point remote from the loaded part at the surface of a body are practically the same as if that part were replaced by a statically equivalent system. Therefore, in all cases of loading, the pressure distribution curve tends to have its major ordinate close to the direction of the resultant of forces acting at the given loaded area although stresses at the base of the structure or close to it may be thrown toward the edges (see Fig. 28). Upon application of the principle of superposition to a uniformly loaded circular disk both the Boussinesq and Fröhlich formulas give satisfactory results; namely, in both cases stresses are concentrated under the center of the disk as they should be according to Saint Venant's principle. This means that in both cases the principle of superposition holds, at least approximately.

[57] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1089.

[58] *Proceedings*, International Conference on Soil Mechanics, Vol. 3, p. 74 (Paper E–15).

Principle of Superposition.—It has been already shown that, apparently, the principle of superposition always involves an approximation, and the discussion which follows is a proof of this statement. Generally, the problem of superposition as applied to soils is not new. Its origin may be traced to the work of Bastian,[59] about 1906. Kögler and Scheidig [60] discussed the problem of superposition in soils and came to the conclusion that it applies approximately. In numerous "loading experiments" made in the past fifty years, the principle of superposition was used freely. The test procedure was to: (1) Measure the pressures caused by the unloaded earth (mostly sand) at the bottom of the experimental box (Reading *A*); (2) measure the pressures caused by both the earth and the load (Reading *B*); and (3) subtract Reading *A* from Reading *B* to obtain the pressure caused by the load alone. It is obvious that this subtraction is the application of the principle of superposition in an implicit form. An exception to this procedure is noted in the experiments by Faber which have been introduced in the discussion by Professor Tschebotareff. However, the results of Faber's tests check with others, quantitatively at least. Model experiments show that small disks settle practically proportionally to the square root of their areas; or (which is the same), proportionally to their diameters. This rule cannot be applied, however, in comparing contact settlements obtained in small loading tests with those observed under actual structures. A large structure settles less than it should according to that rule; and, in the writer's opinion, application of the principle of superposition to any earth mass furnishes stress excess at some points of the foundation. The writer greatly appreciates the able discussion of the principle of superposition by Mr. Hrennikoff. Especially fascinating is his statement that the principle of superposition does not hold in the case of earth disturbance, because the boundary of the disturbed zone is not the same for the three loads: Loading 1, Loading 2, and Loading 1 + Loading 2. This very potent argument, which appears to contradict Fröhlich's theory of "concentration factor," in reality proves that the principle of superposition never holds, except perhaps for very light loadings. This is because the disturbed zone is being formed in all cases of heavy loadings, including the case of metals (see Fig. 24 and Fig. 27(*b*)).

---

[59] "Organ für die Fortschritte des Eisenbahnwesens," 1906.

[60] "Die Bautechnik," 1927–1929.

The mistake made by Fröhlich and all others (including the writer) who have written about the "concentration factor" was the lack of a clear-cut statement that the use of the principle of superposition in this case (as in others, incidentally), is an approximation.

Principal Stresses: Coulomb Formula.—At a greater depth, soil particles are compressed by the action of principal stresses; no shear failure is possible there except small movements and changes in the shape of individual grains. Hence, Mr. Middlebrooks' question, as to whether the major principal stress or the vertical pressure is to be taken into consideration in computing consolidation, is to be answered in favor of the action of the major principal stress; and these stresses are to be computed at all points where their action may produce a more or less considerable effect. A doubt as to why vertical pressures are used instead of principal stresses in computing settlements, is expressed also by Mr. Hrennikoff. In this connection the writer wishes to state that principal stresses are to be computed from the combined action of the weight of the earth mass and the given load; and this furnishes lines of major principal stresses which at greater depths possess almost vertical tangents so that the actual error in replacing the major principal stress with the vertical pressure may be insignificant in many cases. The action of the minor principal stress is thus disregarded.

Some explanations as to Equation (35) should be included under this caption. This formula states the "condition of plasticity" of a granular mass expressing the least ratio of principal stress as a function of the angle of friction. Without arguing about the angle of friction (which, after all, is indefinable), suppose that ϕ is the correct value of the angle of friction at a given point located at a great depth and that Equation (35) is not satisfied. Then, according to Mr. Hrennikoff, a very small sliding should occur; but this sliding would not modify the principal stresses, s_1 and s_2, at the given point since they depend only on the value of the given load and its position. Hence, the situation still remains the same, and the sliding should continue indefinitely. What happens in reality is not so much the mutual slip of particles, as the change in shape of individual grains due to the shearing stress developed in each of them considered as a separate body. As to the Coulomb formula (Equation (34)), it is valid beyond question, at a given point, but only under given circumstances, since the actual value of c is also variable. Both coefficients, f and c, have been introduced to represent, in a more or less tangible form, some elaborate phenomena; and it is inadvisable to interpret them too literally and to base categoric statements on formulas containing these values.

Discussion of Fig. 17.—Mr. Taylor is to be commended for preparing Fig. 17 which conveys a number of useful ideas. At the top, Fig. 17(*a*) shows that there is no continuity of strains at the upper layers of a sand mass loaded with a non-rigid load. The break at the edges of the loaded area indicates that this is not yet a body in the sense used in mechanics, but merely an agglomeration of particles. The upward movement shown in the sketch is simply a dynamic process, or movement of particles which have not been deprived of all degrees of freedom as in a body. Hence, such terms as "modulus of elasticity" or "modulus of deformation" cannot be applied to the upper strata of a sand mass such as that shown in Fig. 17(*a*). This mass becomes a body only at a certain depth. The stress distribution at the bottom of Fig. 17(*a*) is that which the writer obtained by using Saint Venant's principle. The most ardent defender of the validity of the principle of superposition in sands would not be able to prepare a more convincing sketch than Fig. 17(*a*). The remainder of Fig. 17 contains still more useful information as to settlement in deeper strata. Stresses in a rigid structure are always influenced by this settlement, whether or not it is even. Investigators in soil mechanics must correct their views on the given subject to accord with this valuable statement by Mr. Taylor.

Small Strains; Stress-Strain Compatibility.—Admittedly, the theory of the semi-infinite elastically isotropic body is based on the assumption that strains are very small, as already stated at the beginning of this discussion. In turn, stresses may be very great and even infinite, as at the edges of an absolutely rigid plate (Equation (16)), provided, however, that the corresponding strains are kept below a reasonable limit and are continuous. Apparently, the latter conditions are not satisfied in some papers on soil mechanics [26, 27] mentioned by Dr. Fröhlich.

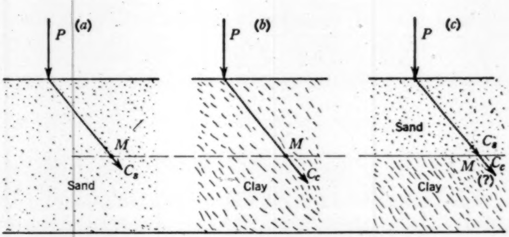

FIG. 29.—STRESS-STRAIN COMPATIBILITY

An example of the lack of stress-strain compatibility is given in Fig. 29 which, for the sake of simplicity, is treated as a plane problem. The plane stress distribution does not depend on the elastic constants of the material; hence, the stress at Point M is the same whether the earth mass is of sand or of clay (Fig. 29(*a*) and Fig. 29(*b*)). The situation is quite different if Point M is in a plane that separates sand and clay (Fig. 29(*c*)). Since the elastic constants of these two materials are different, there should be two different displacements, C_s and C_c, at Point M. Since in reality there is only one displacement, this means that there should be some stress re-arrangement at the plane in question. This circumstance may be of special interest to Messrs. Middlebrooks and Buisson who are working on the stress determination at a surface separating two different materials.

Equivalent Load at the Center of Gravity of a Loaded Portion.—Mr. Feld proposes to sub-divide the loaded area and to apply equivalent loads at the center of gravity of each sub-division. Apparently, this method may indicate some excess in pressure if the point where Pressure p_z is determined is not far from the vertical line passing through the center of gravity of the uniformly loaded foundation. Such is the case of the example in Fig. 6, in which the difference in values computed by Mr. Feld and by the writer is about 14% taking the writer's value as 100. If the point where p_z is to be determined, is outside the foundation, Mr. Feld's results may be smaller than those of the writer, although the difference may be practically negligible. For the sake of simplicity, the latter statement will be proved for the case of a uniformly loaded strip of a length, a, situated at the boundary of an elastically isotropic body ($n = 3$, $n_1 = 2$). Assume that the radius vector to the equivalent line load, $\bar{p} = p\,a$ (Fig. 30), makes an angle, α_0, with the vertical. Using Equation (33) by Mr. Feld, substituting $\alpha = \alpha_0$; making p_z equal to the pressure of the strip load; and remembering that $dA = da$:

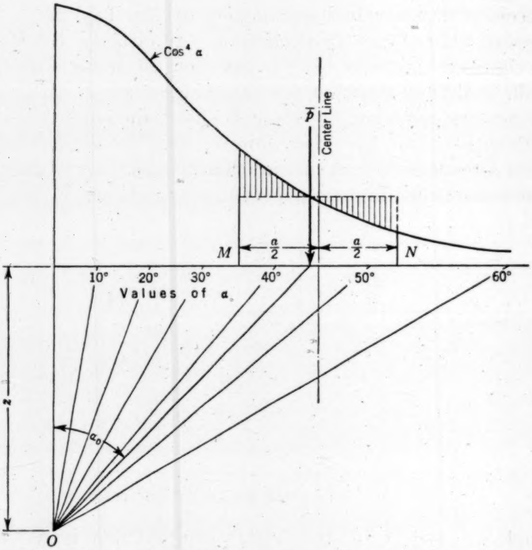

FIG. 30.—COMPARATIVE ACTION OF CONCENTRATED AND DISTRIBUTED LOAD

$$\frac{2\,\bar{p}}{\pi\,z}\cos^4\alpha_0 = \frac{2\,p}{\pi\,z}\,\Sigma\,da\cos^4\alpha \ldots\ldots\ldots\ldots\ldots\ldots (40)$$

Multiplying and dividing the right side of Equation (40) by a:

$$\cos^4\alpha = \frac{1}{a}\,\Sigma\,da\cos^4\alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots (41)$$

The right side of Equation (41) is the average ordinate of the sub-divided area, $\Sigma\,da\cos^4\alpha$, corresponding to the loaded portion, $M\,N$. Equation (41) shows that a line load, $\bar{p} = p\,a$, and the distributed strip load, $p\,a$, produce equal vertical pressures at Point O, if the line load, $\bar{p}$, passes through the centroid of the part of the area, $\Sigma\,da\cos^4\alpha$ (corresponding to the loaded part, $M\,N$) (see Fig. 30). The vertical passing through this centroid may not pass through the middle of the loaded part, $M\,N$, however.

Graphic Integration.—Graphic integration of expressions of the type of $\Sigma\, d\omega\, f(\alpha)$, (in which $d\omega$ is an element of area and $f(\alpha)$, a trigonometric function), is a simple operation if the given area, ω, is sub-divided into circular rings, and if these rings are represented as "transformed areas," in the manner described in this paper. An example is given by Mr. Eremin. Since the angle designated by Kögler and Scheidig as ϕ is assumed to be constant, the right side of Equation (39) must be broken into two integrals:

$$p_z = c\,[\Sigma\, dA \cos^5\alpha - \cot\phi\, \Sigma\, dA \sin\alpha \cos^4\alpha] \dots\dots\dots (42)$$

in which c is a constant to be determined by Equation (39). The integral, $\Sigma\, dA \sin\alpha\cos^4\alpha$, may be obtained graphically from the integral, $\Sigma\, dA \cos^5\alpha$, by multiplying each ordinate of the curve which bounds the area expressing the latter integral, by the variable, $\tan\alpha$; thus:

$$[dA \cos^5\alpha]\tan\alpha = dA \sin\alpha\cos^4\alpha \dots\dots\dots\dots\dots (43)$$

Professor Converse proposes an interesting simplification of the writer's "reduced area method." Instead of drawing the "reduced area," Professor Converse draws a "pressure curve" (which, after all, is the reduced area, all ordinates of which are multiplied with the coefficient, $\frac{p\,n}{2\,\pi\,z^2}$). The possibility of a complete elimination of graphical construction also merits attention. Simplifications of the "reduced area method" are always welcome because this method may be applied not only for determining vertical pressures in an earth mass, but also for solving several other problems of mechanics. Mr. Buisson's remark that the method of graphical integration has been known for years is true, of course; but the principal feature of the writer's method consists not in the application of the graphical integration as such, but in its combination with the transformation of the loaded area, and this considerably simplifies the procedure.

Failure Lines.—The writer has been much interested in Mr. Buisson's studies of "failure lines" which according to his statement are close to the trajectories of maximum shearing stress. In a personal conversation with the writer, Hardy Cross, M. Am. Soc. C. E., expressed the following idea: Since the shearing stress and the shearing value of the earth material are not constant along such a trajectory, equilibrium will be broken first at some part of the theoretical "failure line." Then, this part of the "failure line" will be "out of service," and the body under consideration will therefore be transformed to a different condition of stress. Subsequent failure will be along a line or surface which may well be quite different from the original line. In about 1922 the writer visited a locality in Russia where previously many landslides had occurred, and was shown a mass of land about to slip. There was a crack at the top, and the entire wedge was literally hanging at the remainder of what may be called "shearing surface." It is obvious that the stress condition at this surface was not the same as determined by theory, exactly as Professor Cross states.

Two questions arise in the light of these statements: (*a*) Why are "failure lines," as observed in model experiments, more or less close to the trajectories of maximum shearing stress? and (*b*) do small scale models truly represent "failure lines" in an actual case? These questions will be answered simultaneously.

It should be noticed that "failure lines," "slip lines," or "Lüders' lines," as observed in the case of metals also "have a shape similar to the shearing stress trajectories in the most highly stressed portion under a concentrated load.* * * How nearly exact this is, however, has not yet been investigated."[61] The situation being thus rather obscure, only hypotheses can be advanced. In the writer's opinion a quick application of an excessive load to a small model causes instantaneous failure in the "highly stressed portion," both in metals and in soils, which may be compared to an explosion; and shear occurs along the trajectories of maximum shearing stress, which offer least resistance. Apparently, this model action has no analogy in building practice since cases of quick loading (without impact) are exceedingly rare. Another type of model action as described by Mr. Buisson is slow changes in loading. The earth mass consolidates and flows plastically; and, finally, under a "critical load," fails. In this case particles move plastically along certain trajectories close to those of maximum shearing stress.

What happens in reality is that a building of a constant (and not variable) weight begins to tip and after a certain interval of time (in some cases 24 hr), stops. There is no doubt that this is a shear action consisting of both a separation of a part of the mass from its remainder, and plastic flow. Small models as described in the discussion do not explain such failures; and, obviously, "failure lines" in these cases are not trajectories of plastic flow but rather a succession of shearing surfaces as described by Professor Cross.

Experiments conducted by Mr. Buisson are of great value for students of physical properties of soils. For instance, they show clearly the influence of consolidation on the shearing value, or the fact that a soil at the liquid limit still may possess a shearing value. The method of recording the path of particles by taking successive pictures and superposing them is very interesting. W. S. Housel, Assoc. M. Am. Soc. C. E., applied a similar method recording the movement of particles by a time-exposure photograph.[62]

Other Remarks.—Some of the discussions of this paper are veritable contributions to the field of soil mechanics, and only a few items will be mentioned in addition to those the writer has already discussed. Professor Tschebotareff gives a comprehensive discussion of the influence of some geological factors on the design of structures, and makes valuable additions to the list of research projects cited by the writer. Professor Hennes discusses the necessity of "statistical" approach to questions of settlement. The writer believes that similar methods may be adequate in spreading popular knowledge of soil mechanics after corresponding items have been studied formally.

EARTHQUAKE RESISTANCE OF ELEVATED WATER-TANKS

By ARTHUR C. RUGE,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. N. H. Heck, Mason A. Stone, H. C. Boardman, Franklin P. Ulrich and Dean S. Carder, and Arthur C. Ruge

Synopsis

The problem of building elevated tank structures that are truly earthquake-resistant is considered in detail; and a new type of construction, embodying increased flexibility combined with snubbing action, is suggested as a practical solution. Extensive model studies, directed toward obtaining engineering data for design purposes, are described and the results summarized. The writer concludes that the commonly used statical method of design against earthquakes cannot be applied safely to elevated tank structures, and that the suggested new type of construction has a safety factor in stress of at least 2 over the standard type of tower. Experiments in which reproductions of actual earthquake motions were applied to a model of a 60 000-gal, 100-ft structure show that dangerous stresses are not avoided by designing against a statical horizontal force of one-tenth the weight of the tank and contents. Rules are given for designing structures of the new type suggested, and reasonable limits of applicability are set.

Introduction

Purpose of Paper.—Consideration of the large number of failures and near failures of elevated water-tanks during the earthquake of March 10, 1933, at Long Beach, Calif., has led to serious study of the earthquake resistance of these structures by many engineers. The importance of the problem is already so well known as to require but passing comment. The actual money value of the structures is in itself not so very important; it is in connection with the fire, life, and health hazards generally accompanying earthquakes that the effective value of a water supply system increases out of all proportion to its actual cost.

Note.—Published in May, 1937, *Proceedings*.

[1] Asst. Prof. of Eng. Seismology, Mass. Inst. Tech., Cambridge, Mass.

A very important class of elevated tank structures is that comprising the gravity sprinkler-supply systems for industrial plants and for many other buildings of moderate height. Elevated sprinkler tanks generally vary in capacity from 50 000 gal to 150 000 gal and in height from 75 ft to 150 ft. This paper is largely concerned with structures that vary within these ranges of size, but more specifically with independent tank structures of all-steel construction. Some of the results, however, obviously apply also to structures of reinforced concrete, wood, or mixed construction.

The purpose of this paper is to present the principal results of an extended series of model studies which were directed toward: (1) The determination of the stresses produced in elevated water-tank structures by earthquake motions; (2) the determination of the effect of strengthening the structures by present methods of statical design; and (3) the investigation of a new type of tower design which was developed in the course of the research. That the experiments described herein were restricted to a small part of a very large and important field will be obvious to the reader. Without a comparatively large fund at hand for the work, practical results could be obtained only by narrowing the range of the research.

Nature of the Problem.—At first glance, the design of an earthquake-resistant elevated water-tank seems to be a simple engineering problem. It is not uncommon to find practical engineers reasoning that, since competent engineers can design buildings of six or eight stories to resist moderate earthquakes with considerable confidence, the design of a water-tank tower should present no difficulty, since it is a much simpler structure and of a mass far inferior to that of a building. This kind of reasoning, unfortunately, is the result of a misconception to the effect that a relatively limber, top-heavy structure such as an elevated tank will behave dynamically like a low, rigid building. Indeed, the practical treatment of earthquake-resistant design from the standpoint of dynamics has been, for the most part, of a very superficial nature in the past. The tendency has been to simplify the design methods on the basis of intuition without first attempting a rigorous analysis.

First, it is important to realize that earthquakes manifest themselves as inexorable motions, rather than as forces. The expression, "earthquake force", has become so widely used that many engineers conceive of the problem of quake-proof design as one of simple stress analysis in which the "forces" are determined definitely by the violence of the earthquake alone. The "forces" produced by the earthquake motion depend primarily upon the characteristics of the structure suffering the motion. Various frequencies, or periods, are associated with the inexorable motions of an earthquake, and, although the actual motions may be highly irregular, certain periods may sometimes appear more prominently than others.

If a structure is acted upon by a ground motion which has a period five or six times that of the structure, then it is possible, with reasonable accuracy, to compute the stresses in the structure on the basis of the accelerations of the ground motion. In this case, the forces acting upon the structure are taken as the product of the various masses and the ground acceleration. This simple rule, however, cannot be extended to structures such as elevated water-tanks, which commonly have natural periods within the range of the periods associated with major earthquakes. Here, it is necessary to proceed with extreme caution; nor can one rely upon intuitive reasoning unless it is backed by a thorough grasp of the dynamics of vibrating systems.

The type of tower now in common use was not developed for earthquake resistance, but merely to fulfill the purpose of elevating the water supply on a structure which has to resist a certain intensity of wind force in addition to carrying the vertical load. For this use it is practically ideal; but there is no reason to accept it as the ideal structure for withstanding earthquake motions, which actual experience and repeated laboratory tests have proved it certainly is not.

The dynamic behavior of elevated tanks is not amenable to simple mathematical analysis because of the complications introduced by the action of the water in the tank. The system is analogous to one made up of a gravity pendulum suspended at the top of an elastic vertical frame work (see Fig. 1), except that the water action in the tank is more complex than that of the pendulum. It will be seen subsequently from the experimental results that the water motion exerts a cushioning effect upon the deflections in a tank tower of moderate size.

(a) ELEVATION (b) DETAIL OF ROOF CONNECTION (c) FOUNDATION LAYOUT

FIG. 2.—STRUCTURAL DESIGN OF PROTOTYPE TESTS IN PART I

It is to be noticed in Fig. 1 that a compound pendulum (not a simple pendulum) represents the water and the tank. This feature corresponds to the restraining action of the tank walls upon the water mass which forces part of the water to move with the tank as it vibrates. A simple pendulum would correspond approximately to a shallow, saucer-shaped tank of water, in which there is little restraint on the lateral motion of the contents.

The problem of determining the earthquake resistance of elevated water-tanks can be solved mathematically in a qualitative way only, not because the mathematical process is unknown, but because of the tremendous work involved in obtaining results of practical value to engineers. Those who have attempted to calculate the effects of irregular transient disturbances on vibrating systems will recognize at once the advantages of the experimental approach to the earthquake problem. The model method, to be sure, is not the only practical way to avoid mathematical difficulties, but, at present, it appears to be the most convenient one. The greatest advantage of the model method lies in its directness, with the attendant simplicity in interpretation of results.

It will be seen that a system is involved which is dynamically complex in itself; it is subjected to ground motions of a transient and complex nature. The problem is to obtain information which has engineering significance in the sense of being truly quantitative rather than merely numerically precise. That there can be a tremendous difference between precision and true quantitativeness is a fact easily overlooked in research. Thus, the results obtained in the simple harmonic motion studies described herein can be regarded as reasonably precise, but from the engineering standpoint their quantitative aspect is rather poor, because they do not directly represent the conditions set up by actual earthquakes. On the other hand, the results of the recorded earthquake-motion tests, although probably less precise, are certainly far more quantitative from the engineering standpoint.

Scope of the Research.—The experimental investigation was divided into two main parts: (1) Tests of a 1:46.5 scale model, using simple harmonic motion to simulate earthquake motion; and (2) tests of a 1:25 scale model, using the horizontal ground-motion components recorded during the Long Beach earthquake of March 10, 1933. In each part, the same model was made to represent both the standard type of construction and the new type described in this paper.

Each of the two parts is so distinctly different in technique from the other that each will be treated separately in this paper for the sake of clarity.

The scope of the research was limited to one particular class of tanks and to one particular recorded earthquake motion in addition to the simple harmonic motion studies. The first restriction was necessitated by considerations of economy; the second by the fact that only one complete record of a violent earthquake existed at the time the research was conducted. It will be evident, however, that the results are not so narrowly restricted in application as might at first appear to be the case.

PART I.—EXPERIMENTS IN SIMPLE HARMONIC MOTION

STANDARD DESIGN; MODEL SCALE, 1:46.5

Considerations Relative to Building and Testing the Model.—A standard 60 000-gal hemi-spherical bottom tank on a 100-ft tower was chosen as the first object of study. It was situated about 33 miles from the epicenter of the Long Beach earthquake (March 10, 1933), and about $6\frac{1}{2}$ miles from the point where the earthquake motion used in this research was recorded. Several bracing rods in the top panel were permanently stretched and one rod was broken during the earthquake. The general design of this structure is shown in Fig. 2. The results obtained therefrom, although probably typical of a fairly wide variety of elevated tanks, cannot be applied indiscriminately to other designs. However, they do point to certain general important conclusions as to the inadequacy of present design methods.

The behavior of a water-tank supported on a steel tower is controlled by two kinds of physical forces: (1) Gravity (or weight) forces, which affect the motion of the water within the tank; and (2) elastic forces produced by the tower, which affect the motion of the tank as a whole. These two kinds of forces interact in a complex manner when the tower is subjected to vibratory motions. Therefore, in constructing a model of such a system, it is necessary to maintain the same relation between these two physical forces in the model as exists in the prototype if true similarity is to be attained; that is, gravity forces and elastic forces must be scaled down in the same proportion. This condition precludes the possibility of using a simple geometrically scaled model. It becomes necessary to adopt a common artifice of model technique—scale distortion—to preserve similarity. This may be accomplished by using different scales for the tower and the tank; but there is a simpler and more practical solution.

As far as the interaction between the tower and the tank is concerned, it is easily seen that the tower could be replaced by any other elastic system capable of producing the same horizontal deflection per unit horizontal force applied at the tank, without affecting the behavior of the tank during an earthquake. In other words, the tower merely provides an elastic restoring force proportional to the deflections of the tank, tending to restore it to its position of statical equilibrium. In building a model, it is advantageous to make use of this fact in order to avoid a costly tower model which might prove to be of doubtful accuracy. Accordingly, it was decided to support the model tank on two flat steel bars acting as simple vertical cantilevers, the length of the bars being made adjustable in the laboratory to permit an accurate setting of the stiffness. A symmetrical four-post tower, being equally stiff in all directions, can be simulated in the model by making the supporting bars of the proper stiffness in one direction only and then testing the model in that direction. In this manner the model "tower" can be made strong enough to hold the tank weight safely, and at the same time flexible enough to permit very large deflections without danger of failure.

It is not intended, of course, to determine the ultimate—or failing—strength of the prototype, because the engineer is interested primarily in building structures so that they will not be stressed above the elastic limit. The results of a model study of this kind, therefore, must be interpreted as valid for the prototype to the point where its elastic limit is reached. It is neither practical nor very useful to attempt to duplicate the ultimate strength conditions in a model, because the range of experimentation would thus be greatly curtailed indeed unless one were willing to build a great many models, each of which would have to be discarded as soon as its elastic limit was exceeded.

The point next in importance to be considered is the choice of scale for the model. There is no simple rule for the determination of what constitutes the ideal scale. The upper limit of model size is fixed largely by considerations of laboratory convenience, expense, and capacity of the available testing equipment. In the lower limit the choice of scale is restricted by the difficulties in recording the minute motions accurately and also in controlling the testing conditions. Other difficulties with very small scale models are brought about by the effect of surface tension and viscosity in the liquid which tends to destroy the similarity, and by the attendant speeding up of the model motions which renders accurate recording and timing more difficult. Traffic vibrations also are likely to become troublesome when very small scales are used.

After considerable study it appeared that a scale of about 1 to 50 would be satisfactory. This proved to be the case. The model of the tank itself was made of No. 26 gage, sheet aluminum, the bottom and roof being spun and the joints rolled together. The resulting tank model gave the proper ratio between weight of shell and weight of water, which is a necessary condition for similarity.

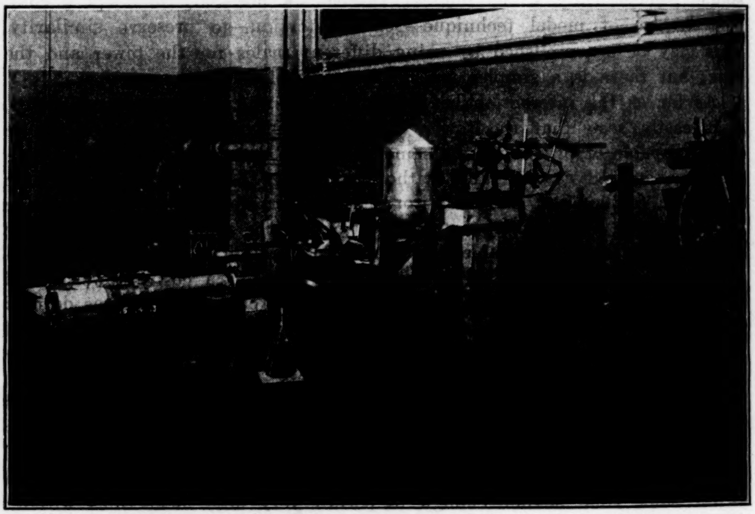

FIG. 3.—MODEL ON FIXED TABLE, SHOWING ARRANGEMENTS FOR ADJUSTING STIFFNESS AND MAKING FREE VIBRATION TESTS

The complete model mounted on a stationary table for stiffness adjustment and free vibration tests is shown in Fig. 3. It will be seen that the legs are clamped at the base so that the stiffness of the model tower is easily adjusted to the desired value. The method of determining the stiffness is also shown in Fig. 3. A known force is applied horizontally at the center of gravity of the tank by means of a weight-and-pulley arrangement, the resulting deflection of the tank being measured by a micrometer microscope reading on a fine scratch on an index attached to the tank.

The tank was attached to the tower legs by means of spring hinges soldered to the top of the legs and to the bracket on the tank. Each hinge consisted of a strip of spring steel, 0.003 in. thick, having an unsupported length of about 0.01 in. This type of hinge is practically frictionless and, at the same time, remarkably rugged. It exhibited no deterioration during the entire set of tests. The tank bracket was riveted to the shell.

It should be remarked that in determining the stiffness of the model tower it is necessary to have the proper quantity of water, or equivalent weight, in the model tank, because the vertical load on the legs has an effect upon their stiffness which needs to be considered. The following relations between model and prototype are easily deduced from model theory[2]: If the length scale $= \lambda$, the time scale $= \sqrt{\lambda}$, and the stiffness scale for the tower $= \lambda^2$. For the actual model the length scale, λ, was 46.5. This gives a time scale of 6.82; that is, a duration of 1 sec in the model corresponds to 6.82 sec in the prototype. The following list of weights, in pounds, shows the relations between the laboratory model and the full-sized tank:

	Weight, in pounds
Weight of water in prototype tank (3 in. from top)	503 000
Weight of empty tank, balcony, etc.	31 000
Equivalent tower weight concentrated at center of gravity of tank	11 000
Total concentrated weight at center of gravity of tank	545 000
Weight of water in model tank	5.00
Weight of empty tank	0.24
Equivalent tower weight constructed at center of gravity of tank	0.11
Attachments	0.04
Total concentrated weight at center of gravity of tank. (The model weight corresponds with the prototype weight; thus: $5.39 \times (46.5)^3 = 543\ 000$ lb)	5.39
Stiffness of prototype tower (calculated), in pounds per inch of deflection at center of gravity of tank.	16 000
Stiffness of model tower (as adjusted in laboratory), in pounds per inch of deflection at center of gravity of tank; and $7.37 \times (46.5)^2 = 15\ 940$ lb per in.	7.37

---

[2] *Civil Engineering*, August, 1935, pp. 457–458.

The stiffness of the prototype tower was computed by applying a horizontal force of 1 000 lb at the center of gravity of the tank to one bent of the tower and calculating the resulting deflection of the tank (0.125 in.). The corresponding angular tilt of the tank was also computed and was found to be only 8 sec under this load; consequently, it is obvious that the rotation need not be considered in building the model, which further simplifies the laboratory work by permitting the use of vertical instead of battered legs.

The foregoing scale factors establish the magnitude and period of the artificial earthquake motion to be applied to the model in order to simulate a given earthquake. For instance, an earthquake in Nature, having a period of 1 sec and an amplitude of 2 in., would be simulated in the model by a motion having a period of $\frac{1}{6.82}$ sec. and an amplitude of $\frac{2}{46.5}$ in.

The shaking-table was loaded with a dead weight of approximately 300 lb, so that the model weight was less than one-fifteenth of the dead weight of the table. This is an important consideration because, if this ratio is not made large, the reactions of the model may seriously affect the table motion. Of course, in the region of resonance this effect is unavoidable, but during the early stages of the motion the effect of the model on the table motion will be quite small, and, after all, it is the early part of the motion that is of greatest interest.

The interpretation of the model results in terms of the full-sized structure is quite simple. The model is so constructed that its deflections are related to those of the prototype according to the length and time scales. Therefore, the deflections that would exist at any instant in the full-sized structure may be determined easily. Having once computed the stresses in the tower, corresponding to a known deflection, the determination of the magnitude of the stresses at any given instant is a matter of simple arithmetic. It is obvious, then, that a record of the motion of the model tank relative to its base is sufficient for the determination of both the stresses and deflections that would be produced in the prototype, as well as the time at which they would occur.

Artificial Earthquake Motion.—In this part of the research an earthquake motion of cosine form was adopted, that being the most convenient to work with in the writer's laboratory. When the table is vibrating by itself, the shaking-table motion is so slightly modified by damping that, over a range of 15 or 20 cycles, the attenuation is quite negligible. When a model is placed upon the table, the record of the table motion appears as a damped cosine wave. This is due to the absorption of part of the energy of the table by the model.

The range of periods chosen for these tests covers the generally discussed band of earthquake frequencies, although there is considerable yet to be learned about the upper and lower limits of earthquake periods. Apparently, the commonly accepted "destructive periods" of approximately 0.75 sec to 1.5 sec, are based largely on the destruction to buildings, the natural periods of which often fall close to that range. It is not to be assumed, however, that severe ground motions of much longer periods do not exist during severe earthquakes; and it is certain that there are much shorter periods present.

Notation.—The symbols used throughout this paper are defined where they first appear. An effort has been made to conform as nearly as practicable with "Symbols for Mechanics, Structural Engineering, and Testing Materials",[3] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

Functions of the "Dummy Tank".—It was considered to be of interest to compare the behavior of the actual water-tank with that of an equivalent solid mass in order to determine the effect of the water on the motions. Consequently, a small inverted pendulum was constructed and its period adjusted to the proper value. This pendulum is referred to as the "dummy tank" because it behaves in exactly the same manner as the actual tank if the water was replaced by a solid dummy mass of equal weight. In other words, the motions of the dummy tank represent the effects of earthquakes upon a water-tank which is frozen solid.

The dummy tank was made to serve another important purpose at the same time, namely, that of controlling the accuracy of the laboratory work. The calculation of the theoretical motion of the dummy pendulum being a relatively simple matter, it is possible to check the correctness of the work at any time. Since the dummy pendulum and the actual tank were always tested simultaneously, it is safe to assume that if the theoretical dummy motion checks the recorded motion satisfactorily, the motions of the actual tank must also be correct.

The proper natural period, P, for the dummy pendulum is found as follows:

$$P = 2\pi \sqrt{\frac{W}{g\ k}} \qquad \text{.......................} \quad (1)$$

in which W = weight of tank plus contents (assumed to be solid); g = acceleration due to gravity; and k = spring factor of tower (restoring force per unit deflection). From the foregoing lists of weights and scale relations: $P = 2\pi \sqrt{\frac{545\,000}{32.2 \times 12 \times 16\,000}} = 1.863$ sec for the prototype. Then, since the time scale is $\sqrt{\lambda} = 6.82$, $P_m = 1.863 \div 6.82 = 0.273$ sec for the model. The correctness of the model-scale relations is easily verified by calculating P_m, using the actual model constants; thus: $P_m = 2\pi \sqrt{\frac{5.39}{32.2 \times 12 \times 7.37}}$ $= 0.273$ sec. (The dummy pendulum was adjusted by trial to a period of 0.271 sec, within 1% of the theoretical.)

It is easily proved that the dynamic response of a pendulum of this type is dependent only upon its natural period, and independent of its physical dimensions. Therefore, it was not necessary to make the mass and spring factor of the dummy identical with those of the tank model. The dummy pendulum was made by attaching a small mass (about 0.5 lb) at the top of a vertical flat steel bar. This type of small pendulum was adopted in order to reduce the total effect of the models upon the table motion to a minimum.

---

[3] A S A—*Z10a*—1932.

Laboratory Procedure.—The laboratory work was divided into two main parts—free vibration tests and shaking-table tests. In the free vibration tests, the model was mounted on a rigid stationary table and the tests were made by suddenly releasing the model from a pulled-back position. The resulting motions of the tank were recorded photographically. Fig. 3 shows the general arrangement used for recording the free vibrations. The pull-back and release were accomplished by means of standard link fuses. One end of the fuse was clamped to a small bracket (see at the top of the left tower leg); the other end was clamped to a bracket attached to the table, the latter bracket being arranged with screw adjustment to permit varying the amount of pull-back at will. The shield over the fuse kept the light of the flash from striking the recording paper. A 110-volt circuit, shorted across the fuse, gave a very fast release.

At the right of the tank is a swiveled mirror and lens arranged to trace the model motions on the recording drum, the source of light being just above the front of the drum (extreme right of Fig. 3). Immediately to the right of the recording mirror is another lens for recording the time intervals which are marked by the passage of a periodic electric spark. The spark-gap is shielded, but the terminals where the leads connect may be seen in Fig. 3.

The shaking-table motions were produced in a manner similar to that of the free vibrations, except that it was necessary to use a short length of resistance wire, instead of a link fuse, in order to deflect the stiff springs of the table. A special form of wire link was developed for this purpose, which proved to disintegrate very rapidly under a 110-volt current with no detectable effect upon the table motion. This was accomplished by reducing the length of the wire to be burned to about $\frac{1}{8}$ in.

The set-up for the shaking-table test has been amply described elsewhere[4]. The table itself was suspended entirely by piano wires and actuated by springs. Lateral guy wires leading to the floor prevented any tendency of the table to twist due to unbalanced forces.

Three mirror-and-lens systems, which received light from three illuminated slits beneath the recording drum, were arranged so that one recorded the motions of the shaking-table relative to the floor, while the second recorded the motions of the tank relative to the shaking-table (the deflections); and the third recorded the deflections of the dummy pendulum relative to the table. A fourth lens system recorded the time marks. The records were made on bromide paper.

Fig. 4 represents a part of a typical record. The axes of the three motions were separated purposely for the sake of ease in reading the records.

---

[4] *Civil Engineering*, August, 1935, p. 458, Fig. 7.

Just before releasing the table, the drum was revolved once with the lights on, and the timer off, to provide base lines for measuring the deflections. The entire record (39 in. long) being made in about 5 sec, it was necessary to time the recording procedure carefully to prevent awkward overlapping. The switchboard which controlled the table release, lights, timer, and recording drum, is seen in Fig. 3.

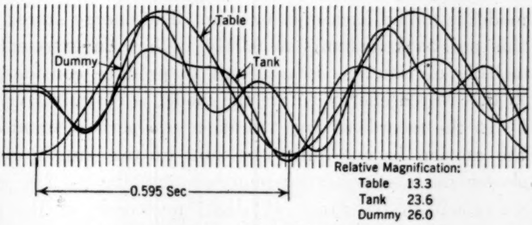

FIG. 4.—PART OF A TYPICAL RECORD

Free Vibration Characteristics.—As the pull-back amplitude is varied, the resulting free vibrations prove to be very uniform in character. Analysis of the records shows the system to be remarkably linear, in view of the complex action of the water inside the tank. Fig. 5 is a plot showing various successive maximum amplitudes of free vibration, expressed in terms of the percentage of the original pull-back before releasing. (In this and all succeeding diagrams all data are given in terms of the full-sized tank in order to avoid confusion as to scale relations.) In a perfectly linear system such as one made up of springs and weights, these curves would all be horizontal straight lines. In the water-tank the curves are quite straight, but all show more or less deviation from the horizontal. However, the percentage deviation within any reasonable working deflection of the tank is quite small. On the basis of this observation one might expect that the system would exhibit nearly linear characteristics in the shaking-table tests, and this was found to be the case.

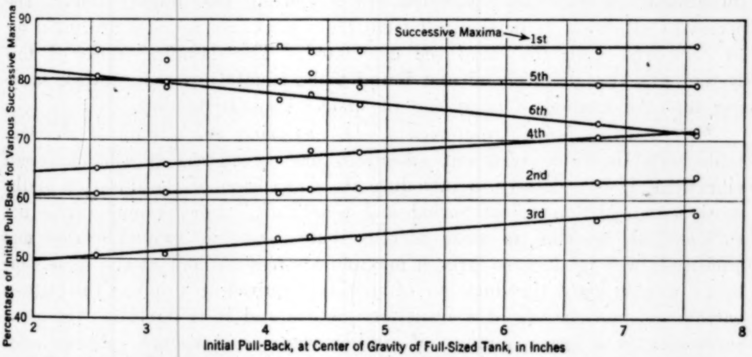

FIG. 5.—FREE VIBRATION BEHAVIOR OF TANK WHEN SUDDENLY RELEASED FROM PULLED-BACK POSITION

The curves in Fig. 5 are not extended below deflections of 2 in., because it was found that as the deflections became quite small the characteristics of the pull-back fuse began to affect the resulting free vibrations sometimes by as much as 5 or 6 per cent. It is easily seen why this can be true when it is realized that, corresponding to a pull-back in Nature of 1 in., the model is pulled back only 0.02 in. The energy stored in the model tower for this pull-back amounts to 0.0016 in-lb. An extremely short lag during the melting of the fuse is sufficient to produce considerable percentage change in this stored energy before the model is entirely free.

In the records of free vibration two periods stand out distinctly, although the motion is not quite the sum of two simple harmonic motions. The slower mode of vibration consists principally of a swinging motion of the water within the tank. A slight movement of the tower accompanies this mode. The second and faster mode consists of a swaying back and forth of the tank as a whole, while a large part of the water moves with the tank. This mode resembles the action of a simple inverted pendulum. These two periods were estimated from the records to be 0.39 sec and 0.24 sec, respectively, for the model. (The corresponding periods for the full-sized structure are 2.7 and 1.6 sec.)

It is interesting to compare these periods with that of the dummy tank model which has a period of 0.27 sec. The change from 0.27 to 0.24 sec and the addition of the secondary period of 0.39 sec are created entirely by the freedom of the water to move relative to the tank.

In order to verify the accuracy of the model and laboratory work, free vibration tests were also made with the tank filled with a mixture of sand and sawdust, of volume and weight equal to that of the water (5.00 lb). This mixture was solid enough to act as an inert mass in the tank so that it duplicated the conditions assumed for computing the dummy tank. The period of vibration as determined from these tests was found to be 0.272 sec as compared with the 0.273 sec calculated. The damping ratio of this system was also investigated and found to be small (less than 1.015), showing that the method of mounting the model was satisfactory.

Forced Vibration Characteristics.—In analyzing the results of shaking-table tests in which transient vibrations are considered as well as forced vibrations, it is necessary to introduce the conception of the duration of the motion in addition to its period and amplitude. For example, it is not sufficient to be able to state merely that a certain ground period and amplitude will produce so large a maximum stress without at the same time being able to state the duration of motion required to produce this stress; earthquake motions are of a transitory nature and it is doubtful whether a succession of a larger number of similar waves ever occurs. Accordingly, the data have been studied in the light of the maximum stresses (or deflections) that occur up to various periods of time, the measure of time adopted being the number of ground cycles elapsed since the start of the motion. This arrangement of data gives a clearer view of the matter than one in which time intervals are expressed in seconds, because it is the number of ground vibrations rather than the absolute duration of time that is of greatest interest.

Fig. 6 presents the results of the shaking-table tests in a condensed form. The maximum amplitudes of the tank and dummy are shown as functions of the ground period, holding the maximum acceleration of the ground constant at 3% of that due to gravity. (These data are given in terms of the maximum ground acceleration because many engineers are accustomed to compute earthquake stresses on the basis of acceleration alone. The value, 3% of gravity, was chosen as a base for plotting the results because the structure would have a safety factor of 2 when subjected to a constant horizontal acceleration, 0.03 g; that is, according to the statical method of earthquake design the structure would have a safety factor of 2 for any earthquake having a maximum acceleration of 0.03 g.) Because the system was found to be so nearly linear it is possible to derive other values of acceleration by direct proportion. Of course, this is slightly approximate at certain points on the curves and probably would not hold true for very large accelerations (say, greater than 0.15 g) even if the elastic limit point were indefinitely high.

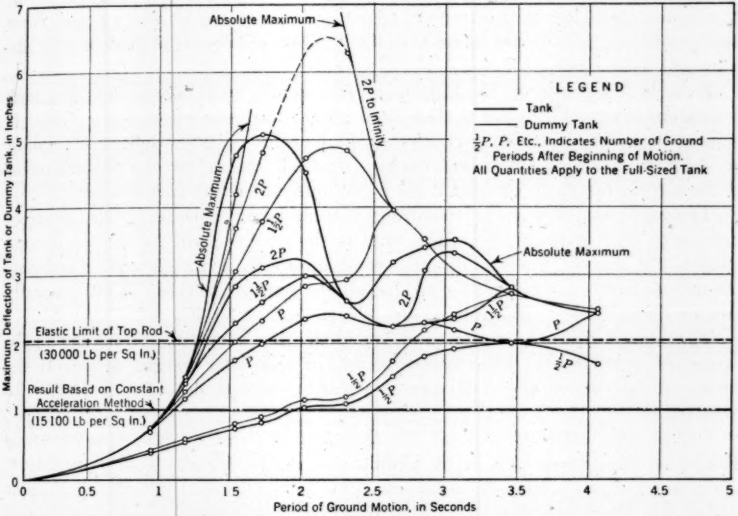

FIG. 6.—RESULTS OF SHAKING-TABLE (MAXIMUM GROUND ACCELERATION = 3% OF GRAVITY; FOR OTHER VALUES USE DIRECT PROPORTION)

One of the most outstanding characteristics of these curves is the extreme difference between the form of the early maximum curves and that found in the absolute maximum curves. First considering the actual tank, one notes in the absolute maximum response the appearance of two distinct resonance points. These points correspond to the natural periods observed in the free vibration tests. (The maxima in Fig. 6 do not coincide with the natural periods—2.7 and 1.6 sec—because of the method of plotting the results. If Fig. 6 is replotted, keeping the ground amplitude constant instead of the maximum acceleration, it will be found that the maxima then appear at the natural periods of the system.) The resonance point corresponding to the natural period of the water is suppressed, a natural result of the non-linearity in this region. In the early stages of the motion, these two resonance points are almost entirely obscured by the presence of the transient vibrations.

Equally outstanding in Fig. 6 is the rapid building up of the tank deflections, even at ground periods well away from the resonance points. It is seen that, for the most part, two ground cycles produce deflections almost as great as a series of several cycles. Indeed, the relatively flat character of the curves for *P* (1.5 *P* and 2 *P*) is obviously of great significance.

The response curves for the dummy tank begin with a pattern roughly similar to that of the water-tank; but, as the duration of the motion is prolonged, the curves for the dummy tank approach a form having a single resonance point corresponding to its single natural period. The generally greater deflections of the dummy are clearly shown in Fig. 6.

The elastic-limit deflection and the deflection resulting from the application of a horizontal force equal to 3% of the dead weight acting at the center of gravity of the tank, are also shown in Fig. 6 to form a basis for comparison.

Comparison with Results of the Statical Method of Earthquake Stress Analysis.—The results given by simple statical theory are shown on Fig 6, but a more direct comparison between the actual conditions and the simple theory is given in Fig. 7. The maximum acceleration of the ground (expressed as a percentage of gravity) necessary to produce elastic-limit stresses during one and two ground vibrations is plotted as a function of the ground period. It is obvious that the simple theory based on a constant acceleration fails to fit the true conditions, even as a rough approximation.

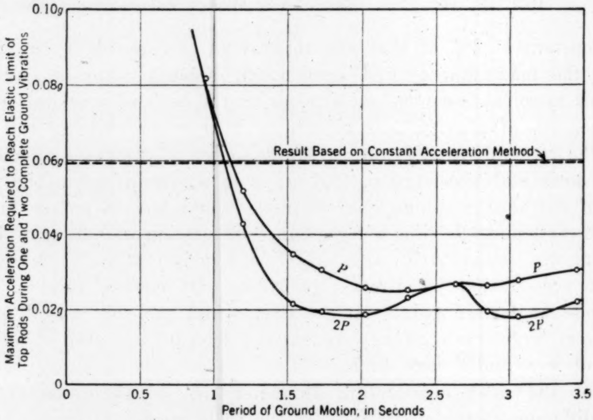

FIG. 7.—COMPARISON WITH SIMPLE THEORY OF DESIGN

The curves cross in the vicinity of the 1-sec ground period, but this is a coincidence rather than a result of the assumptions upon which the simple theory is based. The inadequacy of this type of tower is shown strikingly in Figs. 6 and 7.

Conclusions Pertaining to the Standard Design.—The most important conclusion to be drawn from the results of this part of the research concerns the inadequacy of the generally accepted method of designing elevated tank towers against earthquakes. It is clearly shown that the assumption of a static horizontal force proportional to the maximum ground acceleration leads to large errors over practically the entire band of possible earthquake frequencies. If earthquakes did not exhibit periods shorter than 5 or 6 sec, the fixed-force method of analysis could be considered fairly satisfactory for tank design provided a reasonable factor of safety was adopted. Unfortunately, the more violent motions of the ground during an earthquake are known to contain periods considerably shorter It would be possible, of course, to make the simple theory fit elevated tank design fairly well by building the towers of such stiffness that the natural period of the structure would be shortened, say, to 0.25 sec; but with a mass of 500 000 lb elevated approximately 100 ft above the ground, such a design would be extremely expensive. In other words, unless the natural period of the structure can be reduced to at least one-third or one-fourth that of the shortest important earthquake period to be expected, the dynamical effect of the ground motion can not safely be ignored.

It will have been observed from Figs. 6 and 7 that the effects of earthquakes upon the structure are expressed in terms of motions or deflections, the unit stresses produced by these motions being incidental to them and not controlling them. It may be seen that, in any given tank tower, the best effect that can be had from a moderate amount of strengthening is obtained by strengthening those members which are inherently weak until all the members of the structure reach ultimate stresses simultaneously. Then the structure achieves the maximum possible safe deflection; this means that, for the tower studied in this research, an increase in the size of the rods in the upper panels would strengthen the tower dynamically to some extent (since they are the highest stressed rods); but that, paradoxically enough, if all the rods were increased in cross-section by the same percentage, the tower would have the same strength dynamically as it had originally, because the safe deflection would be unchanged.

The conclusion that large tower deflections can be produced in short periods of time over a wide range of earthquake frequencies is obvious from the data of Fig. 6. This conclusion leads further to the consideration that an actual earthquake motion may introduce dangerously large amplitudes even if the condition of resonance or near resonance is entirely lacking.

It is clear that although they indicate in a general way the effect to be expected, the simple harmonic motion tests do not offer a practical means of arriving at quantitative engineering data on the effects of actual earthquake motion. On the basis of the familiar Fourier harmonic analysis, the simple harmonic test can be regarded as a reliable "measuring stick" for comparing the dynamic behavior of one system with that of another system; but beyond demonstrating the possibility of the process mathematically for certain structures one cannot practically go very far toward converting the results of simple harmonic motion tests in terms of the effect of a given irregular earth motion.

Spring Element Design; Model Scale, 1:46.5

Considerations Relative to Development of Earthquake-Proof Tank Structures.—A study was made of a number of possible types of tank and tower construction, with a view toward finding a type or types suitable for active seismic regions. Some of these types, of course, appear to be fantastic or impractical, whereas others are uneconomical. Among the former may be listed such arrangements as roller supports for the foundations or tanks, various ways of hanging or suspending the tank so as to decrease its vibrations, etc. Among the uneconomical designs are those which seek to give the structure adequate quake-resistance by providing an extremely stiff or rigid tower. The data in Table 1 will serve as an illustration. Thus, it is clear that it is quite uneconomical to attempt to give very short natural vibration periods to heavy tanks on towers of this height. For capacities of 100 000 gal and more, and for towers of greater height, the situation is very much worse.

TABLE 1.—Comparative Designs, 60 000-Gallon Tank on a 100-Foot Tower (Distance from Column Base to Balcony = 108 Feet)

Item No.	Design (1)	Number of panels (2)	Weight, in tons, more than Item No. 1 (3)	Natural vibration period, P, in seconds (4)

4........	Extra heavy design..................	4	11.50	0.93

* Diagonal rods, 1 sq. in. in area.

If the natural period cannot be reduced to about 0.5 sec, it is doubtful whether the tank is very much more likely to survive a violent earthquake than a standard design built for wind resistance only. The odds will depend upon the nature of the particular ground motion to which it may be subjected and upon the foundation conditions.

The natural conclusion from a prolonged study was that, barring fantastic and impractical designs, the best way to obtain adequate quake-resistance is to provide the tower with a greater range of elasticity; that is, if the tower can be built so that the safe deflections are large enough, there will be no danger of failure. This does not necessarily imply that the tower must be extremely limber or weak, although a certain degree of limberness is almost always created by increasing the allowable deflection of a structure. This concept, of course, is not a new one, but it has been most often discussed in relation to buildings; and, in this connection, the writer wishes to emphasize that the present discussion is in no way intended to apply to buildings.

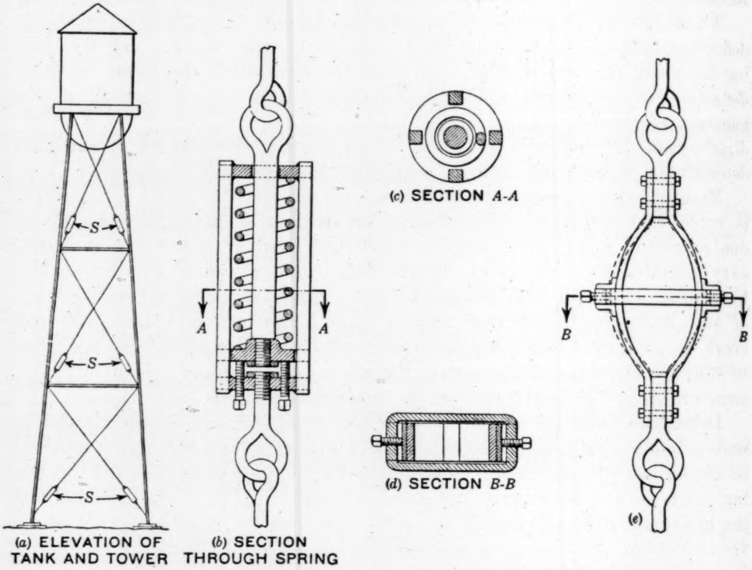
There are two general methods of increasing the allowable or elastic deflection range of a structure such as a water-tank tower: (1) By making the tower of some type of open framework in which the forces resisting deflection are produced by bending stresses set up in some or all of the members of the framework; and (2) by artificially increasing the allowable direct-stress deformations of some or all of the members of a statically determinate tower. Of course, combined systems will also suffice.

Method (1).—The first method has one serious drawback—if the tower is made with sufficient deflectibility for quake resistance, the deflections due to strong winds are likely to be undesirably large and the tank will sway considerably with every light wind. This difficulty can be avoided by adding a system of diagonal bracing to the tower, the bracing being of such strength that it will safely stand ordinary wind force but will break or collapse when a serious earthquake occurs, leaving the tank free to sway as far as need be during the quake, and yet not endangering the structure as a whole (if it is made inherently stable).

Difficulties arise in the design of a fool-proof collapsible bracing system, since a bracing failure on one side only or on one panel only would probably be disastrous. Furthermore, questions arise as to the advisability of taking chances on hurricane or near-hurricane winds which would break the bracing and leave nothing to resist them but the bending action of the frame (which, for towers about 100 ft high, is rather small if the design is economical). The replacement of bracing (or of breakable links in the bracing) after an earthquake does not present any serious objection. All in all, it may be stated that this method is at least worthy of serious consideration and perhaps it would be well worth while to study the behavior of models representing various towers of this general type.

Method (2).—The second method can best be explained by reference to Fig. 8 which illustrates schematically a device developed during this research. If spring elements such as those in Figs. 8(*b*) and 8(*e*) are introduced at Points *S* into the bracing of the tower (Fig. 8(*a*)), it will be seen that the allowable elastic deflection of the tower can be increased at will within very wide limits. Furthermore, it will be noticed that the spring elements are provided with a means of applying arbitrary initial stresses to the springs, so that up to the limit of the initial stresses they are perfectly rigid, thus preventing undesirable sway of the tank from ordinary wind forces. When an earthquake of serious magnitude occurs, however, the initial stress is quickly overcome and the elements act as simple springs to the point at which the coils close up tight, when they again become perfectly rigid.

It is evident that this method of construction has the advantage over the first method in that here extremely high winds or hurricanes will never lack adequate tower resistance as long as the main members of the tower are large enough to take the stresses. Furthermore, a slight dissymmetry will not be disastrous, as compared with the effect of breaking the bracing on one side of the tower.



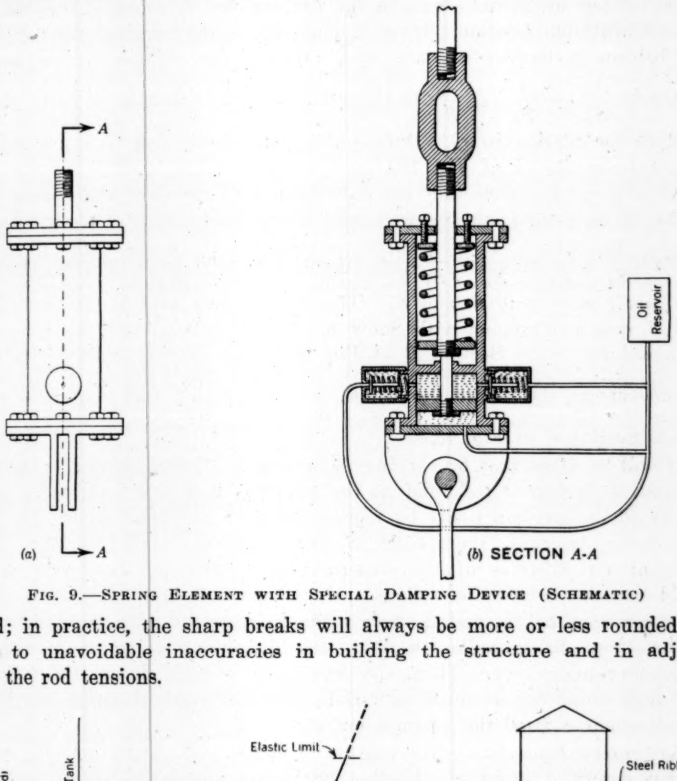
(a) ELEVATION OF TANK AND TOWER (b) SECTION THROUGH SPRING

FIG. 8.—SPRING ELEMENT CONSTRUCTION (SCHEMATIC)

There are so many possible types and combinations of spring elements that no attempt will be made to catalog them all. One special type that is of interest, however, is shown in Fig. 9, in which a damping device has been added to the spring element as a means of decreasing the amplitudes of vibration. It is surprising to find how little damping force is needed to produce a very beneficial effect in the behavior of this type of construction.

Description of Model Technique.—In dealing with an entirely new type of construction, where there are no definite data at hand on which to base design, it is desirable to investigate a number of possible designs under similar conditions. To build a series of models, each representing some variation in design, would obviously be a very expensive and difficult procedure. Therefore, it was decided to conduct this preliminary study by means of a single model which could be adapted to represent a number of designs and, at the same time, would entail a minimum of time and expense.

In order to understand how this was accomplished, it is first necessary to examine the statical, or load-deflection, characteristics of a structure equipped with spring elements. Fig. 10 shows the typical theoretical load-deflection curve for the new style of tower. This curve is obviously idealized; in practice, the sharp breaks will always be more or less rounded off due to unavoidable inaccuracies in building the structure and in adjusting the rod tensions.



(a) (b) SECTION A-A

FIG. 9.—SPRING ELEMENT WITH SPECIAL DAMPING DEVICE (SCHEMATIC)

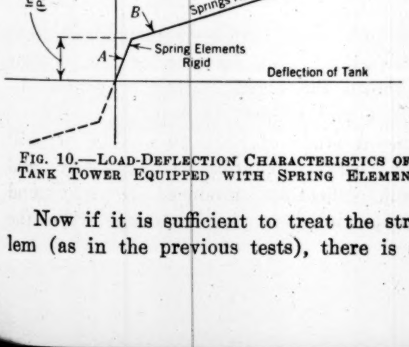


FIG. 10.—LOAD-DEFLECTION CHARACTERISTICS OF A TANK TOWER EQUIPPED WITH SPRING ELEMENTS

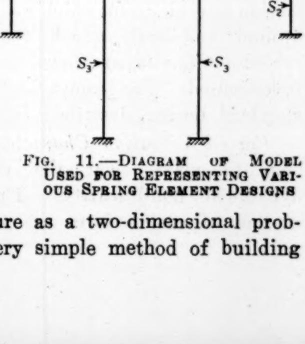

FIG. 11.—DIAGRAM OF MODEL USED FOR REPRESENTING VARIOUS SPRING ELEMENT DESIGNS

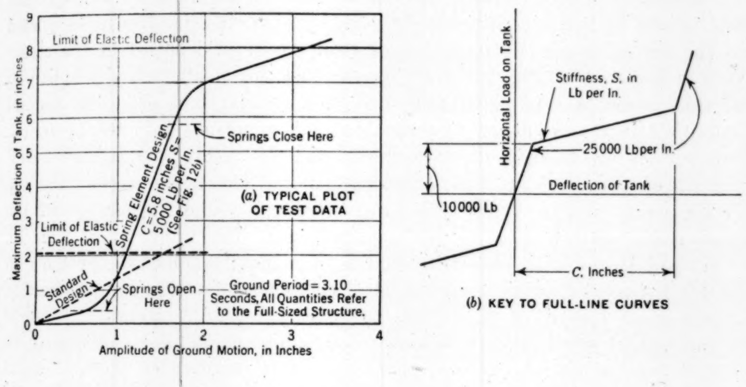
Now if it is sufficient to treat the structure as a two-dimensional problem (as in the previous tests), there is a very simple method of building its dynamical equivalent. Fig. 11 shows how the model was constructed by simple changes in the original model of the standard design. Screws *a* are set to put an initial stress in the flat springs, S_1, when the system is in its equilibrium position. If, then, one deflects the tank over to the left, say, Ribbon r_L buckles at once, and, at first, the stiffness of the tower system is $\frac{1}{S_3} + \frac{1}{S_3} + \frac{1}{S_2}$ to the point where the initial stress in S_1 is equal to the tension in r_R. During this part of the deflection the model represents Section *A* of Fig. 10.

As soon as the deflection proceeds farther to the left, the spring, S_1, begins to separate from Screw *a* and the stiffness of the tower system becomes $\frac{1}{S_3} + \frac{1}{S_3} + \frac{1}{S_2} + \frac{1}{S_1}$, in which the term, $\frac{1}{S_1}$ dominates because S_1 is small relative to S_2 and S_3. The stiffness now remains at this value until S_1 comes in contact with Screw *b*. During this part of the deflection the model represents Section *B* of Fig. 10. Any further deflection to the left encounters the original stiffness, $\frac{1}{S_3} + \frac{1}{S_3} + \frac{1}{S_2}$, and, therefore, represents Section *C* of Fig. 10.

It will be noted that by varying the settings of Screws *a* and *b* and the stiffness of Springs S_1, S_2, and S_3 (by altering their free lengths), a wide variety of designs can easily be represented with the same model. In the tests herein described, the springs, S_2 and S_3, were not changed since they represent the stiffness of the structural framework of the tower which would not change for the various spring-element designs considered. The adjustments of S_1, S_2, and S_3 were made independently by using the conventional weight-and-pulley loading, the deflections being read with a micrometer microscope. Then, the set-up was assembled and the settings of Screws *a* and *b* were made by "trial and error" until the measured load-deflection curve fitted the assumed curve.

Laboratory Procedure.—The routine of shaking-table tests was the same as that described under the heading "Standard Design." Several possible designs were chosen for study, and each design was put through a series of simple harmonic motion tests in which both period and amplitude were varied. For each design, curves were drawn showing the maximum deflection of the tower as a function of ground amplitude for a given ground-motion period, from which could be determined the largest simple harmonic ground amplitude which the structure could safely withstand at that period. Fig. 12(*a*) shows a characteristic plot for one of the designs investigated. For comparison is shown the corresponding curve for the standard design described in Table 1 and supporting text.

Forced Vibration Characteristics.—A study of Figs. 10 and 12 (*a*) will help to make clear the relation between statical non-linearity and dynamical non-linearity. The tank deflections produced by a ground motion of cosine form are not proportional to the amplitude when the period is held constant, as was the case with the simple standard structure. This phenomenon is due to the fact that the natural vibration period of the structure changes as the amplitude of its vibration varies. Thus, from



(b) KEY TO FULL-LINE CURVES

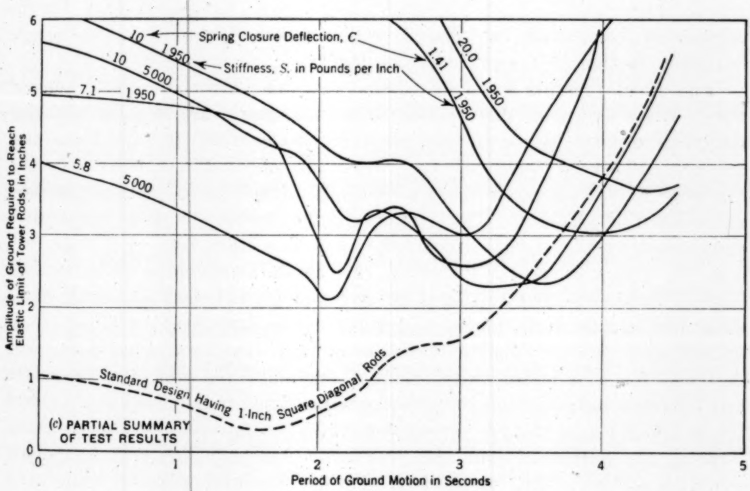


FIG. 12.—EARTHQUAKE RESISTANCE OF SPRING ELEMENT DESIGNS COMPARED WITH THAT OF STANDARD DESIGN

Fig. 10, it is evident that over the range, *A*, the natural period is constant and is equal to that of the same structure without spring elements. As soon as the amplitude of vibration passes over to the range, *B*, however, the natural period becomes progressively longer with increasing amplitude because the effective stiffness (that is, the ratio of the horizontal load to the corresponding deflection) becomes progressively less. This state of affairs continues until the amplitude of vibration begins to enter the range, *C*, when further increase in amplitude will result in progressive shortening of the period that the structure had at the end of the range, *B*. However far the deflection may go in the *C* range, the natural period can never be as short as the period in the *A* range.

In such a system, then, it is obvious that the amplitude of the ground motion can be just as critical as its period. Thus, in Fig. 12(*a*), the period of the ground motion is much longer than the natural period of the structure in Range *A* of Fig. 10. As a consequence, for small ground amplitudes of this period, a very small tank deflection occurs; but when the ground amplitude increases enough to throw the tank amplitude into Range *B*, the two periods are brought closer together, and the result is a sudden building up of vibration due to a quasi-resonance. The break-over at the top of the curve in Fig. 12(*a*), of course, represents the disappearance of the quasi-resonance condition as the amplitude goes into Range *C* of Fig. 10.

It will be noted at once that studies of markedly non-linear systems in simple harmonic motion, such as the spring-element tower designs, cannot give a clear picture of the effects to be expected from irregular motions of an actual earthquake. Indeed, these experiments were restricted to simple motions only because at that time actual earthquake motions could not be reproduced in this laboratory; but it was recognized that, for the purpose of comparing one design with another dynamically, the simple harmonic motion is a serviceable yardstick.

Fig. 12(*c*) presents a partial summary of the results of several hundred tests. Also, shown on this diagram, for comparison, are the corresponding results of tests on the standard design previously investigated. These data are represented in terms of the amplitude of simple harmonic ground motion required to reach the elastic limit of the tower rods for various ground-motion periods. The points on the curves in Fig. 12(*c*) were determined by the absolute maximum tank deflection reached during each test. In almost every test, however, this absolute maximum deflection was reached within the first two or three cycles of ground motion. Thus, if the data were restricted to motions of three cycles duration, the figure would change very little. The rod-bracing of the tower in these tests was designed for a safe horizontal load of one-tenth the weight of the tank and contents acting at the center of gravity of the tank. Had the standard tower bracing (see dotted curve, Fig. 12(*c*)) been designed for the same loading, the ordinates would be practically unchanged in magnitude, but would be shifted a little to the left. Thus, the minimum point would move from a period of 1.6 sec to about 1.3 sec, with no change in magnitude.

The superiority of the spring element design over what is generally thought of as the principal part of the earthquake spectrum is very marked, but for earthquake periods beyond about 3 sec the standard design compares favorably with it.

Some preliminary experiments were made with a frictioning device in order to study the effect of damping. The results indicated that surprisingly small damping forces would suffice to raise the low points on the curves well above the curve for the standard design. These tests were not sufficiently quantitative to warrant extended discussion.

Conclusions Pertaining to Spring Element Design.—These preliminary experiments suggested that the new form of construction has very definite possibilities as a means of overcoming the earthquake hazard for elevated water-tanks. The conclusions to be drawn are quite limited by the very nature of the tests:

(*a*) For earthquakes characterized by short-period vibrations (not more than about 2.5 or 3-sec periods) the simple spring-element design can be considered a satisfactory solution. For such earthquakes the data in Fig. 12(*c*) show that the greater the closure deflection, *C*, the more violent shocks the structure can withstand.

(*b*) For earthquakes in which moderately large long-period vibrations are present (say, between 3 and 6 sec) dangerous stresses may be reached; and, without damping, the spring-equipped structure may be no better off than one of standard design. For such earthquakes the data in Fig 12(*c*) seem to indicate that closure deflections of more than 7 or 8 in. may be undesirable.

(*c*) The presence of a slight degree of damping action would greatly help the structure in the long-period range without appreciably reducing its effectiveness in the short-period range.

(*d*) In order to obtain design data for engineering purposes, tests should be made with actual earthquake motions. The model preferably should be three-dimensional and large enough to permit accurate determination of the damping forces required for practical design. (In the model of 1:46.5 scale the measurement of damping forces is made difficult by the fact that the force-scale is $(46.5)^3$, or 100 500; that is, a force of 1 000 lb in Nature corresponds to less than $\frac{1}{6}$ oz in the model. Although there is no difficulty in measuring very small elastic forces in a frictionless structure such as that shown in Fig. 11, it is difficult to produce and measure frictional forces below the level of 0.5 oz with reasonable accuracy. No such difficulty appears in measurements of deflections, however, since the scale of deflection is equal to the scale of the model).

PART II.—EXPERIMENTS WITH ACTUAL EARTHQUAKE MOTION

Model Characteristics and Testing Procedure

Introductory—Four important questions were left unanswered by the research discussed in Part I:

(*a*) How will the new construction behave in three dimensions?

(*b*) What will be the effect of actual irregular earthquake motions as compared with the simple harmonic motion previously used?

(*c*) How much damping is needed to avoid excessive stresses?

(*d*) How does the proposed structure compare with the standard type of structure in dynamic behavior when subjected to actual earthquake motions.

Before further model studies could be directed profitably toward answering these questions, it was necessary to construct a shaking-machine capable of reproducing actual earthquake motions. The design of this machine[5] was begun in the fall of 1934. Construction was completed in the summer of 1935; and by September, 1935, the operation of the machine was considered quite satisfactory for conducting the research.

The research described in Part II should be regarded as only a part of the program of tank-tower investigation that was originally planned. Limited funds made necessary the curtailment of the planned program, with the result that the data are not nearly so extensive as could be desired. Sufficient engineering data have been obtained, however, to make possible for the first time rational design of a fairly wide range of sizes of elevated water-tank structures for seismic regions.

It is not intended to suggest that the spring element design is the only practical solution to the problem. It is the only solution which the writer has (to date) considered sufficiently practical for actual construction.

The Model.—A three-dimensional model was constructed on a scale of 1:25 to represent a 60 000-gal tank on a 100-ft tower. Spring elements were built into the model to simulate the new type of construction to be investigated.

The basic theory applying to models of water-tank structures was discussed[6] by the writer in 1935, who then showed that perfect geometrical scaling will result in dissimilarity unless the model tower is built of a material having a modulus of elasticity of $\frac{\rho_m}{\rho\lambda}$ times that of the steel in the prototype (ρ and ρ_m being the densities of the liquids in the prototype and model tanks, respectively; and λ is the scale of the model). This means that if mercury was used as the liquid in the model, and brass ($E = 13\,800\,000$ lb per sq in.) for the structural parts and tank shell, then a geometrically scaled model with $\lambda = 29$ would be entirely satisfactory (with a minor correction for the density of the brass).

A consideration of the hazards and difficulties involved in the use of a mercury-filled model led to the decision that this procedure should be avoided. This was done by means of a scale distortion analogous to that applied in earlier studies. The expense of building an accurately made geometrical-scale model of a water-tank and tower would have been very great, and the problem of simulating riveted connections exactly to small scale has not been solved. Fortunately, in tank towers of conventional design, the structure is so nearly statically determinate that it makes little difference whether the joints are rigid or pinned, as far as the dynamical behavior of the structure is concerned. Usually, they are somewhere in between, probably being nearer the rigid condition, except where the struts are actually pinned to the columns, as is sometimes the case. The eccentricity of the members coming together at a joint is often of more consequence in affecting the tower stiffness than the degree of rigidity in the joint itself

---

[5] *Civil Engineering*, March, 1936; and *Bulletin*, Seismological Soc. of America, July, 1936.

[6] *Civil Engineering*, August, 1935, p. 455.

It was decided to make the joints of the model rigid (the prototype joints were riveted) and to preserve the eccentricities as they are in the actual design chosen for study. In this manner the net tower stiffness can be simulated closely by a simple model.

In order to arrive at the model-member design required for a given over-all length scale, λ, the model theory referred to in Part I is merely extended to the individual parts of the structure.[7] The following relations are easily obtained:

For structural members,

$$\frac{A}{A_m} = \frac{\rho}{\rho_m} \frac{E_m}{E} \lambda^3 \qquad (2)$$

$$\frac{I}{I_m} = \frac{\rho}{\rho_m} \frac{E_m}{E} \lambda^5 \qquad (3)$$

and, for thickness of tank and roof plates,

$$\frac{t}{t_m} = \sqrt[3]{\frac{\rho}{\rho_m} \frac{E_m}{E} \lambda^4} \qquad (4)$$

in which A = area of member in prototype; A_m = area of member in model; t = plate thickness in prototype; t_m = plate thickness in model; I = moment of inertia of prototype member; and I_m = moment of inertia of model member. The thickness scale for the tank and roof plates is correct only if the principal shell distortions are due to the bending of the plates and not to direct stresses. This is obviously the case for tanks of the type studied herein.

It is important to realize that these relations, although resulting in true dynamical similarity, do not result in similarity of unit stresses, from which it is to be concluded that a model built according to these relations properly represents the prototype, in so far as statical and dynamical deflections are concerned, to the point where elastic limit stresses are reached either in the model or in the prototype. Beyond this point true similarity ceases to exist, and the interpretation of the model results becomes a matter of judgment. Once the model deflections are known, it is a simple matter to calculate the corresponding stresses in the prototype as explained in Part I.

To satisfy, simultaneously, both the $\frac{A}{A_m}$ and the $\frac{I}{I_m}$-relations for $\lambda = 25$ (the scale chosen) and $\frac{\rho}{\rho_m} = 1$ (water in the model tank) is a practical impossibility for the sections comprising a standard tank tower; but there is a simple solution of the problem. If the scale of $\frac{I}{I_m}$ is made correctly, the area scale can be corrected by artificially giving to the members the compliance (force per unit elongation) they would have if the area scale could be maintained. If C and C_m are the compliance of prototype and model, respectively, it can be shown that for the model in question the following relation must be satisfied[7]:

---

[7] *Bulletin*, Seismological Soc. of America, July, 1934, pp. 170 to 230.

$$\frac{C}{C_m} = \frac{\rho}{\rho_m} \lambda^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

In the present problem it was found that, when the proper $\frac{I}{I_m}$-ratio was maintained, the areas of the model sections were invariably much too large. Consequently, the introduction of additional spring action into the members was necessary. Instead of altering the compliance of all the members of the frame, it was found much more convenient to attach appropriate springs to the diagonal rods only in order to correct for the stiffness of the tower as a whole. The reader will observe that the necessary calculations are straightforward, the model springs being chosen so that with a horizontal load acting at the tank, the total deflection in any one panel was made the same as it would have been had all the members in the panel been corrected.

FIG. 13.—TYPICAL MODEL JOINT DETAIL

Fig. 13 illustrates the construction of a typical joint; the correction spring is above the joint and the spring element below. The individual spring elements were all completely calibrated, assembled, and set for initial load and closure point before they were put into the tower. All connections were joined thoroughly with medium hard solder. The pins shown were inserted for construction purposes only. The nuts and turnbuckles were secured with solder after final adjustment to prevent their loosening during vibration of the model.

The adjustment of the tie-rods gave the only real difficulty in the entire work of building the model. This had to be done largely by gaging

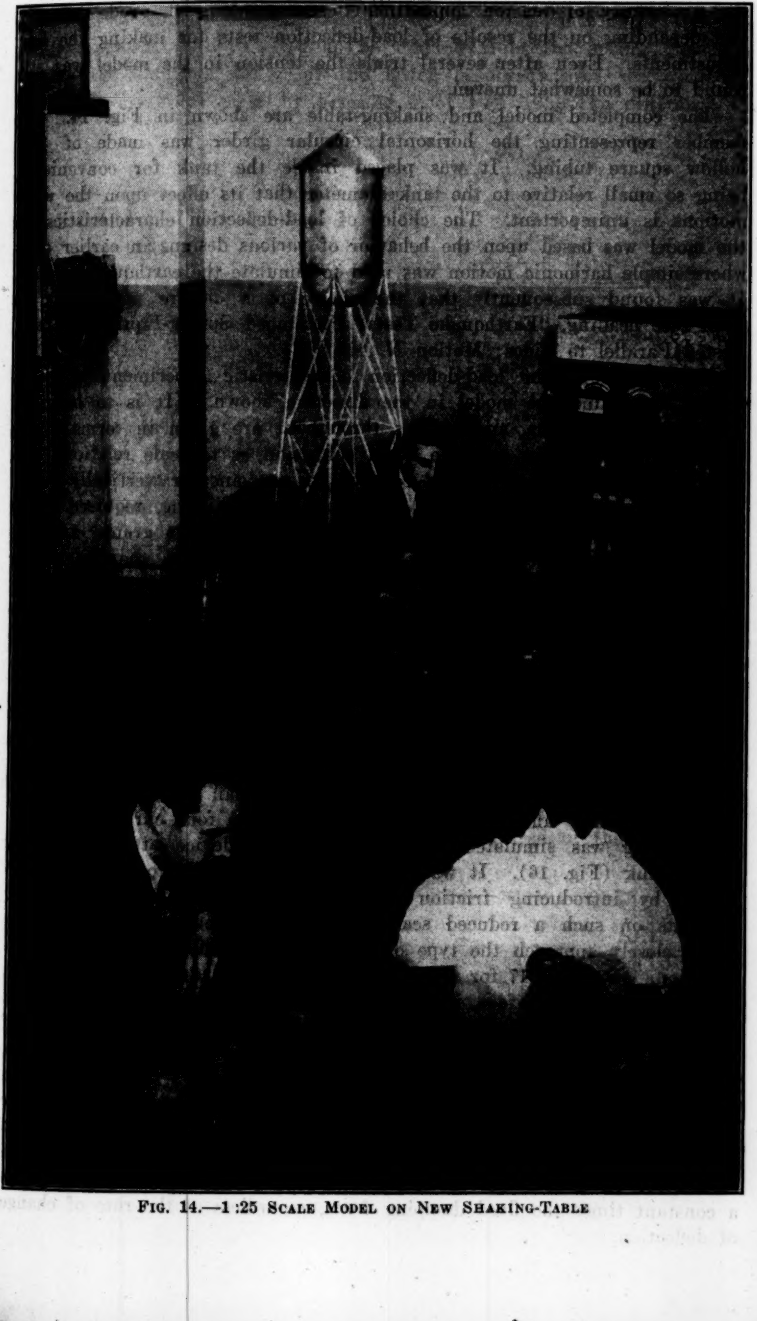

FIG. 14.—1:25 SCALE MODEL ON NEW SHAKING-TABLE

the uniformity of tension approximately by touching the rods laterally, and depending on the results of load-deflection tests for making the final adjustments. Even after several trials the tension in the model was still found to be somewhat uneven.

The completed model and shaking-table are shown in Fig. 14. The member representing the horizontal circular girder was made of ¼-in. hollow square tubing. It was placed inside the tank for convenience, being so small relative to the tank diameter that its effect upon the water motions is unimportant. The choice of load-deflection characteristics for the model was based upon the behavior of various designs in earlier tests, where simple harmonic motion was used to simulate the earthquake motion. It was found subsequently that the choice of a closure point was not ideal (see heading, "Earthquake Tests; Undamped Spring-Equipped Tower, Tested Parallel to Sides; Motion N. 40° E.").

Fig. 15 shows the load-deflection characteristic experimentally determined by pulling the model in the direction shown. (It is to be noted that loads, deflections, and periods throughout are given in terms of the full-sized structure, in order to avoid confusion as to scale relations.) A slight shifting of these curves relative to one another vertically would make them coincide very well, the maximum shifting required being about 1 200 lb. In the model, this amounts to about 35 grams, and represents the variations in adjusting the initial tension in the twenty-four tie-rods. Considering the small scale used, it is doubtful whether much better uniformity of rod tension can be obtained practically, and there is no reason to believe that an actual full-sized structure would be more uniformly adjusted as to tension by a field gang.

Shaking-table tests, first in the *A*-direction and then in the *C*-direction, showed no appreciable difference in dynamic characteristics. Indeed, this is what one would expect, since the natural period of the structure varies approximately with the square root of the area beneath the load-deflection curve, which means that for amplitudes greater than 2 or 3 in. the period is not appreciably affected by the variations in the four curves.

Damping was simulated by a solid friction device attached directly to the tank (Fig. 16). It was not considered possible to obtain reliable results by introducing friction into the twenty-four individual spring elements on such a reduced scale. The solid friction used in testing would closely approach the type of damping contemplated for actual construction. (See Fig. 17 for sectional assembly of a large unit equipped with damping device.) In fact, it is possible that a satisfactory element might be built more economically with pure solid (sliding) friction instead of the piston and cylinder arrangement shown in Fig. 17.

The choice of solid friction (or the equivalent) as a damping medium instead of the more conventional damping proportional to velocity (or some power of velocity) is justified by a consideration of the stresses that might be set up by the latter in the case of fast ground movements. Constant-force damping limits the stresses to those produced by deflection, plus a constant times the fixed damping force, regardless of the rate of change of deflection.

It will be noticed that the damping device shown in Fig. 16 does not exactly represent the damping to be derived from the spring elements, because the damping action of the latter is absent over the range of tower deflections indicated by Section *A* of Fig. 10. The difference in effect is small, however, and simply means that the damping force observed in the laboratory tests should be increased by 8%, or by 10% at the most, to secure the equivalent damping force required of the spring ele-

ments for the same degree of earthquake resistance. (This has been generously allowed for in Conclusion (8), "General Conclusions Drawn from Research.")

The structural design assumed for this investigation is shown in Fig. 18. This design gives a calculated stiffness to the tower of 23 kips per in. of deflection before the springs begin to act.

The model was transformed into a standard tower for later tests by connecting the tie-rods directly to the joints instead of through spring elements. Fig. 19 (full line) shows the measured load-deflection curve for this condition. The calculated stiffness of the structure in this investigation is 44% greater than that of the standard tank studied in Part I; it was designed for a horizontal load of 43.5 kips at the center of gravity of the tank, whereas the tower originally studied was designed for 19.5 kips at the same unit stresses (18 kips per sq in., rod stress). The purpose of the stiffening was twofold: (1) The structure had to be built somewhat stronger to enable it to withstand large deflections as a spring-equipped tower; and (2) it was desired to learn just how much benefit would result from a reasonable degree of strengthening in a standard tower. Curve C, Fig. 19, represents the load-deflection curve computed for the design shown in Fig. 18. (The calculations were made assuming no initial tension in the tie-rods.)

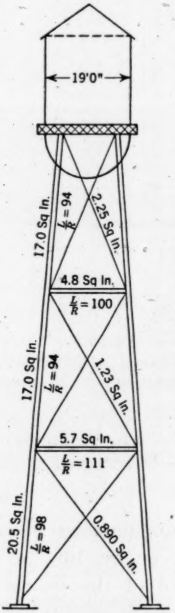

FIG. 18.—STRUCTURAL DESIGN OF PROTOTYPE; TESTS, PART II

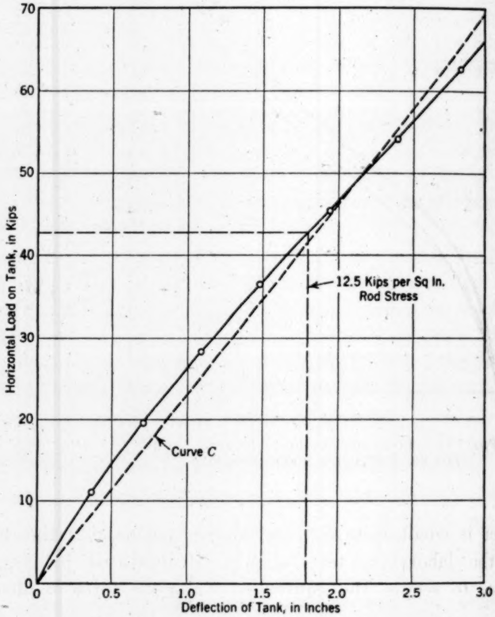

FIG. 19.—LOAD-DEFLECTION CURVE, STANDARD TANK; TESTED AT 45° TO THE TOWER SIDES

Testing and Recording Procedure.—The model (see Fig. 14) was first tested statically to obtain the data in Fig. 15. Then it was mounted on the table of the shaking-machine so that the motion of the base was applied parallel to the tower sides. Later, the tower was turned through 45° so that the motion was applied diagonally for reasons given subsequently. All tests (including those for load deflection) except one, were made with the tank full of water.

The motions used for testing the model dynamically were taken from the data on the Long Beach earthquake of March 10, 1933. These valuable data consist of tabulations of ground displacements at intervals of 0.120 sec for the three components of that earthquake, as calculated from the accelerograms recorded at the Subway Terminal Building, in Los Angeles, Calif. The two horizontal components were plotted on cross-section paper and, after eliminating some very long period waves which were obviously unimportant, a polar plot was made for each component. The polar plots were made into optical cams[8] for driving the machine by cutting them along the plotted lines representing the ground motion. The cam for the component, N. 40° E, is seen in Fig. 14. No tests were made with the vertical component. (There is no direct evidence of dangerous earthquake stresses in the columns of steel tank towers due to vertical motions. Such column failures as have occurred appear to have resulted from poor details and not from true column failure in the proper sense of the word. However, it would be very desirable to extend the investigation to include earthquake effects in the vertical direction. From this standpoint a spring-equipped tower would behave substantially like a standard structure.) The two horizontal components are referred to throughout as the Los Angeles motions, N 40° E and S 50° E. The reader will understand that they are motions of the Long Beach shock as recorded in Los Angeles (37 miles from the epicenter).

A number of free vibration tests were made with the model as a spring-equipped structure (with and without damping), and as a standard structure. As in earlier tests, the procedure was a sudden release from a pulled-back position.

The procedure used in recording the motions during tests was essentially the same as that followed in earlier studies. For each test, the table motion, the deflection of the tank relative to its base, and time marks, were recorded simultaneously on one photographic record. Free vibration tests were recorded in the same manner.

The arrangement for testing and recording is shown in Fig. 20. A rigid wooden framework moving with the shaking-table carries the recording mirrors and lenses so that the tank deflections are recorded directly. The same frame also carried the friction device shown in Fig. 16.

Free Vibration Tests.—All free vibration tests were made diagonally to the tower, in order to be consistent with most of the earthquake tests. The maximum amplitudes of successive swings in the free vibration of the standard structure are given in Fig. 21(*a*) in terms of the percentage of the original pull-back before releasing, plotted against the pull-back amplitude. One observes here about the same degree of linearity as in the case of the smaller model investigated previously. The exact form of the free vibration is not the same as before because the present model represents a stiffer structure. The absence of damping action is shown by the persistence of large amplitudes in the 5, 6, and 7 maxima. (By "damping" is meant the dissipation of energy (usually in the form of heat) by the action of forces resisting motion.)

---

[8] *Bulletin*, Seismological Soc. of America, July, 1936.

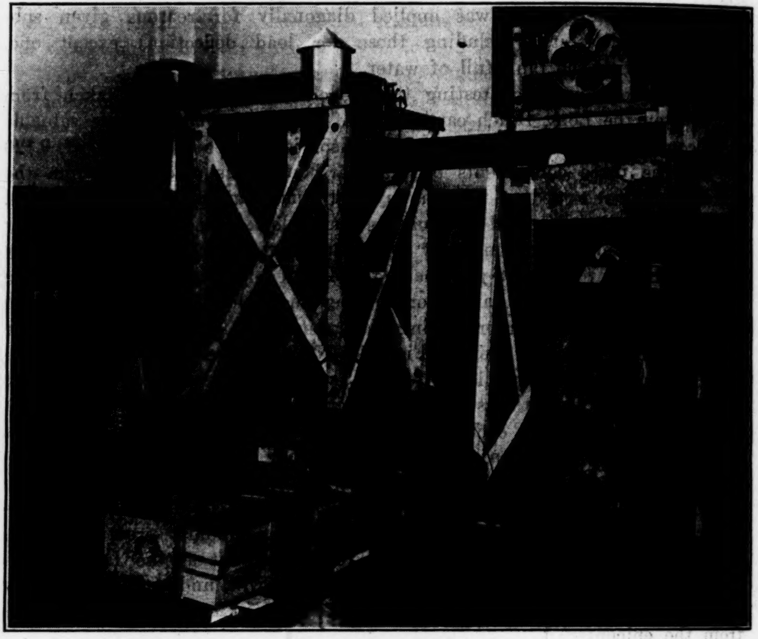

FIG. 20.—SET-UP FOR TESTING AND RECORDING ACTUAL EARTHQUAKE MOTION EXPERIMENTS

It must not be inferred that because the amplitude has dropped to 60% of the initial pull-back by the seventh swing that the stored energy has dropped to 60% of the original. The original energy has merely been changed from all potential to part potential and part kinetic (that is, the water is surging when the tank stands still at the end of a swing), the total energy being scarcely diminished in the first five to ten swings. Similar pull-back tests made by the United States Coast and Geodetic Survey[9] on full-sized structures show very little decrease in energy even after twenty to thirty swings of the tank. The absence of appreciable damping in standard tank structures and their foundations is the greatest hindrance to making them earthquake resistant by any ordinary means. From the free vibration tests, the principal period of vibration was found to be 1.3 sec (2-in. amplitude). The secondary period (mainly due to the water swinging in the tank) is about 2.7 sec.

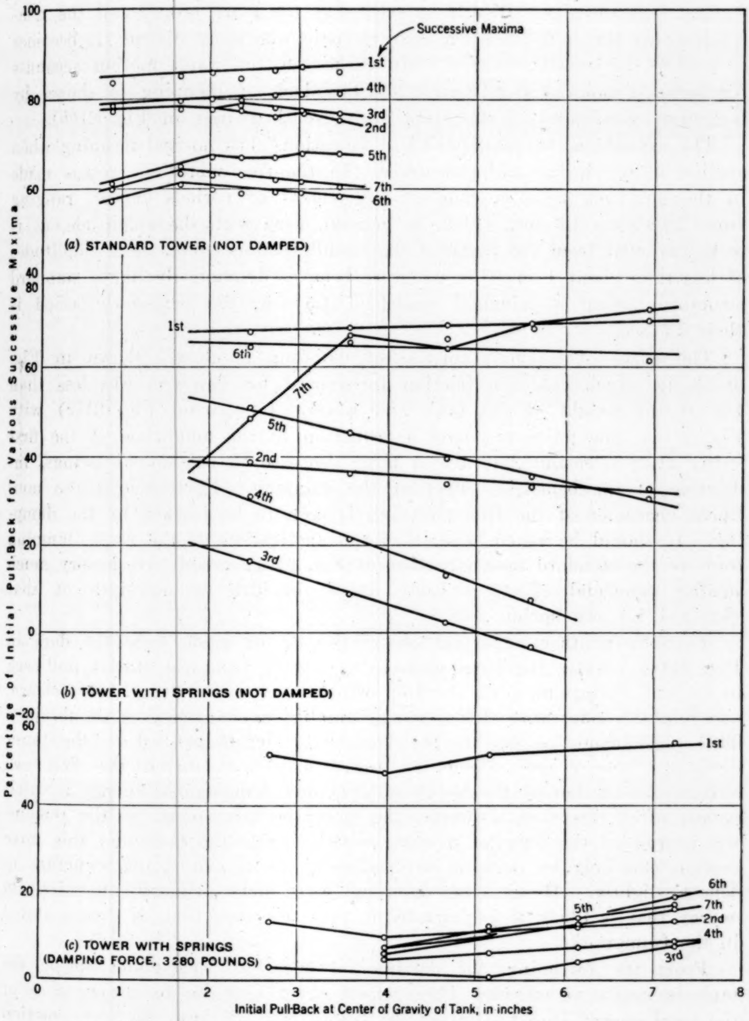

FIG. 21.—FREE VIBRATION OF TANK WHEN SUDDENLY RELEASED FROM A PULLED-BACK POSITION

Fig. 21(*b*) shows graphically the free vibration characteristics of the spring-equipped structure with no damping acting. Here, a pronounced non-linearity is observed, as evidenced by the great deviation of some of the plotted lines from the horizontal. Comparing Fig. 21(*b*) with Fig. 15, one can obtain a further conception of the relation between dynamical and statical non-linearity. It will be seen that the more pronounced the non-linearity of the load-deflection characteristic, the more difficult it becomes to predict dynamical behavior. (In each case, the water motion accounts for some dynamical non-linearity.) The lack of damping is shown by the large amplitudes of the sixth and seventh swings in Fig. 21(*b*).

The expression, "natural period of vibration," has no real meaning when applied to the spring-equipped tower. In the free vibration records made in the pull-back tests, a complete assortment of periods appear, ranging from 3.5 sec to 1.5 sec, which, in general, vary with the amplitude, as is to be expected from the shape of the load-deflection curve. For amplitudes of less than about 1 in., this structure behaves dynamically like a standard structure having a principal period of 1.5 sec; the secondary period is then 2.7 sec.

The effect of a small amount of damping is clearly shown in Fig. 21(*c*), in which case the friction force used for damping was less than 1% of the weight of the tank and water. Comparing Fig. 21(*c*) with Fig. 21(*b*), one notes not only a reduction in the amplitude of the first swing after releasing, but also a large decrease in subsequent swings, indicative of the beneficial effect of the damping. Furthermore, the non-linear character of the free vibration is seen to be masked by the damping. It should be noted, also, that the application of the same damping force to the standard tank structure of Fig. 21(*a*) would have a very much smaller beneficial effect, probably about one-fifth or one-sixth of that obtained for the spring tower.

There is another important observation to be made from the data in Fig. 21(*c*). After the large drop in amplitude from the initial pull-back to the first swing and from the first swing to the remainder of those shown, one might wonder why the decay in amplitude changes pace so abruptly. This phenomenon is due to the fact that friction applied to the tower dissipates energy only when the tower deflects. During the first two swings, the motion of the tower is large and considerable energy is dissipated; after this time, however, the water contains most of the remaining energy in the form of a wave motion inside the tank and this wave motion can only be damped out indirectly as it causes the structure to deflect slightly. Hence, the damping force acts primarily to dissipate energy that is likely to be harmful to the structure; that is, energy stored in the framework.

From the foregoing, the detrimental effect of baffle-plates inside the tank is easily visualized. Their effect could only be to throw more of the total energy into the structural frame and less into the wave motion of the water. In the case of very large and flimsy storage tanks, the capacity of the tank shells to withstand the surging motion of the water may well be questioned. The shells of the standard elevated tanks of capacities not greater than 100 000 or 150 000 gal are most likely quite strong enough to stand the water forces, provided the strength of the roof is properly utilized to support the upper part of the shell.

SPRING ELEMENT DESIGN; SCALE OF MODEL, 1:25

Earthquake Tests; Undamped Spring-Equipped Tower, Tested Parallel to Sides; Motion N 40° E.—The behavior of the undamped spring tower was first investigated by applying the Los Angeles, N 40° E, earthquake motion to its base, the direction of motion being parallel to the sides of the tower. To insure the safety of the model, the amplitude of this motion was reduced by the factor, 0.72, of the actual earthquake amplitude. This factor is referred to throughout this paper as the "Amplitude Factor" and signifies the ratio of the testing amplitude to the amplitude of the actual earthquake as recorded by the accelerograph in the Subway Terminal Building, in Los Angeles.

Tests made by applying the described motion at various speeds are plotted in Fig. 22(*a*). The maximum deflection of the tank (relative to its base) occurring during the application of the earthquake motion is plotted against the time factor. The "Time Factor" represents the ratio of the duration of the earthquake in the test to the duration of the actual earthquake as recorded by the accelerograph. Thus, a time factor of 1.10 denotes that T sec of actual earthquake occupied 1.10 T sec in the test; that is, a time factor greater than 1.00 indicates that the motion was more slowly applied than the actual earthquake. Since as previously mentioned, all data in this paper have been expressed in terms of the full-sized structure, no attention need be paid to scale relations, and all the curves may be interpreted directly as if the tests had been made on the full-sized structure.

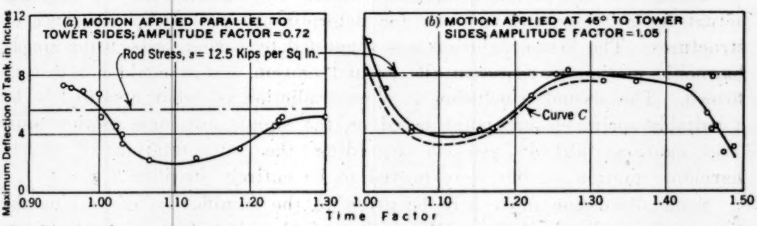

FIG. 22.—MAXIMUM DEFLECTION-TIME FACTOR CURVES, TOWER WITH SPRINGS; NOT DAMPED; LOS ANGELES MOTION, N 40° E.

The horizontal broken line in Fig. 22, and in subsequent diagrams, is a reference line for comparing the various sets of tests. It represents the deflection at which a rod stress of 12 500 lb per sq in. is developed, and by noting the position of the curve of tank deflection relative to this line one can interpret the results in terms of stress. Fig. 15 will also be found helpful in this respect. The reference stress line was chosen at the break-over point of the load-deflection curve (see Fig. 15). To be consistent, the same stress was used as a reference line for the standard tower data (see Figs. 19 and 25). It is for comparison only and does not represent "safe" or "working" stress.

Fig. 22(*a*) indicates that without damping the spring elements cannot be considered very satisfactory because, although dangerous deflections are not reached anywhere on the curve, they certainly might be if the amplitude factors were raised from 0.72 to 1.00, or more. Two important conclusions were drawn from these tests. It was evident: (*a*) That damping should be present if the Los Angeles earthquake records can be accepted as representing a possible kind of motion to be found in Nature; and (*b*) that it would have been much better to have chosen a structure capable of about double the maximum safe deflection originally chosen. In other wards, instead of having the springs close at a deflection of about 6 in., they should close as far out as the structure can safely be deflected (15 in. is a practical figure from the standpoint of column bending and spring design, although 20 in. does not seem unreasonably large.)

These two conclusions emphasize clearly the desirability of applying actual irregular ground motions for determining earthquake resistance of structures. The first conclusion was suggested by earlier tests, using simple harmonic motion to represent the ground motion, but it could not be confirmed. The second conclusion is a contradiction of what appeared to be a suitable spring-closure point based on the simple harmonic motion tests. The cautions already stressed regarding the interpretation of simple harmonic motion studies were proved to be entirely justified.

Some discussion must here be given to the significance of varying the time and amplitude factors. Variation of the time factor can be interpreted in two ways: (1) With a given structure, varying the time factor makes it possible to find what effect the earthquake would have if it happened faster or slower, but with the character of the motion preserved as recorded; and (2) with a given earthquake, varying the time factor has the same effect as changing the natural vibration period of the structure. In other words, by varying the time factor the experimental results can be generalized considerably, whereas if only a time factor of unity is used the results can be applied only to one particular earthquake acting on one particular structure.

The significance of varying the amplitude factor is obvious. It makes it possible to generalize the results in another direction, so that the effect of the same motion changed in amplitude can be seen.

Fig. 23(*a*) represents a series of tests following those previously described, the purpose being to find how the behavior of the structure would vary with changing amplitudes of the same earthquake motion. The time factor was held constant. These results show that the maximum tank deflection is very sensitive to small changes of earthquake amplitudes when no damping is present. They emphasize the correctness of Conclusions (*a*) and (*b*), cited in discussing Fig. 22(*a*). No attempt was made to carry the amplitude factor near to unity for fear of over-stressing the model.

Earthquake Tests; Undamped Spring-Equipped Tower, Tested Diagonally; Motion N 40° E.—Since there were not sufficient funds available to permit building and testing a model to represent the design suggested by the tests just described, it was decided to turn the model so that the motion could be applied diagonally. In this position, the safe deflection is increased by $\sqrt{2}$, and it was thought that the results would be interpretable.

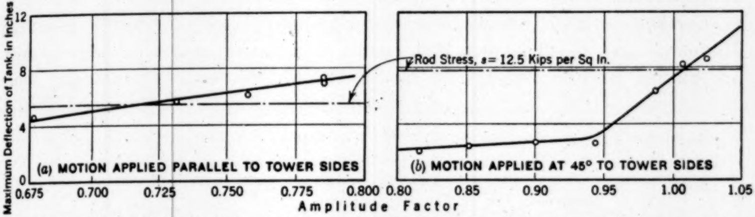

FIG. 23.—MAXIMUM DEFLECTION-AMPLITUDE FACTOR CURVES, TOWER WITH SPRINGS; NOT DAMPED; LOS ANGELES MOTION, N 40° E; TIME FACTOR, 1.02

Fig. 22(*b*) (full line) is a plot of the results of a series of tests with earthquake motion at N 40° E applied diagonally to the tower and with an amplitude factor of 1.05. The reference stress line will aid in comparing with Fig. 22(*a*). In order to determine how well the diagonal tests could be used for interpreting the behavior parallel to the tower sides, Curve 1 was computed from the data of Fig. (22*a*), as if the structure were linear; that is, it represents the behavior of the tower under the same conditions, as computed by compounding the tests parallel to the sides. The agreement indicates that it is probably safe to accept the results of the diagonal tests as also applying to tests parallel to the sides of the same tower, by resolving into components as for a linear system.

Of course, a direct interpretation can be made by noting that the diagonal tests merely represent a tower with a load-deflection characteristic somewhat different from Fig. 15. It makes no difference in what direction this characteristic is taken to be; the behavior is dependent only on the moving mass and the character of the load-deflection curve.

From this study, it was concluded that applying the test motion diagonally would serve the purpose quite well. Conclusions (*a*) and (*b*), cited in connection with Fig. 22(*a*), were further substantiated.

A set of tests was then made to find the effect of changing the amplitude factor when shaking the structure diagonally. The results are plotted in Fig. 23(*b*). The form of the curve here closely resembles that obtained by varying the amplitude of the simple harmonic motion applied in earlier experiments (see Fig. 12(*a*)). Fig. 23(*a*) would show the same characteristics had the curve been extended far enough to the left. As long as the deflections of the structure do not pass the upper break in Fig. 15

(or the corresponding point for diagonal tests), the shape of the part of the load-deflection curve beyond this break has no effect upon the results, and one can just as well imagine that the break has been moved farther out to the right, as it should be. (The upper break in Fig. 15 is caused by the closing up of the spring elements. Its position can be varied between wide limits by a proper choice of springs.)

Earthquake Tests; Damped Spring-Equipped Tower, Tested Diagonally; Motion N 40° E.—The principal results of a large number of experiments are plotted in Fig. 24(*a*). As in Fig. 22(*b*), the testing conditions were

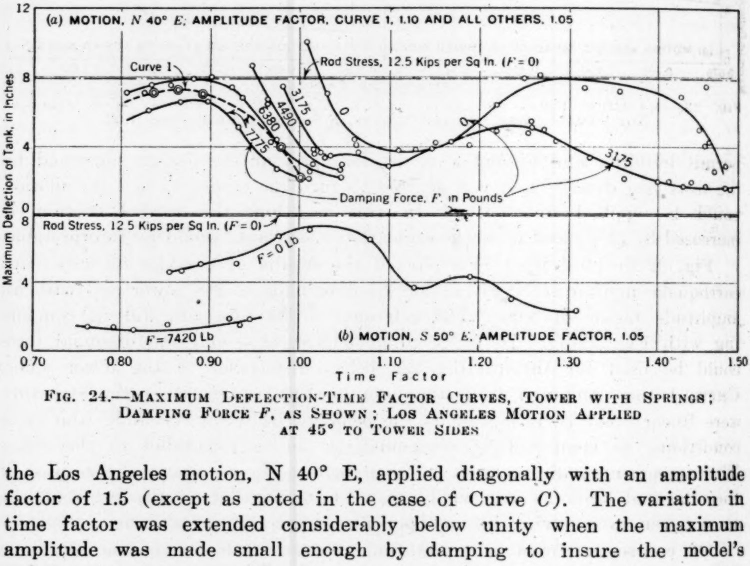

FIG. 24.—MAXIMUM DEFLECTION-TIME FACTOR CURVES, TOWER WITH SPRINGS; DAMPING FORCE *F*, AS SHOWN; LOS ANGELES MOTION APPLIED AT 45° TO TOWER SIDES

the Los Angeles motion, N 40° E, applied diagonally with an amplitude factor of 1.5 (except as noted in the case of Curve *C*). The variation in time factor was extended considerably below unity when the maximum amplitude was made small enough by damping to insure the model's safety.

Within the limits of the damping force applied in these tests the maximum tank deflection progressively decreased as the damping was increased, the beneficial effect tapering off as the damping became greater. Since the maximum stresses set up in the tower members result from the maximum tower deflection and the frictional force acting together, it is obvious that there must be some optimum frictional force beyond which the reduction in maximum amplitude due to a further increase in friction will be more than offset by the additional stresses produced by the increase in the friction itself. That this point was not reached in the tests plotted in Fig. 24, will be seen by noting that increasing the damping force, *F*, from 6 380 lb to 7 775 lb (or 1 395 lb) reduced the maximum deflection by about 1.2 in., which by Fig. 15 amounts to a reduction of more than 3 500 lb in the pull on the tower due to deflection; that is the net gain in reducing tower stress corresponds to a horizontal load of more than 2 000 lb at the tank.

The reasoning just given leads to the important consideration that most likely there are load-deflection characteristics much more desirable than that chosen for this particular study. Thus, it seems fair to conclude from the data obtained that the same structural design, equipped with somewhat more limber springs and adequate damping, would exhibit considerably lower stresses under the same earthquake conditions. The economic considerations involved in the choice of design could not be investigated with the funds available. Here is perhaps the most inviting field for future research, and it should be explored thoroughly if the new type of construction is to be applied to any extent in practice.

One set of tests was made with the amplitude factor increased to 1.10 to observe the sensitivity of the damped structure to amplitude changes. Curve 1 in Fig. 24(*a*) is a plot of the results of these tests (frictional force = 7 775 lb). The maximum of this curve is only about 10% greater than that of the corresponding curve for amplitude factor (= 1.05), indicating that the amplitude sensitivity has been reduced to a reasonable value by the damping action (compare Figs. 23(*a*) and 23(*b*)).

Limited as the data of Fig. 24(*a*) of necessity had to be, they demonstrate definitely the possibilities of the damped spring-element type of construction as a practical engineering approach to the problem of building earthquake-proof tank towers, and perhaps some other types of engineering structures as well.

Earthquake Tests; Spring-Equipped Tower, Tested Diagonally; Motion S 50° E.—The effect of the S 50° E component of the Los Angeles motion on the spring-equipped structure was found to be much less than that of the N. 40° E component. Fig. 24(*b*) is a plot of the results of tests made under the same conditions as those in Fig. 24(*a*) except for the different earthquake component. The tank motion proved to be so much more gentle than that for the other component that, after exploring the response of the undamped structure over a wide range of time factors, it was decided to limit the damping tests to one set (7 420 lb of frictional force). The significance of these curves is obvious. (Compare the relative effects of the two components on the standard structure, Figs. 25(*a*) and 25(*b*)).

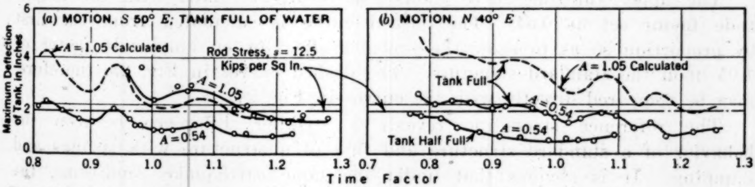

FIG. 25.—MAXIMUM DEFLECTION-TIME FACTOR CURVES, STANDARD TOWER; NOT DAMPED; LOS ANGELES MOTION APPLIED AT 45° TO TOWER SIDES; AMPLITUDE FACTOR, *A*, AS SHOWN

Standard Tower; Scale Model, 1: 25

Earthquake Tests; Standard Tower, Tested Diagonally, Motion S 50° E.—It was felt that this research would be somewhat inconclusive without some experiments giving a comparison of the dynamical behavior of a standard rod-braced tower with that of a spring-equipped tower under identical earthquake conditions. Accordingly, the model was made to represent the standard structure described in connection with Figs. 18 and 19. The S 50° E component was first applied because it was expected to be the gentler of the two. The motion was applied diagonally to the tower to allow the maximum possible safe deflection. (In the case of the standard tower, the load deflection characteristic is practically identical in all directions, so that the tests described herein apply equally well to other directions.) The amplitude factor was fixed at 1.05 as before and a set of tests was made by varying the time factor from 1.28 to 0.96, at which point it was decided that it might be dangerous to the model to proceed farther without reducing the amplitude factor (see Fig. 25(*a*), upper full-line curve).

In order to explore the response for smaller time factors, the amplitude factor was reduced to 0.54 and tests were made over a wide range of time factors. The results are plotted in the lower full-line curve in Fig. 25(*a*). Knowing the approximate linearity of the structure from statical and free vibration tests, it was assumed that the results obtained with the reduced amplitude factor could be extended fairly well to larger amplitudes by computation. The dashed curve in Fig. 25(*a*) shows how this assumption agrees with the facts. This curve was obtained by simple proportion from the lower full-line curve, each ordinate of the former being $\frac{1.50}{0.54}$ times the corresponding ordinate of the latter.

Earthquake Tests; Standard Tower, Tested Diagonally; Motion N 40° E.—It seemed wise to apply the N 40° E component with the reduced amplitude factor of 0.54 also, because of the danger of overstressing the model. Fig. 25(*b*) is a plot of the results obtained with this motion.

The upper full-line curve shows the results observed with the amplitude factor set at 0.54. The dashed curve is calculated from the first by proportion so as to show the probable effect of an amplitude factor of 1.05 upon the standard structure. The dashed curves in Fig. 25, therefore, may be compared directly with the curves in Fig. 24.

The reference stress-line reveals a striking difference between the behavior of a standard structure and that of a structure with springs and damping. It is obvious that under the same earthquake conditions, the stresses in the standard tower reach values two or three times as great as those in the spring-equipped structure having about 7 000 lb of friction damping. This situation is brought about as follows: The rigidity of a standard tower, by giving it a relatively short natural period of vibration, results in considerably smaller earthquake deflections than are produced in a moderately damped spring-equipped tower with its longer period.

On the other hand, the rigidity of a standard structure is so much greater than that of a spring-equipped tower, that the beneficial effects of the decreased deflections are more than offset by the large forces required to produce them.

In Fig. 25, one is impressed by the small decrease in maximum tank amplitude as the time factor changes from 1.00 to 1.15. Recalling the second interpretation of the time factor variation stated in discussing Fig. 22, it is clear that, as the time factor goes from 1.00 toward the right, the results indicate the probable behavior of a structure stiffened even further than the one chosen for the present research. Thus, at Time Factor 1.15 the results may be interpreted as closely representing the effect of the earthquake upon a tank structure having a natural period $\frac{1}{1.15}$ times that of the structure described in Figs. 18 and 19, and since the natural period varies inversely with the square root of the tower stiffness, the new stiffness would be $(1.15)^2 \times 23\,100 = 30\,500$ lb per in. This is 1.9 times as stiff as the standard structure studied in earlier investigations. To achieve this stiffness requires a surprising area of steel.

Thus, it must be concluded that the degree of direct strengthening that is generally applied cannot be expected to insure the ability of the structure to withstand the earthquake motions in question. (In this connection it is interesting to note that if the areas of the rods in the lower two panels, Fig. 18, are doubled, leaving the top rod areas as shown, the resulting earthquake unit stresses will be increased by more than 15 per cent. The rod areas in Fig. 18 have been chosen to give a safe deflection much greater than that achieved in the usual "quake-proof" structure, in which no particular attention is given to balanced design. Furthermore, the unit stresses used in this design were very conservative—20 kips per sq in. rod stress at 10% gravity loading. If higher unit stresses are used, the natural period will be lengthened.) Although only the motions of one particular earthquake were available for these studies, the fact that the same conclusion was reached from the results of the application of simple harmonic motion in earlier experiments indicates that it cannot be ignored in any serious discussion of quake-resistant design for elevated water-tanks.

That strengthening of towers, as now practiced by some designers, does generally serve to produce a better design with sounder structural details is not to be gainsaid; indeed, improvement in that direction is commendable and much needed. It must not be imagined, however, that the process has a rational dynamical basis.

Earthquake Tests; Standard Tower with Tank Half Full, Tested Diagonally; Motion N 40° E.—The lower full-line curve in Fig. 25(*b*) represents a series of tests made with the tank half filled with water. All other conditions were kept the same as for the tests plotted in the upper full-line curve. These results help to answer the much-asked question about the behavior of a partly filled tank.

The reduction in deflection in the half-full tests must not be attributed directly to the change in mass. It is brought about solely by the shortened period resulting from the decrease in the ratio of mass to tower stiffness. Had the stiffness of the structure at the same time been reduced by one-half, the behavior would be closely represented by the upper full-line curve in Fig. 25(*b*). The dynamical behavior is purely a matter of the natural periods of the structure and is not directly dependent upon its physical proportions.

That this is so may be verified by replotting the curve for the half-full tank, giving each point the same ordinate but multiplying its time factor by $\sqrt{2}$. This procedure is equivalent to treating the results as applying to a full tank with a natural period $\frac{1}{\sqrt{2}}$ times that of the actual full tank studied. The result will be a curve to the right of Time Factor 1.08 coinciding very well with the experimental curve for the full tank.

Extending this reasoning in the direction of added mass instead of decreased mass, it is evident that unless the tower stiffness increases in proportion to the capacity of the tank, the natural period will be greater than that of the structure taken as the prototype in the present research, which is the same as working to the left of Time Factor 1.00 in Fig. 25. Keeping in mind the fact that the natural period of the structure tested in these studies was about 1.3 sec, with a stiffness 1.44 times that of the original tank, one cannot avoid the conclusion that, for larger tanks and for tanks on higher towers, the natural periods cannot economically be made short enough to help matters very materially. (Mr. D. S. Carder has presented valuable data[10] on observed tank periods. In this connection, it is important to bear in mind that a small amount of initial tension in the rod-bracing can produce a natural period for small amplitudes which is considerably shorter than the natural period for amplitudes such as exist during an earthquake.) Besides, one must consider the fact that non-rigid foundations will invariably lengthen the period of a structure, which might annul, partly or totally, the beneficial effect of the increased tower stiffness.

It should not be inferred that the lengthened natural period brought about by the introduction of spring elements is a desideratum; in itself it is to be regarded rather as an unavoidable, and not necessarily desirable, effect resulting from the necessity of providing a greater range of deflection to the structure. The increased limberness makes it possible to introduce damping action into the system and requires a far smaller damping force than would be needed for a stiff structure.

COMPARISON OF EARTHQUAKE STRESSES IN STANDARD AND SPRING-EQUIPPED TOWERS

In comparing the earthquake stresses in the standard and spring-equipped structures one must take account of the fact that, in Nature, the two components of ground motion occur simultaneously, whereas they were treated separately in the laboratory work. This means, of course, that the orientation of the structure in question relative to the recorded components of motion is of importance. Since it is beyond the scope of this paper to compare the two structures under all possible orientations, the writer has chosen to compare them only when oriented in such a manner that the standard structure has every advantage over the spring-equipped structure.

---

[10] *Bulletin*, Seismological Soc. of America, January 1936, Tables I and II; also, *Special Publication No. 201*, U. S. Coast and Geodetic Survey, pp. 75–95.

A study of Figs. 24 and 25 and of the laboratory records shows that, if the recorded ground-motion components are simultaneously applied parallel to the tower sides for both structures, the standard tower will be stressed about 25% less than at its worst possible orientation, whereas the spring-equipped tower is oriented so as to receive within 5% of its worst possible stresses. The comparison will be made on the basis of an amplitude factor of 1.05.

The stress calculations involve only straightforward statical analysis, once the deflections are known from the experimental data (the gravity effect must not be ignored in computing the stresses). The deflections of the standard tower will be substantially the same regardless of the direction of the applied earthquake motion, because the tower stiffness is substantially the same in all directions. The maximum deflections of the damped spring-equipped tower, however, will be somewhat greater parallel to the sides than in the diagonal direction for the same earthquake motion. In the following data, the deflections parallel to the sides are assumed to be 35% greater than the diagonal deflections for the spring tower, which the writer considers a generous allowance. Data are also given for the case in which no such assumption need be made. In the absence of complete data to determine the value of 35%, the writer has set what seems to be an upper limit, based on his experience with the system. He prefers the more direct interpretation of stresses given in the last paragraph of this section, since the element of estimation is there eliminated entirely.

For the standard tower under the conditions specified, the rod stress at a time factor of 1 would be more than 28 kips per sq in.; and for the worst case ($P = 0.82$) the rod stress would be about 40 kips per sq in., which is beyond the normal yield point. It is not necessary to postulate any great increase in the violence of the ground motions closer to the epicenter in order to explain the failures which occurred, knowing that few of the existing structures could safely withstand as much deflection as the structures studied herein, and that most of the larger ones corresponded to time factors of considerably less than unity.

As a matter of fact, some rods were stretched permanently in a tank tower situated 3.7 miles from the Subway Terminal Building, in Los Angeles, where the motions used in this research were recorded. This structure is a 100 000-gal tank on a 100-ft tower, and, at the time of the Long Beach earthquake, was braced for wind velocity of 100 miles per hr. At that time, it corresponded to a time factor of about 0.9. The calculated maximum rod stress for this structure, based on the experimental data in Fig. 25, proves to be 56 kips per sq in. for an amplitude factor of

1.05 and a time factor of 1.00, or 53 kips per sq in. for the earthquake as it was recorded. (These high values, of course, are fictitious, since the elastic limit of the material would be passed at lower stresses.) Failure might easily occur, therefore. Several other tank structures within a few miles of the Subway Terminal Building also showed evidence of very high stresses. Since, in these cases, there were indications of flaws in material, workmanship, or details, they are not cited herein as numerical examples.

The stresses set up in the damped spring-equipped structure, under identical earthquake conditions (allowing 35% extra deflection), prove to be quite low in comparison. With a damping force of about $\frac{7\,500 \text{ lb}}{\sqrt{2}}$ (parallel to sides) the rod stress at a time factor of 1 would be less than 10 kips per sq in. (compared with more than 28 kips per sq in. in the standard tower). In the worst case ($P = 0.88$) the rod stress would be less than 20 kips per sq in. (compared with a stress beyond the yield point in the standard tower). Thus, even with a generous margin in favor of the standard structure, the damped spring-equipped tower shows a minimum safety factor of at least 2 over the standard tower. A 25% increase in damping would raise this safety factor to above 2.25; or, if a more direct interpretation is desired (in which no assumption need be made as to deflection increase parallel to sides), the following will suffice: Given a tower whose load-deflection characteristic parallel to the sides is the same as that of the tested structure in a diagonal direction, and given a damping force of 7 500 lb, the rod stress in the worst case ($P = 0.88$) would be less than 19 kips per sq in. (minimum safety factor, greater than 2). It is to be remembered that the assumed orientation is such as to give the advantage to the standard structure by perhaps 20%, which was ignored in calculating the safety factors.

General Conclusions Drawn from Research

It is not intended to list herein a set of conclusions that may be read casually and without a careful study of the supporting text. Such a procedure would be worse than useless; it might even be dangerous. Certain general conclusions, however, can be drawn from the results of this research, provided the limitations and cautions already set forth have been thoroughly digested. These conclusions are:

(1) The standard type of elevated tank tower now in common use is poorly adapted for withstanding earthquakes of destructive intensity, both on acount of the absence of damping action and of its inability to withstand large deflections.

(2) A moderate degree of strengthening does not, and can not, improve the earthquake resistance of a standard tower very materially; that is, if the recorded motions of the Long Beach earthquake of 1933 can be taken as indicative of what may be expected in future earthquakes. The data from these motions indicate that a properly balanced strengthening is somewhat

better than a straight wind design, but in the absence of a more general knowledge, of possible earthquake motions, this conclusion cannot, of course, be accepted without reservations. (By "balanced strengthening" is meant strengthening of the tower bracing members in proportion to the loads they carry, as distinguished from the common practice of using the same rod size in two or more panels. The safe deflection of a standard 100-ft tower can sometimes be increased as much as 50% by a balanced design of the bracing.)

(3) It would be impractical to provide sufficient safe deflection to insure the safety of the structure under all conditions by using springs without damping. Given a safe deflection of about 15 in., the undamped spring tower would probably fare better, on the average, than the standard structure but its safety factor would not be dependable.

(4) The presence of sufficient damping in a properly designed spring-equipped tower gives it a safety factor in stress of at least 2 over the standard structure which has been designed for a loading equal to $0.1g$. Damping also provides a safety factor in the duration of violent motion that the structure can withstand—a quantity difficult to express numerically but of great importance. The damping required in the particular design investigated was found to be small enough to be easily achieved in practical design (see Fig. 17).

(5) The results obtained are restricted in scope, and they cannot be extended safely to apply to structures of much greater or much smaller proportions than the tower actually studied. One must not resort to "engineering judgment" in dynamical problems unless one has had considerable experience with them. Practical limits for applying the present results might be 50 000 to 100 000-gal capacities and 150 to 100-ft tower heights, respectively.

(6) The introduction of the proper spring elements does not endanger the stability of the tower structure. Considered as a three-dimensional framework, it is necessary to investigate the effect of possible dissymmetry due to accidental differences in action between the elements on opposite sides of the tower. Although the model did not exhibit serious torsional effects from lack of symmetry, a good engineering design should specify horizontal panels of light rod-bracing at the strut levels, in order to eliminate any undesirable twisting effects which might be produced if some of the damping devices failed to act properly. (The conventional spider can be adapted for this purpose.)

(7) Baffle-plates inside an elevated tank would be detrimental within the limits of the tank size specified in Conclusion (5).

(8) For designing structures within the foregoing prescribed limits of size, the following rules should result in a safe design:

(*a*) Design the structural frame for a static horizontal load of one-tenth the weight of the tank and water applied at the center of gravity of the tank. The columns and struts should be designed so that the rod-bracing would fail first if the structure were tested to destruction by static horizontal loading.

(*b*) Provide a set of springs such that, with the initial compression set for a horizontal force at the tank equal to one-fiftieth of the weight of the tank and water, the tower can deflect at least 15 in. parallel to its sides before the springs close.

(*c*) Design the stiffness of the springs such that at the point of closure the horizontal load is approximately equal to the design load used in Conclusion (8*a*).

(*d*) Design the individual spring elements so that the total tower deflection is about equally distributed between the panels (to avoid high bending stresses).

(*e*) See that the bending stresses in the tower members are not excessive. Use pin-connected struts if necessary, and reduce eccentricity to an absolute minimum. The riser pipe should be equipped with flexible joints if necessary and must be able to follow the tower motions.

(*f*) The damping forces should be such that the energy dissipated by damping during a motion of the tank (parallel to the tower sides) from its equilibrium position out to the maximum safe deflection and back again, is approximately equal to 50% of the energy stored elastically when the structure is at the maximum safe deflection (parallel to the tower sides).

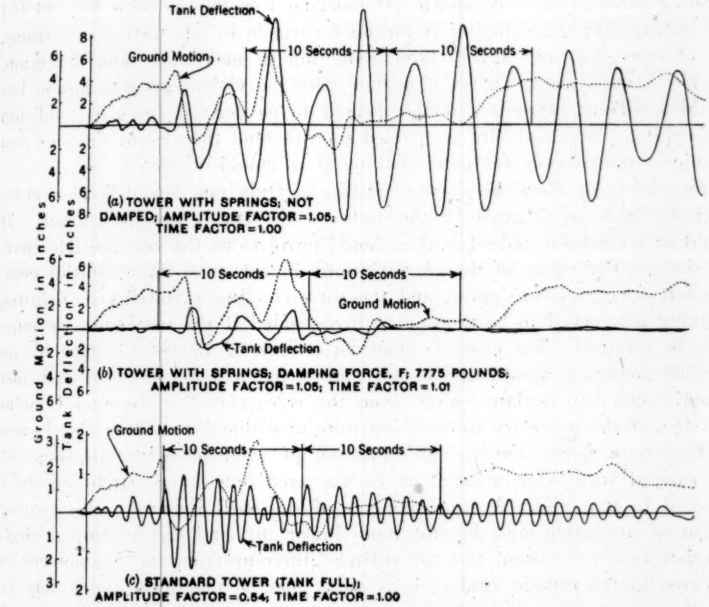
(*g*) The total damping force should be distributed among the spring elements in proportion to the stresses produced in the various rods by a static horizontal load at the center of gravity of the tank. The damping force need not be the same for an outward deflection as for the return to equilibrium, but that for the return stroke should not exceed about 85% of the wind-load initial compression setting; otherwise, all the rods may sag at times.

(*h*) The damping force should be fairly independent of velocity. It would be a good rule to make the damping force corresponding to a tank velocity of 30 in. per sec. (relative to the base) not more than 25% greater than that calculated by Conclusion (8*f*). The damping may be produced by simple sliding friction if desired, in which case the kinetic friction should be made equal to that computed by Conclusion (8*f*).

REMARKS

Relation of Tank Deflection to Ground Motion.—The graphs in Fig. 26 are reduced tracings of records made by applying the Los Angeles motion, N 40° E, to the undamped spring tower, the damped spring tower, and the standard tower, respectively. The time factor is nearly identical for all cases and the scales given are self-explanatory. A careful study of the nature of the tank motion relative to the ground motion in the three diagrams will be found helpful to those who are not well versed in dynamics.

In the first place, one observes that there is no simple relation between tank response and earthquake motion. The notion that statical force equal to the mass of the tank and water times the maximum ground acceleration can be used safely for design against earthquake is seen to be entirely without basis.



(a) TOWER WITH SPRINGS; NOT DAMPED; AMPLITUDE FACTOR = 1.05; TIME FACTOR = 1.00

(b) TOWER WITH SPRINGS; DAMPING FORCE, F; 7775 POUNDS; AMPLITUDE FACTOR = 1.05; TIME FACTOR = 1.01

(c) STANDARD TOWER (TANK FULL); AMPLITUDE FACTOR = 0.54; TIME FACTOR = 1.00

FIG. 26—TYPICAL RECORDS, LOS ANGELES MOTION, N 40° E. APPLIED AT 45° TO TOWER SIDES

Next to be observed, is the serious consequence of the lack of damping shown in Fig. 26 (*a*) and Fig. 26 (*c*). In both cases, the structure continues to vibrate vigorously after the main ground motions have subsided. The cases chosen for discussion are by no means the worst observed in this respect; on the contrary, they are quite typical. What might have happened had there been several more large ground swings immediately following those in the early part of the Long Beach earthquake can only be conjectured, but if such swings happened to be nearly "in step" with the already large tank vibrations shown in Fig. 26 (*a*) and Fig. 26 (*c*), collapse would have been almost certain.

It is to be regretted that the accelerograms taken in Long Beach proper could not be completely analyzed because of the overlapping of the components on the record. Consequently, there is no rational method by which to estimate the relative intensities at Long Beach and Los Angeles except by comparison of destructive effects, and this is admittedly not very satisfactory. However, it is fairly certain that the motions used in the present research cannot be considered as representing the worse conditions to be designed against in an active earthquake zone, such as the West Coast. Hence, the desirability of adopting a generous and real safety factor is apparent.

In Fig. 26 (*b*) the beneficial effects caused by the addition of a moderate damping force are clearly shown. Comparing Fig. 26 (*a*) with Fig. 26 (*b*) and noting that the damping is the only variable in the testing conditions, one observes not only a very large reduction in maximum tank deflection, but also a quick decay in the vibration after the violent ground motion has subsided. Thus, there is a double benefit to be derived from the addition of damping. The structure is enabled to withstand the violent motions and is quickly made ready for more shaking if it should come.

Possibility of More Economical Designs.—Only one load-deflection characteristic was investigated in the tests of the spring-equipped tower. It would be remarkable indeed if this should prove to be the best possible characteristic. The effect of design variations in spring stiffness, initial compression, spring closure point, and the corresponding variations in required damping force need to be thoroughly investigated if the maximum economy is to be attained. For example, consider a tank of 150 000-gal capacity on a 125-ft tower; it would undoubtedly prove far more economical and just as satisfactory to deviate widely from the rules stated in General Conclusion (8), if the necessary information were available for guiding the design.

Extremely Large Tanks.—The question of what procedure to adopt in the case of very large tanks is to be answered only by research especially directed to that end. As the diameter of the shell increases, the surging action of the water must become more important, and the dynamical characteristics of the system may be entirely different from the characteristics observed in the present study. It is quite possible that baffle-plates may be found necessary to prevent dangerous stresses in the shell in some instances.

Size of Riser Pipe.—It has been assumed in the foregoing discussion that the riser pipe is small (say, 6 in. to 12 in. in diameter), so that if made of steel and provided with flexible joints, if needed, it can be forced to conform to the configuration of the swaying tower during an earthquake. Large risers, which in effect tend to act as stand-pipes of considerable stiffness, would be rather difficult to provide for in the spring type of construction. The very considerable vertically distributed mass of water in large risers presents a problem to which the results thus far obtained do not apply.

The Element of Chance.—The extent to which pure chance enters into the destructive effect of earthquakes is perhaps not generally appreciated: The orientation of the structure relative to the direction of the most violent motion; the location of the structure in the shaken region; the relation of the natural vibration period to the frequency spectrum of the earthquake; hidden structural defects; characteristics of tower parts at stresses beyond the elastic limit—all these are factors vitally affecting the behavior of the structure and all are matters of chance over which the engineer has no control whatever.

A careful consideration of the foregoing chance factors leads to an understanding of the difficulties confronting those investigators who have undertaken to formulate design rules based upon field studies of the effects of destructive earthquakes. For instance, there is the fact that a tank tower designed for a static force of $0.1g$ (the only one so designed to the writer's knowledge) survived the Long Beach quake safely. This fact, apparently, has led a number of engineers to accept, tentatively, the $0.1g$ rule as satisfactory for elevated tanks.

Now, had there been, say, forty or fifty tanks of random sizes designed by this rule and a like number designed for wind only, and had they all been fairly well scattered over the destructive region, then there would be a real basis for drawing conclusions as to the superiority of one type to the other from field studies. As matters stand, however, about the most that can be concluded definitely from examination of the effects of the Long Beach quake is that certain tanks did fail totally or partly; and, by examination of the damaged structures, weak points in the details can be brought to light and corrected in the future. To credit the methods of design for saving those structures which did not fail, would lead to some awkward contradictions.

Tanks for Municipal Supply.—It is unfortunate that few municipal storage tanks are small enough to come within the scope of the research described in this paper. As far as importance to the community as a whole is concerned, these structures should receive by far the most serious consideration. It is to be hoped that it will be possible some day to extend present knowledge to this vitally important field.

ACKNOWLEDGMENTS

The writer wishes to acknowledge gratefully the helpful co-operation of all who have contributed to the success of this research project.

The Associated Factory Mutual Fire Insurance Companies and the Freeman Engineering Corporation initiated the research and helped to make possible all the investigations described in Part I, also contributing a very considerable sum toward the construction of the new shaking-table. The engineers connected with these organizations recognized the serious lack of dependable design data and questioned the propriety of applying rule-of-thumb design methods unless they could be shown to produce safe structures. Their helpful and sympathetic attitude has been a source of inspiration as well as a means of keeping the work on a firm practical basis.

Thanks are due to the Chicago Bridge and Iron Works and to the Pittsburgh Des Moines Steel Company, which provided a large part of the funds for the experimental work described in Part II. These funds were given for the purpose of increasing current knowledge of earthquake effects upon tank structures, with no thought of financial gain except to earthquake-ridden communities.

The U. S. Coast and Geodetic Survey has given invaluable aid in providing data on ground motions and on the behavior of actual structures

studied in California, including the data on the Long Beach earthquake of March 10, 1933. Its interest in the work is most gratifying.

The studies, which extended over a period of two years, were made by the writer in the Laboratory of Engineering Seismology of the Massachusetts Institute of Technology. By providing funds for the design and construction of the new shaking-table and for the services of the writer for the duration of the entire research, the Institute has carried by far the greatest part of the financial burden. The Division of Industrial Cooperation has administered the project without making the customary charges for overhead expense to the Institute. In addition, the writer has profited by the valuable advice and assistance of Dr. Vannevar Bush, C. B. Breed, M. Am. Soc. C. E., Professor A. V. deForest, and many other members of the Institute staff.

Especial thanks are due to the four engineers without whose loyal assistance and hard work this research project could not have been carried out with the same degree of economy and success—Messrs. Chester H. Hosmer, Albert L. Grass, George Parmakian, and George W. Hines, all graduates of the Institute.

The data in Table 1 were computed by Mr. H. A. Sweet, Engineer with the Associated Factory Mutual Fire Insurance Companies, of Boston, Mass. Figs. 8 and 9 are reproduced from the drawings used in securing the patents, which are to be administered on a non-profit basis by that organization. These patents cover the general concept of applying spring elements to engineering structures for the purpose of increasing their resistance against earthquakes. The purpose of these patents is to make it possible to prevent the improper use of the new construction; otherwise, no restrictions will be imposed.

DISCUSSION

N. H. Heck,[11] M. Am. Soc. C. E. (by letter).—During recent years attention has been given to earthquake-resistance design of structures. In several places these investigations have been supplemented and based largely upon the results of tests of models of the structure on a shaking platform. At the Massachusetts Institute of Technology, at Cambridge, Mass., a light model can be tested on a platform which may be put into any desired kind of motion, including the reproduction of actual earth motion.

As indicated in Professor Ruge's paper the U. S. Coast and Geodetic Survey has not only made it possible to reproduce the earthquake motion through double integration of the acceleration records of the Long Beach (Calif.) earthquake, obtained at Los Angeles, but it has determined the periods of many tanks of different types and designs, thereby adding greatly to the validity of his conclusions. It will soon be possible to know the degree of accuracy of the deduced earthquake motions through shaking platform tests of the accelerometers made in May, 1937. Although the records have not yet (1937) been studied the results appear promising.

In outlining the special problem Professor Ruge has performed a service which extends to a wider field in showing that the earthquake manifests itself as inexorable motion rather than as direct force, and that the forces exerted depend primarily on the characteristics of the structures undergoing the motion. The complexity of his apparently simple problem becomes obvious when pointed out and indicates the important place taken by tests of a suitably designed model on a shaking platform.

The validity of the term, "artificial earthquake motion" (see heading, "Artificial Earthquake Motion"), may be questioned. Apparently, Professor Ruge has in mind that no earthquake record is yet available that contains the wide range of so-called destructive periods, so he uses the best substitute therefor. When supplemented by the use of earthquake motions actually observed, this procedure is the best available at present.

It should be understood that the Coast and Geodetic Survey has not yet found it possible to integrate all the strong-motion accelerograms that it has, and until this has been done the record cannot be applied to controlling the motion of a shaking platform. Lack of personnel has prevented this work and a special effort is being made to find whether the records can be integrated by the differential analyzer at the Massachusetts Institute of Technology. Furthermore, Frank Neumann, Seismologist, U. S. Coast and Geodetic Survey, is developing a torsion pendulum analyzer which deals with the specific problem. Attention may be called to the fact that although all the strong-motion accelerometers in California are not able to record the greatest possible range of earth motion, twelve instruments are equipped with a double-magnification system so that if the instrument survives a record will be obtained even if the acceleration is 0.5 *g*, or more.

---

[11] Chf., Div. of Terrestrial Magnetism and Seismology, U. S. Coast and Geodetic Survey, Washington, D. C.

In determining the vibration periods and in recording earthquakes in actual structures, the Coast and Geodetic Survey is concerned with design, and is anxious that every possible application be made of the information that it has obtained.[12]

Nevertheless, it must be remembered that it is not engaged in structural design. In some respects this may be inconvenient for the engineer, but on the other hand it has the advantage that results are obtained without any desire to support any particular theories, and this may prove of great advantage in the future. Accordingly, the writer will not discuss Professor Ruge's proposed design further than to state that the Long Beach earthquake proved the inadequacy of present design to resist severe earthquakes and that these structures will have to be designed in some other way in order to survive.

No exception is taken to Professor Ruge's remarks as to the element of chance (see heading, "Element of Chance"), except to note that he fails to emphasize one element that may be the key to the great variety of observed effects—the varying conditions of the geological substratum. This can cause changes in the periods and amplitude of the motion and the amount of energy. However, this merely emphasizes the expressed view that valid conclusions can be based only on a large number of cases.

It should be emphasized that the records of the Long Beach earthquake, at Long Beach, and at Vernon, Calif., and the records of the Lower California earthquake of December 30, 1934, at El Centro, contain valuable information which could be revealed by integration, since each record represents motion of a unique geological formation.

MASON A. STONE,[13] ESQ. (by letter).—Being of interest not only to the limited number of designers who specialize in the elevated water tank, but to those who are called upon to design steel structures carrying heavy loads at the top, Mr. Ruge's paper, of course, has a broader application than the title indicates. Among these steel structures, for instance, are viaducts with a heavy deck traffic, towers in chemical plants carrying tanks or machinery, elevated storage bins, hoisting towers with heavy sheaves or hoisting engines at their tops, etc.

The water tower, or rather the tower carrying the elevated tank, as the author shows, is further complicated by the action of the water surges. Therefore, it is necessary to consider as superimposed on the natural vibration period of the tower the period and amplitude of the motion of the ground due to the earthquake and the period and momentum of the water. A rational method of designing the structure would require the evaluation of the stresses set up by these three motions.

Whether or not such a mathematical analysis is possible, it is highly desirable that the conclusion be checked by experiments with actual models, and it is fortunate, therefore, that the apparatus for conducting such tests is available and that experiments with such models are actually being conducted. This paper must be considered as a progress report of such experiments. It is valuable: (1) Because it demonstrates the errors inherent in designing from the simple theory based on a constant acceleration; (2) because it indicates the difficulties and expense of attempting to meet the problem by increasing the stiffness of the tower; (3) because it suggests a mechanical solution whereby the structure, within certain limits of height of tower and capacity of tank, may be made flexible enough to absorb the stresses; and (4) because it reveals the tendency of the tower to continue vibrating in resonance with the earthquake shock, or after the earthquake shock has ceased, and shows how such vibrations may be damped.

---

[12] "Earthquake Investigations in California, 1934–35," *Special Publication No. 201*, U. S. Coast and Geodetic Survey.

[13] Structural and Mech. Engr., New York, N. Y.

The data given will enable existing towers to be examined for earthquake-resistant properties and, within the limits given, to be re-designed by the addition of the springs and dampening device so that they may be safe. However, the paper affords no general solution for the problem of designing the elevated tank tower. The stresses in the tower are the result of the amplitude of the vibration at the top, caused by the period and amplitude of the earthquake motion, and modified by the momentum of the water in the tank.

Although the stiffness of the tower may be computed, its period of vibration depends on the initial stresses set up in the members during the erection and the stresses due to the weight of water in the tank. Fortunately, reports are available containing data on the stiffness and period of vibration of a number of tank structures. In this connection, however, it may be remarked that the type of tower selected for the experiment and designated as the standard design is a very poor one from the standpoint of earthquake resistance. Apparently, the batter of the legs was considered solely from the standpoint of resisting the overturning moment due to wind. If one is to design for earthquake stresses a much broader base for the tower would seem to be indicated. On the other hand, for a structure of uniform strength to resist a horizontal force at the top a parabolic curve concave on the outside is indicated. This form is approximated in the design of the towers for the support of high-tension transmission lines. The tower with a wider base also recommends itself in connection with the increasing foundation loads due to earthquakes.

There is a considerable record of the magnitude and velocity of earthquake motion, but it is not readily accessible to the ordinary structural designer as it is contained in the reports of the Imperial Japanese Earthquake Commission and the Seismological Society of America which are not to be found in the average library. It is regrettable that Mr. Ruge did not include some statement of the period and amplitude which might be expected in earthquake motions. His statement that there was only a record of one earthquake available for study (that is, for cutting the necessary optical cam) might have been amplified by the explanation that the ordinary seismograph does not give the necessary information; an accelogram is required.

In the tank under consideration, the action of the water is shown to have a dampening effect upon the vibration of the structure, but this might not be true for all proportions of tanks and towers. It would seem a profitable line of investigation to determine the period and forces set up in water tanks of various proportions and capacity, at least for simple harmonic motions. At present, the proportions of the tank are usually determined by the most economical use of the material.

In this connection it may be suggested that waves set up by using only one component of the earthquake motion at a time may not be representative of the actual action of the water during an earthquake. Undoubtedly, the actual motion of the tank is roughly elliptical. Instead of being reciprocal, therefore, the wave would have a circular motion around the tank; it might have a different period and might develop different forces from those determined in experiments using only a reciprocal motion of the shaking-table.

When more is known about the action of the water, it may be possible to determine optimum proportions of tank and tower for the minimum vibration. The possible effects of the riser pipe also appear to merit consideration. Of course, if the pipe is secured at the bottom of the tank and to a foundation in the ground, and if it is also tied to the tower by horizontal braces at the panel points, a vertical column of water will somewhat reduce the center of gravity of the system as a whole. Furthermore, the stiffness of the pipe will add to the stiffness of the structure, although not very materially as it is situated at its neutral axis. In this case the stresses in the connection at the bottom of the tank and the foot elbow on the foundation should be investigated; but the pipe itself might be expected to resist any deflection that the legs of the tower are called upon to take.

It has occurred to the writer, however, that if the pipe is provided with a universal joint at the top and swiveled at the bottom connection so that it may swing freely as a pendulum, its natural period will probably be different from the structure as a whole and from that of the earthquake, and, therefore, it may have a beneficial dampening effect. This idea occurred to the Japanese when building pagodas. They introduced a heavy timber suspended from the top and appear to have had beneficial results with this type of construction.

The idea of designing a structure 100 ft high to withstand a deflection at the top of 15 in. is somewhat startling to a structural engineer. The secondary stresses at the connections between the horizontal struts and legs would have to be given careful consideration unless the author's suggestion of eliminating them by pin connecting the struts was adopted. Furthermore, the stresses in the riveted connection between the tank and the legs may possibly be relieved by the deflection of the tank sheets, but this action might result in the failure of rivets, or sheets.

The author's conclusions for the design of tanks and structures within the limits indicated appear to be valid. Of course, the damping device would have to be one that would not be affected by frost or that would not deteriorate with age and neglect.

H. C. BOARDMAN,[14] M. AM. SOC. C. E. (by letter).—By his painstaking and well directed efforts, Mr. Ruge has developed useful information in a field where it is much needed. The following excerpts from his paper are especially significant:

(*a*) "The type of tower now in common use was not developed for earthquake resistance, * * * ; there is no reason to accept it as the ideal structure for withstanding earthquake motions, which actual experience and repeated laboratory tests have proved it certainly is not." (See heading, "Introduction: Nature of the Problem.")

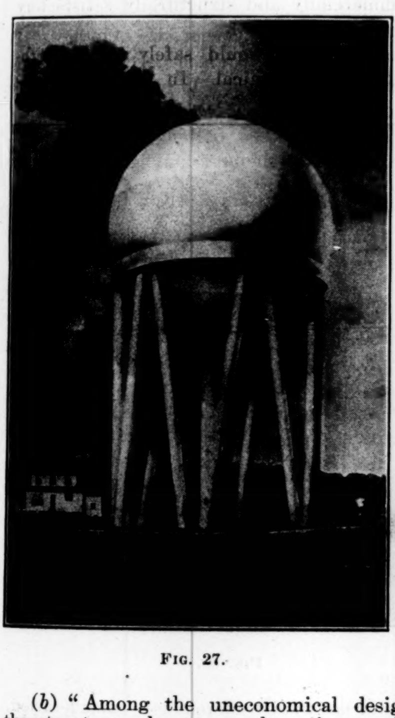


FIG. 27.

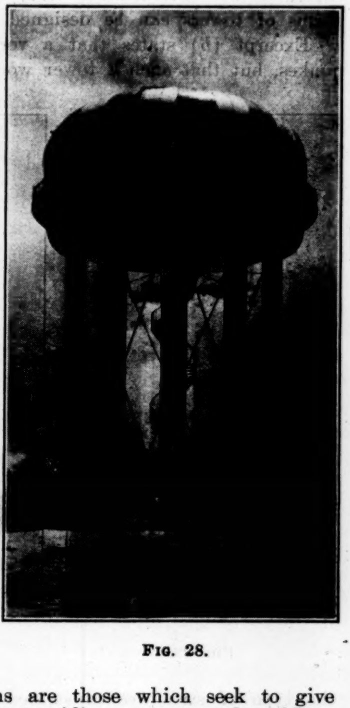

FIG. 28.

(*b*) "Among the uneconomical designs are those which seek to give the structure adequate quake-resistance by providing an extremely stiff or rigid tower. * * * If the natural period cannot be reduced to about 0.5 sec, it is doubtful whether the tank is very much more likely to survive a violent earthquake than a standard design built for wind resistance only." (See following Table 1.)

(*c*) "The natural conclusion from a prolonged study was that, barring fantastic and impractical designs, the best way to obtain adequate quake-resistance is to provide the tower with a greater range of elasticity; that is, if the tower can be built so that the safe deflections are large enough, there will be no danger of failure." (See following Table 1.)

---

[14] Research Engr., Chicago Bridge & Iron Company, Chicago, Ill.

(*d*) "There are two general methods of increasing the allowable or elastic deflection range of a structure such as a water-tank tower: (1) By making the tower of some type of open framework in which the forces resisting deflection are produced by bending stresses set up in some or all of the members of the framework; and (2), by artificially increasing the allowable direct-stress deformations of some or all of the members of a statically determinate tower." (See following Table 1.)

Taken at its face value, Excerpt (*a*) suggests that towers of the conventional type be not used in earthquake zones. Apparently, the author did not intend to convey this meaning. Nevertheless, it is well worth careful consideration, since other commercially and structurally satisfactory forms of towers can be designed.

Excerpt (*b*) states that a very stiff tower would safely resist earthquakes, but that such a tower would be uneconomical. In this connection, the type of structure illustrated by Fig. 27 is offered for consideration. It is stiff, but, nevertheless, offers promise of economy.

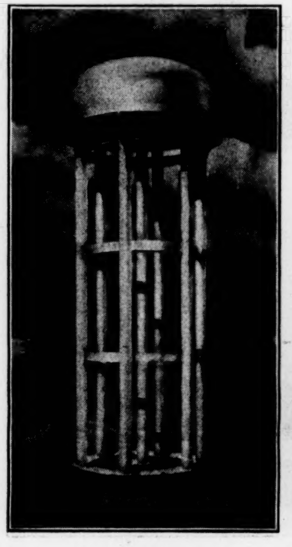

FIG. 29.

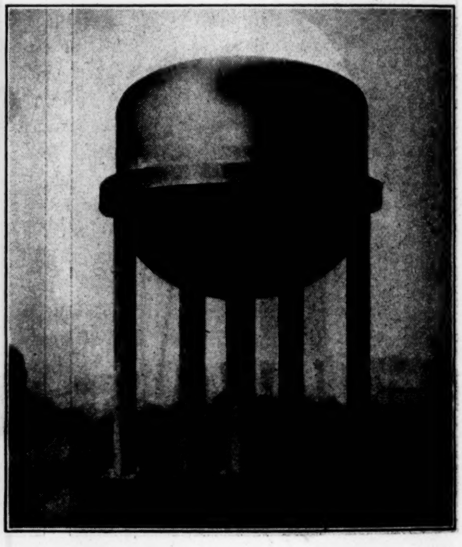

FIG. 30.

Excerpts (*c*) and (*d*) present the author's conclusion that the most practical method of providing earthquake protection is to make the tower flexible, either by use of an open framework with the members subjected to bending stresses, or by increasing the direct stress deformations of some or all of the members by the use of springs or similar devices. It is pertinent to re-emphasize what the author has stated, namely, that many tanks and towers of the conventional design have withstood earthquakes with little damage, except the breaking or stretching of some of the rods, which were easily replaced. Why, then, would it not be feasible to use longer panels and incline the rods more steeply, so that greater horizontal translations of the tower would be required to stretch the rods to the yield point and through the plastic range? Fig. 28 is offered as an example of such a design. Over a period of years, springs would almost surely be subject to serious maintenance troubles, and, therefore, they should not be used if designs not requiring them can be developed. Figs. 29 and 30 illustrate designs of the open type, without diagonals or struts.

FRANKLIN P. ULRICH,[15] M. AM. SOC. C. E., AND DEAN S. CARDER,[16] ESQ. (by letter).—In mentioning structural characteristics and the superficial nature of past earthquake design, Professor Ruge has touched upon a subject which is of considerable interest and for which a large amount of observational data has recently been obtained.

The strong-motion records obtained by the U. S. Coast and Geodetic Survey show the complexity of earthquake motions. The Los Angeles record of the Long Beach shock (used by Professor Ruge) shows periods ranging from 0.12 to 4.8 sec with only a few periods greater than 2.5 sec.[17] Only a few periods were of the same order as the fundamental period of this particular tank which was later measured and found to be about 1.5 sec.

The Coast and Geodetic Survey has made vibration observations on nineteen selected steel water tanks having capacities of 50 000, 75 000, and 100 000 gal, and an elevation of 100 ft above the ground. Vibration observations on eighteen other tanks, including the prototype of Professor Ruge's models, have also been made.[18] For the most part, however, this discussion will be confined to the nineteen tanks selected for comparison at the time the tests were made. All the tanks were filled or nearly filled with water.

Three orders of periods of vibration have been recognized:

(1) The most important type of motion is probably translational vibration which has periods ranging from 0.95 to 1.75 sec depending on the effective water load, the soil conditions, and the elastic properties of the tower. Other things being equal, towers reinforced from 0.08 to 0.15 g for side loads have periods 10% to 30% less than standard towers designed to withstand a 100-mile wind. Towers on piling in yielding soil have periods as high as 20% greater than similar towers on firm ground.

[15] Chf., Seismological Field Survey, U. S. Coast and Geodetic Survey, San Francisco, Calif.

[16] Asst. Observer, U. S. Coast and Geodetic Survey, San Francisco, Calif.

[17] "Destructive Earthquake Motions Measured for First Time," by N. H. Heck and Frank Neuman, *Engineering News-Record*, June 22, 1933.

[18] "Earthquake Investigations in California, 1934–1935," by U. S. Coast and Geodetic Survey, *Special Publication No. 201*, p. 75; and "Observed Vibrations of Steel Water Towers," by D. S. Carder, *Bulletin*, Seismological Soc. of America, Vol. 26, No. 1, January, 1936, p. 69.

The range of periods of translatory vibration lies within the frequency range of some of the possibly destructive earth waves as observed on accelerograms of the Long Beach earthquake. It is to be understood that observed periods of these tanks apply to low-amplitude vibrations. On the tanks where some of the tie-rods went out of action or failed during the earthquake, the periods undoubtedly became variable and much longer, according to Harry A. Williams,[19] Assoc. M. Am. Soc. C. E., perhaps in sufficient amounts to throw the structure out of resonance with the earth. Broken or stretched tie-rods would further serve temporarily to damp the structure. On the other hand, if the rigidity of a tank tower is to be increased, the purpose should be to strengthen the structure rather than to decrease its period, because destructive earth waves have been known to have periods less than 1 or 1.5 sec. For instance, the highest acceleration registered during the October 31, 1935, earthquake at Helena, Mont., was associated with periods of about 0.15 sec, even though a wave with a 1-sec period was also in evidence. At Long Beach, waves having a 0.3-sec period contained the highest acceleration.[17]

(2) Rotary or torsional vibration has been recorded on all tanks of this group. Observed periods of this type of motion usually range from 0.30 to 0.45 sec on standard structures, and from 0.20 to 0.30 sec on towers with an 0.08 g to 0.15 g side-load design. The magnitude of this period is dependent on the elastic properties and the steel load of the tower and perhaps also on the type of soil. It is independent of the water load because the water within the tank does not partake in this type of vibration.

Torsional vibrations of water tanks should not be overlooked in experimental procedure because it is quite possible that large torsional motions may be set up in resonance with destructive earth motions having the same frequency range.

(3) A period of the order 2.7 sec, assigned by Professor Ruge to swinging motion of water within the tank, has been recognized on several tank-tower vibrograms. Observed periods are 2.63 sec on one 50 000-gal tank, 3.0 sec on two 75 000-gal tanks, and 2.85 to 3.0 sec on five 100 000-gal tanks. One of the 100 000-gal tanks which had bracing to withstand an 0.08 g side load, had a period of this order, the same as similar standard tanks, supporting the belief that this period is due to water motion in the tank. However, the observed periods on tanks having different capacities cannot be explained satisfactorily by simple gravitative oscillations of water within the container. Furthermore, a supposition that water in the tank re-acts upon the tower in such a way as to produce a period approximating the translational period of the tower has considerable experimental support.

Strengthening a tank, primarily, to reduce its period of vibration is not the entire solution to making the tank more resistant to earthquakes. It is quite possible to have the reduced periods of the tank equally as destructive, or more so, than the original periods, especially if the reduced period happens to be close to one of the destructive ground periods.

---

[19] "Dynamic Distortions in Structures Subjected to Sudden Earth Shocks," by Harry A. Williams, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 838.

It might be possible to avoid resonance between ground and tank, if the tank had a definite fixed period and if the destructive ground periods for that particular location are known. To date (1937) information on destructive ground periods is too meager to form any definite theory. Observations made by the Coast and Geodetic Survey show that tank periods fluctuate with different types of ground and with changing tank conditions, such as depth of water in the tank or looseness of tie-rods. Tests on one tank showed that the period varied from about 0.36 sec for an empty tank to about 1.0 sec for a filled tank. In another case the period was 1.44 sec with tight tie-rods and 1.66 sec, or more, with loose tie-rods.

The question of merits or objections of spring elements, which Professor Ruge proposes to introduce in the tie-rods, is a structural problem and is beyond the scope of this discussion, but there is little room for doubt that a provision for some kind of damping will reduce, materially, the earthquake hazard of any structure. That standard elevated water tanks are poorly damped has been demonstrated on several of these structures on which a side force of 2 000 to 4 000 lb was suddenly released and the resulting vibrations recorded at the platform of the tank. The ratio of two successive amplitudes (damping ratio) of towers with taut tie-rods is never more than 1.02. One tank tested in this manner had loose tie-rods and the damping ratio was higher—about 1.1. The translatory period of the latter tank at first was 1.74 sec which decreased to 1.65 sec as the amplitudes became smaller. A minute after the release of the side force, vibrations due to elastic properties of the tower became subordinate, and a motion with a period of 2.85 sec was dominant for several minutes until the end of the record. If the idea is correct that this longer period is contributed by swinging action of water in the tank, it appears that this type of motion continued long after structural vibrations had diminished to normal amplitudes. Later, the tie-rods of the tower were tightened and the tests were repeated. The period was then invariable at 1.45 sec and structural vibrations disappeared much more slowly, and the longer 2.85-sec period was not recognized on the record.

The statements in the preceding paragraph should not be interpreted as an argument in favor of loose tie-rods in existing structures, but it does seem that some method of breaking up the high resilience of these structures, without destroying their resistance to dynamic side loads, is desirable. It is possible that Professor Ruge's idea of spring elements, with damping, is a solution.

It is unfortunate that more earthquake data are not available and that Professor Ruge was unable to continue his tests under a wider range of conditions. However, additional tests would probably show results comparable to this series. The errors of small models cannot be avoided and no doubt they are within the limits of error of present-day structural science. It is hoped that several full-sized tanks, embodying the spring design, can be constructed so that comparisons can be made with the present design, and their relative capabilities to withstand earthquakes can be determined.

ARTHUR C. RUGE,[20] ASSOC. M. AM. SOC. C. E. (by letter).—Attention has been called by Captain Heck to the need for further analysis of strong earthquake motions, and he has stated the attitude of the U. S. Coast and Geodetic Survey toward the problem of earthquake-resistant design. Those who are studying the problem recognize the wisdom of the Survey in confining its efforts to collecting data needed for design rather than engaging in the study of design itself, since it thus performs a needful service that could not be done adequately by any existing private institution. Furthermore, the desire to avoid attempting to prove particular theories gives to the work an impersonal character which adds tremendously to its value.

The writer hopes to extend the analysis of earthquake records in cooperation with the Coast and Geodetic Survey along the lines discussed by Captain Heck, and preliminary work in that direction has been in progress for some time. It may be stated herein that the present type of strong-motion accelerometers has been shown to give reliable results and that a convenient means of analysis by integration has been developed.

Mr. Stone notes that the damped spring-element concept can be extended profitably to many other structures. In fact, the patent covering the device does enumerate such uses, and there is every reason to believe that it could be applied satisfactorily in many instances where important structures must be protected against earthquake motions, although the details of the application would be varied considerably to suit individual cases.

The statement of Mr. Stone to the effect that the period of vibration depends upon the initial stresses in the members perhaps needs to be qualified somewhat. It is true that for very small amplitudes the period is considerably affected by the initial stresses in the rods. As soon as the amplitude reaches values of some importance (say, more than 0.25 in.) the initial tension has very little effect upon the period—in fact, any earthquake of destructive character will necessarily induce amplitudes large enough to make the dynamical effect of initial tension negligible.

The comment is made by Mr. Stone that the type of tower selected for experiment is a poor one from the standpoint of earthquake resistance, and a broader tower base is suggested. The tower referred to is of a common type and represents what is considered good practice for sprinkler tanks of moderate size and height. Although a wider base might be desirable for optimum efficiency, one cannot, in general, make the base spread very great unless the efficient use of the plant property is of no importance. Of course, the geometrical shape of the panels does not directly enter into the dynamical conditions stated in Conclusion (8), and the designer will normally choose the most economical layout.

As to the absence of a statement of the period and amplitude to be expected in earthquake motions, the omission was intentional. The writer feels that, unless prefaced by an elaborate discussion, any statement of that kind is almost certain to be misinterpreted by the very readers it was intended to help. A glance at the ground motion shown in Fig. 26 will perhaps serve to make this clear.

---

[20] Asst. Prof. of Eng. Seismology, Mass. Inst. Tech., Cambridge, Mass.

Mr. Boardman has suggested several interesting designs for tank towers. Such designs are probably best suited to large capacity tanks and, as such, have a very special interest, since for these types the ordinary spring element design would be uneconomical or impracticable. The arrangement shown in Fig. 28 would be well suited for the introduction of damping devices in the diagonals, and a careful design of the columns might permit large deflections. In such a case, the columns might be stiff enough to provide most, if not all, of the spring action and the dampers could be relatively simple friction devices.

The point regarding the use of steeper slopes for the rods to obtain a maximum of elastic tower deflection is well taken, and if the economy is not thereby destroyed, the dynamic design is simplified. Rods of steeper slope mean heavier columns and longer rods to handle; but there may be a gain in economy in some cases. However, the writer wishes to emphasize that some damping would be required in any event unless the structure can safely withstand extremely large deflections, and that there is no cheaper way of improving the dynamical behavior than by the introduction of damping. The presence of the springs in a design merely reduces the necessary damping and makes it convenient to produce the damping action.

The designs shown in Figs. 29 and 30 would doubtless need damping systems that could take the form of simple friction devices actuated by a light diagonal system, the spring action being provided by the columns. A tower such as that in Fig. 27 would have to be designed as a short-period system and no data exist for obtaining the stresses.

Messrs. Ulrich and Carder have contributed a helpful discussion to the paper. The field tests made by the U. S. Coast and Geodetic Survey were most helpful in the interpretation of the laboratory results. It may be stated that the model periods agreed with the prototype periods as closely as could be expected, and that the differences can logically be attributed largely to the degree of initial rod tension in the field.

The question of torsional vibration is properly raised, but the writer is of the opinion that even in conventional towers it would be only a secondary effect, since it would have to be set up principally by whatever lack of symmetry exists in the structure. In a structure equipped with the proper spring elements any torsional vibration would be quickly damped out since the elements come into action from torsion as well as from linear deflection of the tower.

BACK-WATER AND DROP-DOWN CURVES FOR UNIFORM CHANNELS

BY NAGAHO MONONOBE [1], M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. J. C. STEVENS, CHESLEY J. POSEY, A. A. KALINSKE, BORIS A. BAKHMETEFF, P. CHARLES STEIN, AND NAGAHO MONONOBE.

SYNOPSIS

Most of the existing formulas for determining back-water and drop-down curves in open channels, are applicable only to channels of simple geometric cross-section. Moreover, these formulas usually yield inaccurate results because in their derivation the effects of variation of velocity head are neglected, or the coefficient, *C*, in Chezy's mean-velocity formula is considered constant. In the present study, rational back-water and drop-down formulas are derived in such a manner that they are applicable to a wide variety of commonly used cross-sections. These formulas are based on accurate mean-velocity expressions of the exponential type, and make full allowance for velocity-head effects. The results of numerous tests in experimental channels are presented, and these results are compared with values computed by existing formulas and by the new formulas derived by the writer. In a thorough treatise entitled "Hydraulics of Open Channels", B. A. Bakhmeteff, M. Am. Soc. C. E., has also introduced the hydraulic exponent to express the characteristics of a channel cross-section. The writer's manuscript was prepared independently and has the merit of simplifying the computation in its application to various cases. This statement does not imply a criticism of Professor Bakhmeteff's treatment, but is intended merely to establish a line of demarcation, in the hope that discussers will avoid confusing the two treatments.

1.—FUNDAMENTAL FORMULAS FOR BACK-WATER AND DROP-DOWN CURVES

In a channel having constant discharge, uniform cross-section, and uniform slope, the flow is said to be non-uniform if the water surface is not parallel to the channel bed. In this case the longitudinal profile of the water surface

---

NOTE.—Published in May, 1936, *Proceedings*.

[1] Director, Experiment Station of Public Works, Home Dept., Japanese Govt.; Prof., Civ. Eng. Dept., Tokyo Imperial Univ., Tokyo, Japan.

takes the form of a curve. If the flow is of the "tranquil" type this curve theoretically extends up stream an infinite distance and gradually approaches the straight-line profile for uniform flow at the given discharge If concave upward the curve is called a back-water curve, and if concave downward it is called a drop-down curve. However, the same differential equation is applicable to both cases, the difference being only in the boundary conditions. The determination of the surface profile for cases of non-uniform flow is a problem of much practical importance.

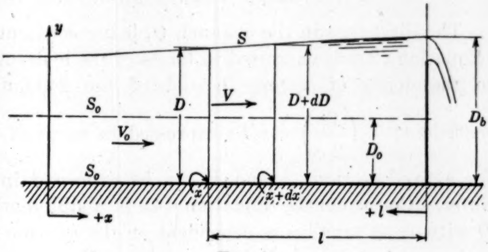

FIG. 1.

Placing the origin of the co-ordinates at any section of the channel, with the X-axis along the lowest line of the channel bed (positive in the downstream direction), and the Y-axis perpendicular to the X-axis, the general equation of motion for non-uniform flow is expressed as follows (see Fig. 1):

$$S = S_0 - \frac{dD}{dx} = \frac{V^2}{C^2 R} + \alpha \frac{d}{dx}\left(\frac{V^2}{2g}\right) \ldots\ldots\ldots\ldots (1)$$

in which S = slope of the water surface when the flow at Section x is non-uniform; S_0 = slope of the channel bed = slope of the water surface for uniform flow; D = depth of water at Section x for non-uniform flow; D_0 = depth of water for uniform flow; D_b = depth of water at weir; D_s = depth of water at point of maximum drop-down; R = hydraulic radius at Section x; C = a coefficient in the velocity formula; α = a correction factor for velocity head $= 1 + \alpha' =$, say, $\frac{10}{9}$.

A general type of mean velocity formula is as follows:

$$V = C\, R^m\, S^p{}_f = C\, R^m\, S^{0.5}{}_f \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which $p = 0.5$ in most cases, and S_f = the slope, S, defined by the frictional head for V and R.

In the Chezy velocity formula, C varies considerably with the depth of water and, if Equation (2) is substituted in Equation (1),

$$S = S_0 - \frac{dD}{dx} = \frac{V^2}{C^2\, R^{2m}} + \alpha\, \frac{d}{dx}\left(\frac{V^2}{2g}\right) \ldots\ldots\ldots\ldots (3)$$

or,

$$S = \frac{Q^2}{C^2\, R^{2m}\, A^2} + \alpha\, \frac{Q^2}{2g}\, \frac{d}{dx}\left(\frac{1}{A^2}\right) \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which Q = discharge; and A = hydraulic area.

A relation between D and x can be found by solving either Equation (3) or Equation (4), if S_0 and C do not vary. Since they do vary for rivers and streams, Equations (3) and (4) are not strictly applicable to natural watercourses. However, if the stream is considered as divided into several reaches, in each of which S_0 and C are nearly uniform, and if the relation between D and x is applied to each reach separately, back-water curves can be obtained more conveniently from either Equation (3) or Equation (4), than from Equation (1), since the latter must be solved by trial.

2.—Various Formulas for Back-Water Curves

The discharge in the channel, Q, being constant, S in the velocity formula (Equation (2)) is expressed in terms of the hydraulic radius, R, corresponding to the depth of water, D, and of the roughness coefficient or velocity coefficient; $\frac{d}{dx}\left(\frac{V^2}{2\,g}\right)$ can be expressed in terms of the hydraulic area, A, and for a fixed section, A and R can be expressed in terms of D, the depth of water. Consequently, Equation (4) is a differential equation that combines D with x, its type being dependent on the relation expressed in Equation (2), and on the shape of the cross-section. Hence, the back-water curve derived by integration is necessarily subject to these two factors.

In determining the back-water and drop-down curves, therefore, it is essential to adopt the velocity formula most appropriate for the channel under consideration and to establish the relation between D and R as accurately as possible. Many of the existing formulas are deficient in one or both of these requirements and, moreover, these formulas do not include the term which expresses a change of velocity head. When the variation of mean velocity is wide, the latter omission introduces a serious error, especially in the case of drop-down curves.

Table 1 contains various types of velocity formulas and channel sections adapted to the determination of back-water and drop-down curves in current use.

TABLE 1.—Types of Existing Back-Water Formulas

Item No. (1)	Investigation (2)	Year of publication (3)	Velocity formula, V, equals: (4)	Type of channel section (5)	Variations in velocity head: (6)	Ratios of $\frac{d}{d_0}$	
						Back-water curve (7)	Drop-down curve (8)
1	Grashof-Bresse.	1860	$C\sqrt{D_0\,S_0}$	Broad rectangle	Considered	$\frac{1}{0.999}$ to $\frac{1}{0.07}$	0.999 to 0.00
2	Dupuit-Masoni	1863	$C\sqrt{R\,S_0}$	Common rectangle	Considered	None	None
3	Rühlmann.....	1880	$C\sqrt{D_0\,S_0}$	Broad rectangle...	Neglected	1.01 to 6.0	0.99 to 0.00
4	Tolkmitt......	1881	$C\sqrt{R\,S_0}$	Broad parabola...	Considered	1.005 to 5.0	0.995 to 0.00
5	Schaffernak....	1913	$C D_0^{0.75}\,S_0^{0.5}$	Broad rectangle...	Neglected	1.013 to 5.0	0.2 to $\frac{1}{1.04}$
6	Ehrenberger...	1914	$\left\{\begin{array}{l}23.78\;D_0^{0.776}\;S^{0.458}\\22.11\;D_0^{0.58}\;S_0^{0.43}\end{array}\right.$	Broad rectangle...	Neglected	1.000 to 5.0	None
7	Baticle........	1921	Q^2 varies as $S\,z^5 = S_0\,z_0^5$.	Approximate trapezoid	Neglected	1.001 to 10.0	None
8	Kozeny.......	1928	$C D_0^{0.7}\,S_0^{0.5}$	Broad rectangle...	Considered	None	0.10 to 0.95
9	Schoklitsch....	1930	$C D_0^{m}\,S_0^{0.5}$	Broad rectangle...	Neglected	1.01 to 5.0	None

Most of the expressions for mean velocity in Column (4), Table 1, are considerably in error because the characteristics of each section of the actual channel vary. Furthermore, in some cases (Items Nos. 3, 5, 6, 7, and 9, Table 1), the important variations in velocity head are neglected. In Item No. 7, Table 1, the symbols, z and z_0, denote $A^2 R$ and z in uniform flow, respectively.

3.—General Solutions

Existing methods of calculating back-water and drop-down curves are scarcely accurate enough for practical purposes; furthermore, the hydraulic theory upon which they are based is very imperfect. The reasons why existing methods are unsatisfactory are, as follows:

Case (*A*).—In order to be able to express the back-water and drop-down curves by functions having a finite number of terms, some of these methods use the Chezy velocity formula with constant C, and consider only broad, shallow, channel sections. Generally, it is impossible to express the back-water and drop-down curves by a function having a finite number of terms unless $\frac{1}{m}$ in Equation (2) is an integer and the broad section is a rectangle.

Case (*B*).—When m has any arbitrary value and when the channel has a broad shallow section, the back-water and drop-down curves may be expressed by functions involving infinite series; but the calculation of the numerical table (Columns (7) and (8), Table 1) is quite complicated in comparison with Case (*A*). The Schaffernak (Item No. 5)[2] and Schoklitsch (Item No. 9)[3] formulas are the simplest in this case. In the Rühlmann formula (Item No. 3)[4] an infinite series is used, laboriously and needlessly, in spite of the fact that the formula should belong to Case (*A*). In the cases of most channels with cross-sections that are not broad in comparison with their depths, the determination of the back-water and drop-down profiles by rigorous mathematical methods involves difficulties which are practically insurmountable.

Unless the Chezy formula is used, the back-water function generally requires the use of infinite series for its expression. Moreover, if the change in the velocity head is considered, two infinite series are derived from one kind of channel. In this case it is extremely laborious to construct tables of the function for all types of sections.

In the following, the writer derives some exponential formulas for the hydraulic area, wetted perimeter, and hydraulic radius, which are sufficiently accurate for practical purposes. The change in velocity head is taken into consideration, and the most appropriate velocity formula is used for each channel. In every case the desired back-water or drop-down function is expressed in terms of two sets of series.

Case 1.—The Most General Case of Non-Uniform Flow.—The hydraulic area, A, the wetted perimeter, P, the hydraulic radius, R, and the average velocity, V, are expressed most generally as functions of D, the depth of water measured from the lowest line of the channel bed; thus, with Equation (2):

---

[2] "Hydraulik", by Forchheimer, Third Edition, p. 208.

[3] "Wasserbau", by Schoklitsch, 1930, Vol. 1, p. 103.

[4] "Hydraulik", by Forchheimer, Third Edition, p. 207.

$$A = a_0 + aD^s \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

$$P = b_0 + bD^k \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5b)$$

and,

$$R = \frac{A}{P} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5c)$$

in which the subscript, 0, refers the symbol to the condition of uniform flow.

Since the amount of flow in the channel is unchanged, $Q = VA = V_0 A_0$ and, therefore:

$$S_f = \frac{1}{C^2}\left(\frac{V_0 A_0}{A}\right)^2 R^{-2m} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which $\frac{V_0^2}{2g}\left(\frac{A_0}{A}\right)^2 = \frac{V^2}{2g}$. By substituting Equations (2) and (5) into the general differential Equation (1):

$$S_0 - \frac{dD}{dx} = \frac{V_0^2}{C^2}\left(\frac{A_0}{A}\right)^2 R^{-2m} + \alpha\,\frac{V_0^2}{2g}\,\frac{d}{dx}\left(\frac{A_0}{A}\right)^2 \ldots\ldots\ldots (7)$$

Replacing A, R, and P, by their values in Equations (5) and writing $\frac{a}{a_0} = a_1$; and $\frac{b}{b_0} = c$:

$$S_0 - \frac{dD}{dx} = S_0\left(\frac{1 + a_1 D^s_0}{1 + cD^k_0}\right)^{2m+2}\left(\frac{1 + cD^k}{1 + cD^k_0}\right)^{2m}$$

$$- \frac{\alpha C^2 S_0}{g}\left(\frac{1 + a_1 D^s_0}{1 + cD^k_0}\right)^{2m} S_{a1}\left(\frac{1 + a_1 D^s_0}{1 + a_1 D^s}\right)^2 \frac{D^{s-1}}{1 + a_1 D^s}\,\frac{dD}{dx} \ldots\ldots (8)$$

Equation (8) is the most general differential equation that expresses the back-water and drop-down functions; but integration of the equation and the calculation of numerical tables become extremely complicated with the expression in this form, since each term in the right-hand side of the equation expands into a double series with respect to D.

Case (2).—In Which the Hydraulic Area, A, Is Monomial.—In common channels or rivers, if D is measured from the lowest line, the monomial expression, $A = aD^s$, for hydraulic area is sufficiently accurate even when $a_0 = 0$. Therefore, when $A = aD^s$; $P = b_0 + bD^k$; and,

$$R = \frac{A}{P} = \frac{a\,D^s}{b_0\,(1 + cD^k)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

then,

$$\left(\frac{A_0}{A}\right)^2 = \left(\frac{D_0}{D}\right)^{2s} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

$$S_f = \frac{V^2_0}{C^2}\left(\frac{A_0}{A}\right)^2 R^{-2m} = S_0\left(\frac{D_0}{D}\right)^{2s(m+1)}\left(\frac{1 + c\,D^k}{1 + cD^k_0}\right)^{2m} \ldots\ldots (10b)$$

and,

$$\frac{V^2_0}{2g}\,\frac{d}{dx}\left(\frac{A_0}{A}\right)^2 = -\ \frac{S_0\,C^2\,S}{g}\left(\frac{c_0 + cc_0D^k_0}{D^s_0}\right)^{-2m}\left(\frac{D_0}{D}\right)^{2s}\frac{1}{D}\,\frac{dD}{dx}\ .(10c)$$

in which $c = \frac{b}{b_0}$; and, $c_0 = \frac{b_0}{a}$.

Let,

$$\frac{S_0\,\alpha\,C^2\,S}{g}\left(\frac{c_0 + cc_0\,D^k}{D^s_0}\right)^{-2m} = D_k \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

then, Equation (7) becomes,

$$S_0\ - \frac{dD}{dx} = S_0\left(\frac{D_0}{D}\right)^{2s(m+1)}\left(\frac{1 + cD^k}{1 + cD^k_0}\right)^{2m} - \frac{D_k}{D_0}\left(\frac{D_0}{D}\right)^{2s+1}\frac{dD}{dx}$$

and, therefore,

$$S_0\ dx = \frac{\left[1 - \frac{D_k}{D_0}\left(\frac{D_0}{D}\right)^{2s+1}\right]dD}{1 - \left(\frac{D_0}{D}\right)^{2s(m+1)}\left(\frac{1 + cD^k}{1 + cD^k_0}\right)^{2m}} = F\ (D)\ dD \ldots\ldots (12)$$

The second term in the denominator of Equation (12) may be expressed by a convergent infinite series, and, as a consequence, the function, $F(D)$, can be expressed in terms of a double series of $\frac{D}{D_0}$; but the labor for calculating the numerical table is far greater than in Case (3), which follows.

Case (3).—In Which the Hydraulic Area, A, and Wetted Perimeter, P, Are Monomials.—In this case the differential equations become reasonably simple, since,

$$A = aD^s \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13a)$$

$$P = bD^k \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13b)$$

and,

$$R = \frac{A}{P} = \frac{a}{b}\,D^{s-k} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13c)$$

It seems somewhat irrational to express P as a monomial function of D. This is especially true in the case of sections such as the rectangle or trapezoid, in which the base width has a finite value. However, in the cases of these sections, as in the cases of most other sections in common use, actual trial shows that it is possible to choose values of b and k in Equation (13b) that will make this equation express the value of P with reasonable accuracy over a considerable range of depths. The fact that the use of this monomial expression for P does not introduce errors of appreciable magnitude into the computation of back-water and drop-down profiles, will be made evident by reference to the many experiments described subsequently herein.

4.—GENERAL FORMULAS FOR BACK-WATER AND DROP-DOWN CURVES

Referring to Case (3), Article 3, and following the form of Equation (13): $\frac{A}{A_o} = \left(\frac{D}{D_o}\right)^s; \frac{P}{P_o} = \left(\frac{D}{D_o}\right)^k; \frac{R}{R_o} = \left(\frac{D}{D_o}\right)^{s-k}$; and $V_o = C\,R^m{}_o\,S^{0.5}{}_o$. Consequently,

$$\frac{V^2{}_o}{C^2}\left(\frac{A_o}{A}\right)^2 R^{-2m} = S_o\left(\frac{D}{D_o}\right)^{-2s}\left(\frac{R_o}{R}\right)^{2m} = S_o\left(\frac{D}{D_o}\right)^{-2s-2m(s-k)} \quad \ldots\ldots(14)$$

and,

$$\alpha\,\frac{V^2{}_o}{2\,g}\,\frac{d}{dx}\left(\frac{A_o}{A}\right)^2 = -\,\alpha\,\frac{V^2{}_o}{g} \times s\left(\frac{D}{D_o}\right)^{-2s-1}\frac{d}{dx}\left(\frac{D}{D_o}\right)$$

$$= -\,K\,D_o\left(\frac{D}{D_o}\right)^{-2s-1}\frac{d}{dx}\left(\frac{D}{D_o}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots(15)$$

in which $K = \alpha\,s\,\frac{V^2{}_o}{g\,D_o}$.

Back-Water.—Substituting Equations (14) and (15) into the general differential Equation (1):

$$S_o - \frac{dD}{dx} = S_o\left(\frac{D}{D_o}\right)^{-2s-2m(s-k)} - KD_o\left(\frac{D}{D_o}\right)^{-2s-1}\frac{d}{dx}\left(\frac{D}{D_o}\right)$$

Hence, by making $\frac{D}{D_o}$ equal to y, the quantity, $d\left(\frac{D}{D_o}\right)$, will equal $dy = \frac{dD}{D_o}$; and, finally,

$$\frac{S_o}{D_o}\,dx = \frac{dy}{1 - y^{-2s-2m(s-k)}} - K\,\frac{y^{-(2s+1)}}{1 - y^{-2s-2m(s-k)}}\,dy \quad \ldots\ldots\ldots(16)$$

Since m is dependent upon the velocity formula used, and s and k are determined by the channel section:

$$\frac{S_o\,dx}{D_o} = \frac{dy}{1 - y^{-r}} - K\,\frac{y^{-(2s+1)}}{1 - y^{-r}}\,dy = \frac{y^r}{y^r - 1}\,dy - K\,\frac{y^{(r-2s)-1}}{y^r - 1}\,dy \ldots(17)$$

in which $r = 2s + 2m\,(s - k)$. Integrating Equation (17) from x to $x + l$ (that is, from D to D_b), the distance, l, from the weir to the point where the depth of water, D, is known, and the rise of the water surface is $D - D_o$ (see Fig. 2):

$$\frac{S_o\,l}{D_o} = \Phi_1\left(\frac{D_b}{D_o}\right) - \Phi_1\left(\frac{D}{D_o}\right) - K\left[\Phi_2\left(\frac{D_b}{D_o}\right) - \Phi_2\left(\frac{D}{D_o}\right)\right] \ldots(18)$$

in which $D_b = D_{x+1}$; $D = D_x$; $K = \alpha s\,\frac{V^2{}_o}{g\,D_o}$; $\alpha = \frac{10}{9}$; $\Phi_1 = \int \frac{y^r}{y^r - 1}\,dy$; $\Phi_2 = \int \frac{y^{(r-2s)-1}}{y^r - 1}\,dy$; and $y = \frac{D}{D_o} > 1$.

Theoretically, the influence of back-water extends backward from the weir an infinite distance. At the point where $l = \infty$, $D = D_0$, or $y = l$. Since both Φ_1 and Φ_2 become infinitely great at this point, their limits of integration are taken to be $y = y_1 = 1.001$; that is, $\frac{D}{D_0} = 1.001$

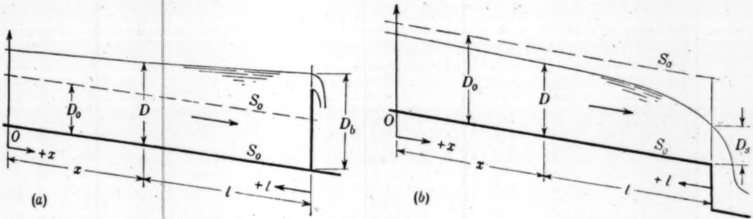

FIG. 2.

Drop-Down.—In this case, $\frac{D}{D_0} < 1$, and for convenience in integration let $z = \frac{1}{y} = \frac{D_0}{D} > 1$. Then, Equation (16) becomes:

$$\frac{S_0\,dx}{D_0} = -\frac{z^{-2}\,dz}{1 - z^r} + K\frac{z^{2s-1}\,dz}{1 - z^r} = \frac{z^{-2}\,dz}{z^r - 1} - K\frac{z^{2s-1}\,dz}{z^r - 1} \quad \ldots\ldots.(19)$$

In Equation (19), $r > 1$; and $z > 1$, and both terms on the right-hand side can be developed into a convergent series of z. Integrating from x to $x + l$ (that is, from D to D_s):

$$\frac{S_0\,l}{D_0} = \Psi_1\left(\frac{D_0}{D_s}\right) - \Psi_1\left(\frac{D_0}{D}\right) - K\left[\Psi_2\left(\frac{D_0}{D_s}\right) - \Psi_2\left(\frac{D_0}{D}\right)\right] \ldots.(20)$$

in which $\Psi_1(z) = \Psi_1\left(\frac{D_0}{D}\right) = \int \frac{z^{-2}}{z^r - 1}\,dz$; and, $\Psi_2(z) = \Psi_2\left(\frac{D_0}{D}\right) \int \frac{z^{2s-1}}{z^r - 1}\,dz$. In this case, also, Ψ_1 and Ψ_2 become infinitely great when $z = 1$, and the lower limit of the integration is taken as $z = \frac{D_0}{D} = 1.001$, or $y = \frac{D}{D_0} = 0.999$.

5.—CALCULATION OF BACK-WATER FUNCTIONS

The Back-Water Curve.—In the expression, $r = 2s + 2m\,(s - k)$, $s =$ the numerical value of the power in the function for hydraulic area; $m =$ the exponent of hydraulic radius in the velocity formula; and $k =$ the exponent of the wetted perimeter in the velocity formula. For open channels and conduits, $1 < r < 6$ and $0.5 < s \leqq 2.0$. The quantity, $\frac{1}{y^r - 1}$, of both terms on the right-hand side of Equation (17) is developed into a convergent series, and their integrals, Φ_1 and Φ_2, may be expressed as follows:

$$\Phi_1 = y - \sum_{n=1}^{\infty} \frac{y^{-(nr-1)}}{nr - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots.(21a)$$

and,

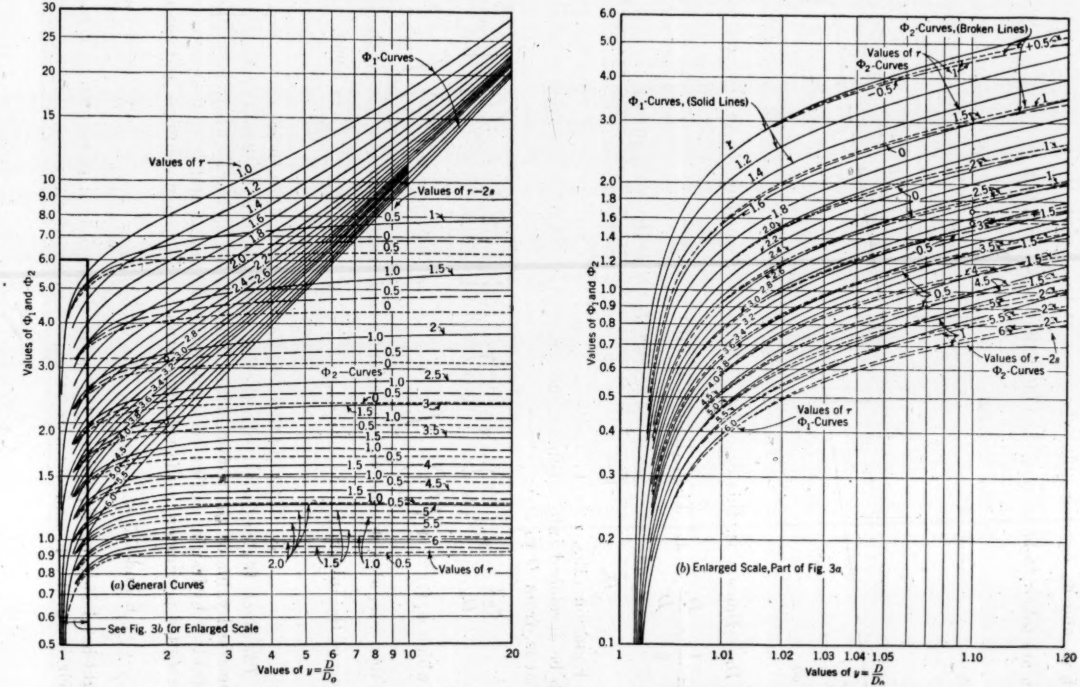

FIG. 3.—BACK-WATER CURVES; VALUES OF Φ_1 AND Φ_2 FOR SUBSTITUTION IN EQUATION (18).

$$\Phi_2 = - \sum_{n=1}^{\infty} \frac{y^{-(nr+2s)}}{nr + 2s} \qquad \text{(21}b\text{)}$$

However, in actual numerical calculation, when y is nearly equal to 1, the rate at which the series converges is very slow. When both r and s are integers or possess special values, Equations (21) can be expressed in a finite number of terms, and in preparing an actual numerical table, Φ_1 and Φ_2 are calculated directly for these special cases and the values of the functions for intermediate values of r and s are obtained by interpolation. The results are shown by groups of curves in Fig. 3, in which, for substitution in Equation (18):

$$\Phi_1 \left(\frac{D}{D_0}\right) = \int_{1.001}^{y} \frac{y^r}{y^r - 1}\, dy \qquad \text{(22}a\text{)}$$

and,

$$\Phi_2 \left(\frac{D}{D_0}\right) = \int_{1.001}^{y} \frac{y^{(r-2s)-1}}{y^r - 1}\, dy \qquad \text{(22}b\text{)}$$

If groups of Φ_1 and Φ_2 curves are constructed by plotting the integrated values thus obtained, the back-water profile applicable to almost any channel can be calculated precisely. Back-water curves published in the past were for a single case of r and s; for instance, in the Grashof-Bresse formula, a broad rectangular section is used so that, with $A = B\,D$, and $P = B$, $s = 1$, and $k = 0$. Since $V_0 = C\,R^{0.5}_0\,S^{0.5}_0$, the exponent, m, $= 0.5$. Therefore, $s = 1$, and $r = 3$.

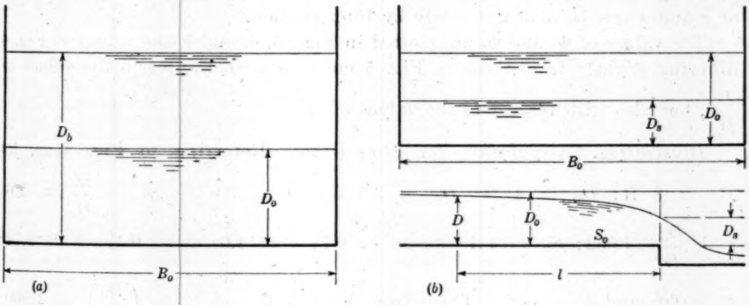

FIG. 4.—EXAMPLES.

In the Tolkmitt formula (Item No. 4, Table 1), a broad parabolic section is used in the Chezy velocity formula so that $m = 0.5$ and $A = \frac{2}{3} BD$; $P = B$; and $R = \frac{2}{3} D$. Consequently, $s = \frac{3}{2}$; $k = 0.5$; and $r = 4$. In the Rühlmann formula (Item No. 3, Table 1) Φ_2 is neglected when $s = 1$ and $r = 3$.

Illustrative Computation for Back-Water.—Referring to Fig. 4(*a*) let $B_0 = 8$ ft; $D_0 = 2$ ft; $D = 2.2$ ft; $D_b = 4$ ft; $S_0 = 1{:}1\,000$; $C = 50$; $m = 0.7$; $s = 1.0$; $k = 0.38$; $r = 2.87$; and $K = 0.212$. Then, from Fig. 3, selecting proper values of Φ_1 and Φ_2, Equations (22) yield: $\Phi_1\left(\frac{D_b}{D_0}\right) = 3.16$; $\Phi_1\left(\frac{D}{D_0}\right) = 1.68$; $\Phi_2\left(\frac{D_b}{D_0}\right) = 2.12$; and $\Phi_2\left(\frac{D}{D_0}\right) = 1.58$. Substituting these values in Equation (18): $\frac{S_0\, l}{D_0} = 3.16 - 1.68 - 0.212\ (2.12 - 1.58) = 1.365$; and, $l = 2\,730$ ft.

Drop-Down Curve.—In this case the drop-down functions are: $\Psi_1\ (z) = \int \frac{z^{-2}\, dz}{z^r - 1}$; and, $\Psi_2\ (z) = \int \frac{z^{2s-1}}{z^r - 1}\, dz$, and each of them can be expressed as infinite series, thus:

$$\Psi_1\ (z) = -\sum_{n=1}^{\infty} \frac{z^{-(nr+1)}}{nr + 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23a)$$

and,

$$\Psi_2\ (z) = -\sum_{n=1}^{\infty} \frac{z^{-nr+2s}}{nr - 2\,s} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23b)$$

For integral or special values of r and s, the integration leads to expressions having a finite number of terms, so that if values of the functions are computed by these expressions, the values of the functions for intermediate values of r and s can be obtained easily by interpolation.

The values of Ψ_1 and Ψ_2 are plotted in Figs. 5, 6, and 7, the values in Fig. 6 differing slightly from those in Fig. 5 not only with respect to the values of $\frac{D}{D_0}$, but also with respect to the values of s.

Illustrative Computation for Drop-Down.—Referring to Fig. 4(*b*), let $B_0 = 8$ ft; $D_0 = 4$ ft; $D_s = 2.5$ ft; $D = 3.8$ ft; $Z = \frac{D_0}{D_s} = 1.6$; $z = \frac{D_0}{D} = 1.052$; $S_0 = 1{:}1\,000$; $m = 0.7$; $s = 1.0$; $k = 0.47$; $r = 2.74$; $C = 60$; and $K = 0.27$. Then, from Figs. 5, 6, and 7: $\Psi_1\left(\frac{D_0}{D_s}\right) = 1.900$; $\Psi_2\left(\frac{D_0}{D_s}\right) = 2.34$; and $\Psi_2\left(\frac{D_0}{D}\right) = 1.45$. Substituting these values in Equation (20): $\frac{S_0\, l}{D_0} = 1.900 - 1.395 - 0.27\ [2.34 - 1.45] = 0.265$; and $l = 1\,060$ ft.

General.—In Figs. 3 to 7, the values of Φ_1, Φ_2, and Ψ_1, Ψ_2, which are shown by groups of curves, are obtained by ordinary integration with respect to a number of sets of values of r and s which furnish directly integrable equations.

Intermediate values of r and s are determined by interpolation. For the back-water curves the direct integration is performed with respect to the following special cases: (*a*) For Φ_1: $r = 1, 2, 3, 4, 5$, and 6; (*b*) $r = 3$ is for Φ_1 in the Grashof-Bresse (Item No. 1, Table 1) and Rühlmann formulas (Item No. 3, Table 1); (*c*) $r = 5$ is for Φ_1 of the Baticle formula (Item No. 7, Table 1); (*d*) values of r and corresponding values of s for integrals of Φ_2 (see Fig. 3) are listed in Table 2; (*e*) $r = 3$, $s = 1.0$ are for Φ_2 of the Grashof-Bresse formula; and (*f*) $r = 4$, $s = 1.5$ are for Φ_2 of the Tolkmitt formula (Item No. 4, Table 1).

TABLE 2.—VALUES OF r, WITH CORRESPONDING VALUES OF s, FOR INTEGRALS OF Φ_2 AND Ψ_2

Values of r	VALUES OF s, FOR:		Values of r	Values of s for Φ_2 and Ψ_2	Values of r	Values of s for Φ_2 and Ψ_2	Values of r	VALUES OF s, FOR:	
	Φ_2	Ψ_2						Φ_2	Ψ_2
(1)	(2)	(3)	(1)	(2)	(1)	(2)	(1)	(2)	(3)
1.0	0.25 0.50 0.75	0.50 0.75 1.00	2.0	0.50 0.75 1.00	3.0	0.75 1.00 1.25 1.50	5.0	1.50 2.00	1.50 2.00
1.5	0.25 0.50 0.75	....	2.5	0.75 1.00 1.25	4.0	1.00 1.50 2.00	6.0	2.00	1.50 2.00 ....

In the drop-down the direct integration is performed with respect to the following special cases: (*g*) For Ψ_1: $r = 1, 2, 3, 3.4, 3.5, 4, 5$, and 6; (*h*) $r = 3$ is for Ψ_1 of the Grashof-Bresse and Rühlmann formulas; (*i*) $r = 3.4$ is for the Kozeny formula (Item No. 8, Table 1); (*j*) $r = 3.5$ is for the Schaffernak formula (Item No. 5, Table 1); (*k*) $r = 4$ is for the Tolkmitt formula; and, (*l*) values of r, with corresponding values of s, for integrals of Ψ_2 are listed in Table 2, in which the combination, $r = 3$ and $s = 1.0$ is the value of Ψ_2 for the Grashof-Bresse formula. Direct integration is possible for seven forms of the integral, Φ_1, twenty-two forms of the integral, Φ_2, eight forms of the integral, Ψ_1, and seventeen forms of the integral, Ψ_2. The integrations were performed by Reidi Ito, River Engineer of the Department of Home Affairs, Japan.

6.—HYDRAULIC AREA, WETTED PERIMETER, AND HYDRAULIC RADIUS

Various shapes of sections which are commonly used for channels, however complicated they may be, can be approximated accurately enough by a combination of straight line, parabolic, and circular curves. Then, establishing the mathematical relation of A, P, and R, or s and k, to the depth of water for these three cases, the factors, s and r, may be obtained for a required depth of water in the case of an irregular section by curves or by direct calculation.

(*a*) *Prismatic Section.*—In the cases shown in Fig. 8 the hydraulic area, A, may be expressed in general terms by:

$$A = a_0 D + a D^2 \qquad \text{(24)}$$

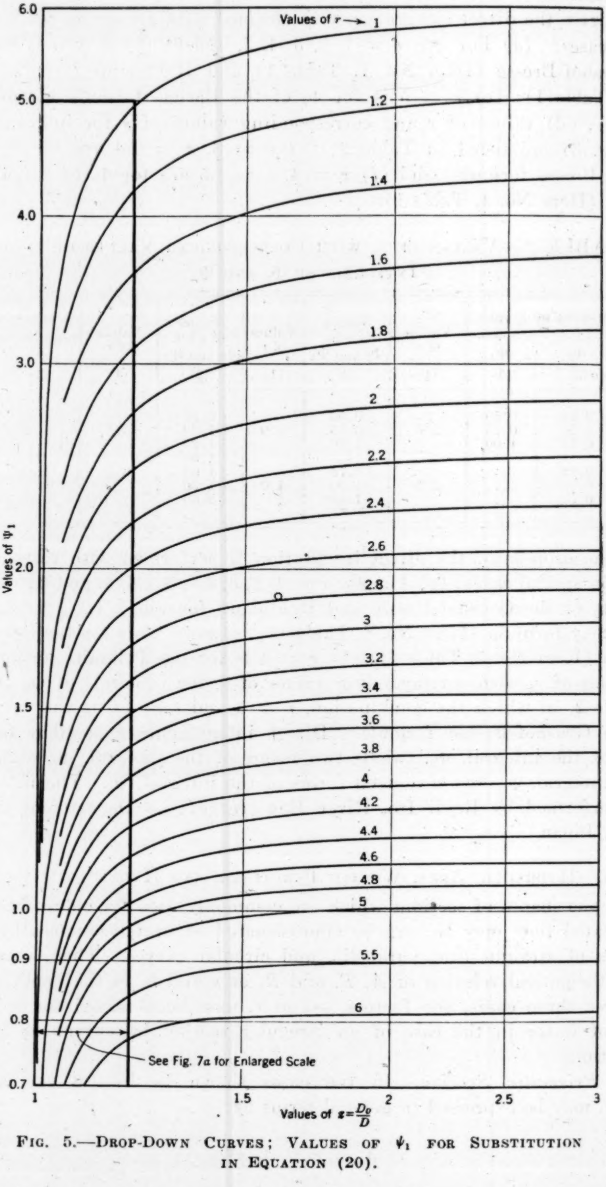

FIG. 5.—DROP-DOWN CURVES; VALUES OF ψ_1 FOR SUBSTITUTION IN EQUATION (20).

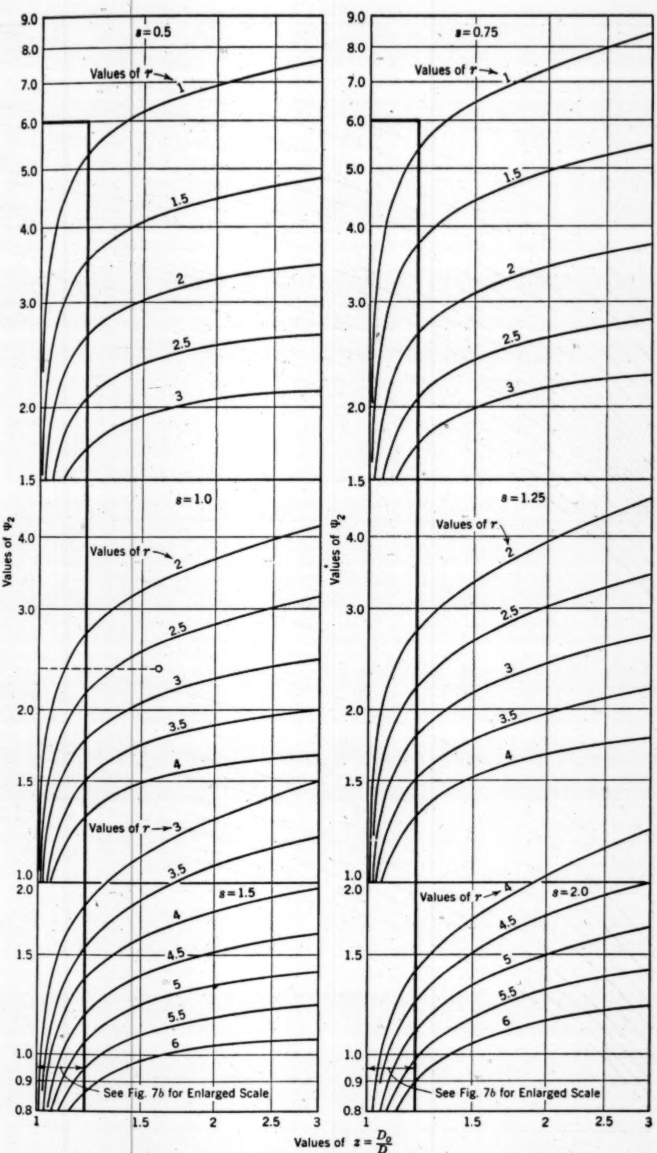

FIG. 6.—DROP-DOWN CURVES; VALUES OF ψ_2 FOR SUBSTITUTION IN EQUATION (20).

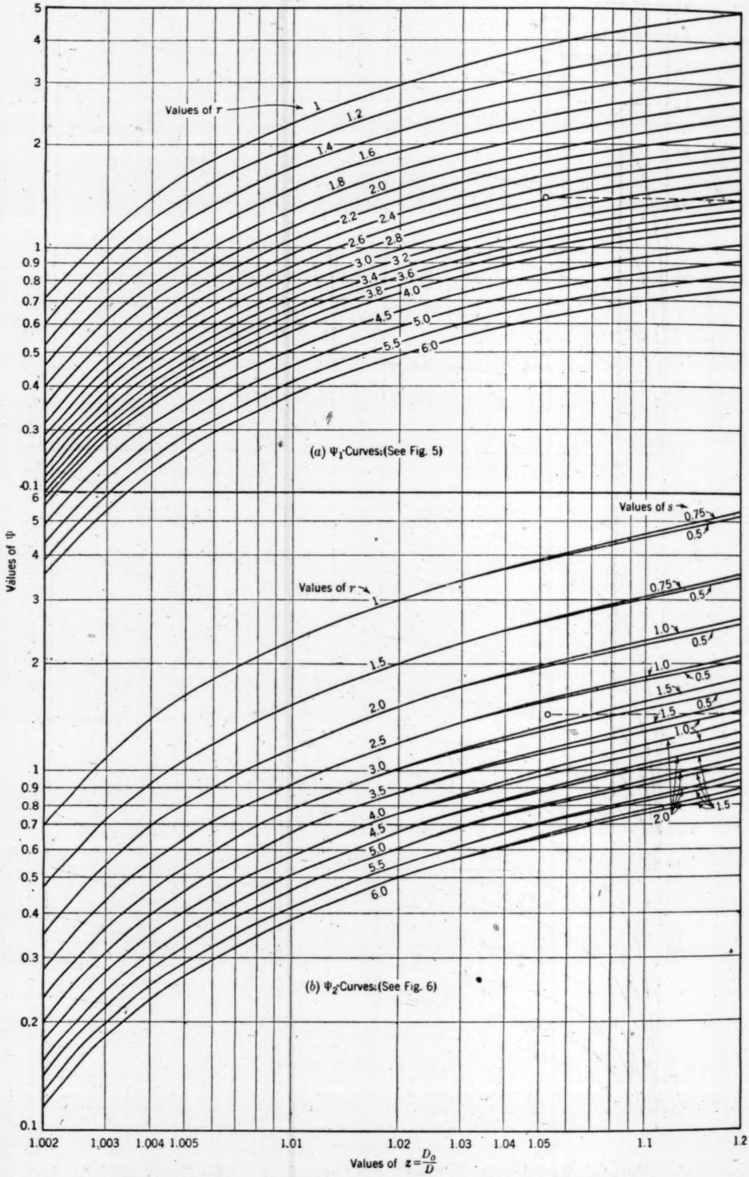

FIG. 7.—DROP-DOWN CURVES, FIGS. 5 AND 6, TO AN ENLARGED SCALE.

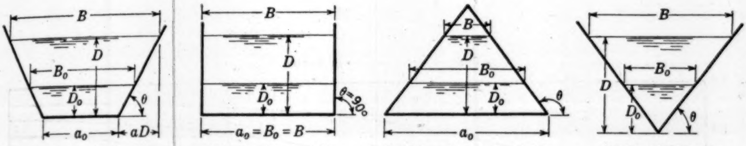

(*a*) Trapezoidal; $a = \cot\theta > 0$ (*b*) Rectangular; $s = 1.0$ and $a = 0$ (*c*) Triangular; $a = \cot\theta < 0$ (*d*) Inverted Triangle; $s = 2.0$ and $k = 1.0$

FIG. 8.—REGULAR CHANNEL CROSS-SECTIONS.

in which $a = \cot\theta$; θ = the angle made by the slope of the bank and the extension of the base line of the channel; and the values of a_o are as shown in Table 3.

TABLE 3.—VALUES OF a_o AND θ IN EQUATION (24)

Description	Trapezoidal section (Fig. 8 (*a*))	Rectangular section (Fig. 8 (*b*))	Triangular section (Fig. 8 (*c*))	Inverted triangle (Fig. 8 (*d*))
a_o	a_o	$B = B_o$	a_o	0
cot θ	+	0	−	+

From Equation (24):

$$\frac{A}{A_o} = \frac{a_o\, D + a\, D^2}{a_o\, D_o + a\, D_o^2} = \frac{y + \dfrac{a}{\mu}\, y^2}{1 + \dfrac{a}{\mu}} = y^s \text{ ....(25)}$$

in which $y = \dfrac{D}{D_o}$; $\mu = \dfrac{a_o}{D_o}$; and $\dfrac{a}{\mu} = \dfrac{D_o}{a_o} \cot\theta$.

The expression involving the wetted perimeter, P, is written as:

$$P = a_o + 2\, D \sqrt{1 + a^2} \text{ ....(26)}$$

from which,

$$\frac{P}{P_o} = \frac{a_o + 2\, D \sqrt{1 + a^2}}{a_o + 2\, D_o \sqrt{1 + a^2}} = \frac{1 + 2\, y \sqrt{\dfrac{1 + a^2}{\mu^2}}}{1 + 2 \sqrt{\dfrac{1 + a^2}{\mu^2}}} = y^k \text{....(27)}$$

Then, s and k, the exponents to y which depend on the ratios, $\dfrac{D}{D_o}$, are computed for various values of $\dfrac{a}{\mu}$ and $\dfrac{1 + a^2}{\mu^2}$, with y varying between 0.1 and 20. The curves are plotted as shown in Fig. 9. For example, referring to Fig. 8(*b*), let a_o = 8 ft; D_o = 2 ft; D_b = 4 ft; D = 2.2 ft; values of y at two sections considered are 2.0 and 1.1; $\mu = 4$; $\dfrac{a}{\mu} = 0$; $\dfrac{1 + a^2}{\mu^2} = \dfrac{1 + 0^2}{4^2}$

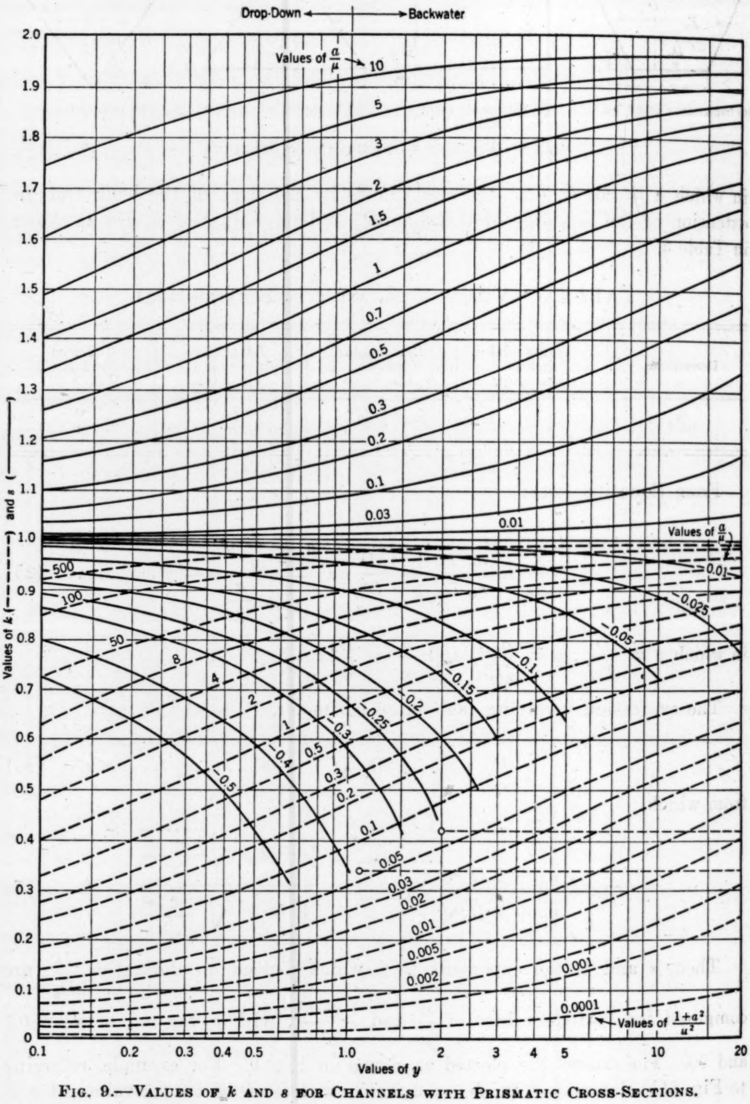

FIG. 9.—VALUES OF k AND s FOR CHANNELS WITH PRISMATIC CROSS-SECTIONS.

$= 0.0625$; and $s = 1.0$, a constant. From Fig. 9, $k = 0.34$ to 0.42, a mean value of 0.38.

(*b*) *Parabolic Section.*—In the case of the parabolic section shown in Fig. 10(*a*), $A = \frac{2}{3} BD$; $A_0 = \frac{2}{3} B_0 D_0$; and $B = B_0 \sqrt{\frac{D}{D_0}}$. Therefore, $\frac{A}{A_0} = y^{\frac{3}{2}} = y^s$; and, $s = 1.5$, a constant. Finally,

$$P = 2\,D_0 \left[\sqrt{y\left(y + \frac{B^2_0}{16\,D^2_0}\right)} + \frac{B^2_0}{16\,D^2_0} \log_e \frac{\sqrt{y} + \sqrt{y + \frac{B^2_0}{16\,D^2_0}}}{\frac{B_0}{4\,D_0}} \right]$$

and,

$$\frac{P}{P_0} = \frac{\sqrt{y\left(y + \frac{1}{16}\frac{B^2_0}{D^2_0}\right)} + \frac{1}{16}\frac{B^2_0}{D^2_0} \log_e \frac{\sqrt{y} + \sqrt{y + \frac{B^2_0}{16\,D^2_0}}}{\frac{B_0}{4\,D_0}}}{\sqrt{1 + \frac{1}{16}\frac{B^2_0}{D^2_0}} + \frac{1}{16}\frac{B^2_0}{D^2_0} \log_e \frac{4\,D_0}{B_0}\left[1 + \sqrt{1 + \frac{B^2_0}{16\,D^2_0}}\right]} = y^k \ldots (28)$$

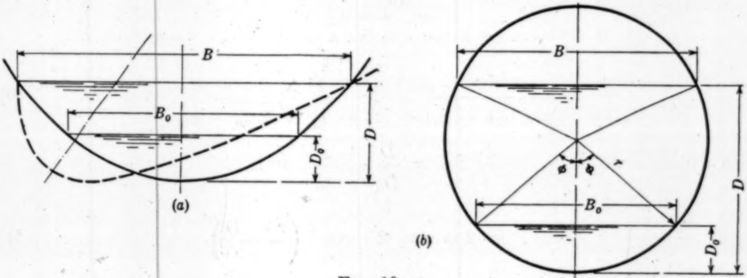

FIG. 10.

For values of y ranging from 0.1 to 20, the exponent, k, corresponding to the ratios, $\frac{B_0}{D_0}$, are calculated and shown by groups of curves in Fig. 11. For example, referring to Fig. 10(*a*), let $B_0 = 80$ ft; $D_0 = 20$ ft; $\frac{B_0}{D_0} = \frac{80}{20} = 4.0$; $D_0 = 40$ ft; $D = 22$ ft; and $y = 2.0$ and 1.1. Then, as shown by the circles and dotted lines in Fig. 11, Exponent k varies from 0.62 to 0.645, with a mean of 0.632.

(*c*) *Circular Section.*—In the case of the circular section shown in Fig. 10(*b*), r is the radius of the circle; ϕ equals one-half the central angle of the wetted perimeter; and

$$A = r^2 \cos^{-1}\left(\frac{r - D}{r}\right) + (D - r)\sqrt{2\,Dr - D^2} \ldots\ldots\ldots (29)$$

so that,

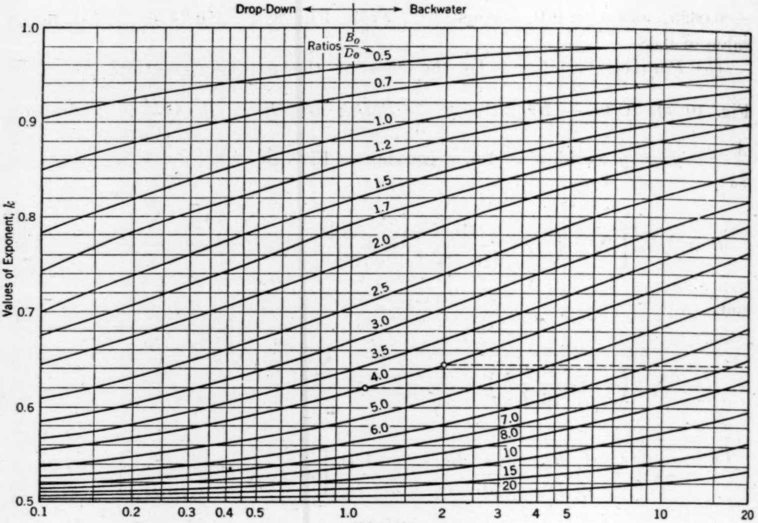

FIG. 11.—VALUES OF k FOR CHANNELS OF PARABOLIC CROSS-SECTION.

$$\frac{A}{A_o} = \frac{\cos^{-1}(1 - x) + (x - 1)\sqrt{2\,x - x^2}}{\cos^{-1}(1 - x_o) + (x_o - 1)\sqrt{2\,x_o - x_o^2}} = y^s \ldots\ldots\ldots (30)$$

in which, $x = \frac{D}{r}$; $x_o = \frac{D_o}{r}$; $y = \frac{D}{D_o} = \frac{x}{x_o}$; and,

$$P = 2\,\phi\,r = 2\,r\cos^{-1}\left(\frac{r - D}{r}\right) \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

Consequently,

$$\frac{P}{P_o} = \frac{\cos^{-1}(1 - x)}{\cos^{-1}(1 - x_o)} = y^k \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

For values of y ranging from 0.1 to 20, the exponents, s and k, corresponding to the ratios of $x_o = \frac{D_o}{r}$ are calculated and shown in Fig. 12. For example, referring to Fig. 10(*b*), let $r = 9$ ft; $D_o = 4.5$ ft; $D_b = 13.5$ ft; $D = 5.4$ ft; $x_o = \frac{D_o}{r} = 0.5$; $Y = \frac{D_b}{D_o} = 3.0$; and $y = \frac{D}{D_o} = 1.2$. Then, as shown by the circles in Fig. 12, Exponent s lies between 1.28 and 1.40 (mean, 1.34) and Exponent k lies between 0.55 and 0.63 (mean, 0.59).

(*d*) *Error Involved in Assuming That Section Indices, s and k, Are Constant.*—Generally, the values of s and k in Equations (13*a*) and (13*b*) in any section differ slightly with changes in the depth of water, D, but, in this paper, the average value for the range in which D changes is used in order to facilitate the integration. To study the degree of error produced by this assumption, comparisons are made between two examples in which rectangular sections are used for the back-water experiments and the results obtained from the Dupuit-Masoni formula.

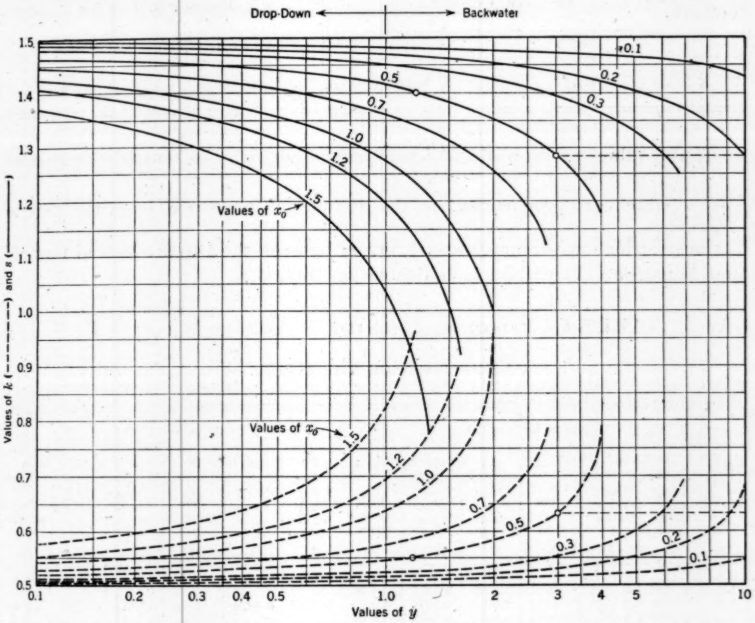

FIG. 12.—VALUES OF s AND k FOR CHANNELS OF CIRCULAR CROSS-SECTION.

Referring to Fig. 4(a), for Example 1, let $\frac{B_o}{D_o} = 2.5; Y = \frac{D_b}{D_o} = 2.0; y = \frac{D}{D_o} = 1.01$; and $k = 0.54$ to 0.46 (mean assumed as 0.5). For Example 2, let $\frac{B_o}{D_o} = 3.0$; $Y = 5.0$; $y = 1.01$; and $k = 0.60$ to 0.40 (mean assumed as 0.5). For convenience in comparing them with the Dupuit-Masoni formula (Item No. 2, Table 1), let $V = C\ R^m\ S^{0.5}$ and $m = 0.5$. Then, $r = 2\,s + 2\,m\,(s - k) = 2.5$;

$$K = \alpha\, s\, \frac{V^2_o}{g\, D_o} = \beta\, \frac{R_o}{D_o} = \beta\, \frac{B_o}{B_o + 2\, D_o} \quad \ldots\ldots\ldots\ldots(33)$$

and,

$$\beta = \alpha\ \frac{C^2\, S_o}{g} = \alpha\ \frac{V^2_o}{g\, R_o} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(34)$$

If k is considered a variable, the Dupuit-Masoni formula results, and the relation between β and K are as shown in Table 4.

TABLE 4.—RELATION BETWEEN K AND β, EQUATIONS (33) AND (34)

Values of:	EXAMPLE; 1 Y = 2.0		EXAMPLE 2; Y = 5.0	
	$\beta = 0.3$	$\beta = 0.9$	$\beta = 0.3$	$\beta = 0.9$
K	0.17	0.50	0.18	0.54

If the values of the ratio, $\frac{D}{D_0}$, are compared with the numerical values of $\frac{S_0 \, l}{D_0}$ (which are proportional to the distance, l, measured from the weir to various sections up stream from it), errors between the Dupuit-Masoni formula and Equation (17) will be as indicated by Table 5.

TABLE 5.—EFFECT OF ASSUMING AN AVERAGE VALUE OF K; COMPARISON OF THE RATIO, $\frac{S_0 l}{D_0}$

Evidently, errors produced by integration, using average values of k which are considered as constants, are insignificant, being usually within 1 per cent. Generally, the errors tend to increase in the up-stream direction where the change in the depth of water is slight. If it is desired to find the shape of the back-water curve more accurately for theoretical reasons, groups of curves similar to those in Fig. 3 are drawn by using the average values of k only for the integration, r being determined by using actual values of k for the depths of water in a given channel. It is possible to find the values of ϕ_1 and ϕ_2 from the curves corresponding to r and s thus obtained; but (except when the weir is unusually high) the calculation is simplified considerably if the average values of k are used.

7.—CALCULATED EXAMPLES OF THE BACK-WATER AND DROP-DOWN IN PRISMATIC CHANNELS

In order to demonstrate the method of computing the back-water and drop-down curves presented in this paper, two general examples are offered.

Example (A).—Back-Water: Case of Trapezoidal Channel.—Referring to Fig. 8(*a*), let the side slope = 1 on 1; $D_b = 30$ ft; $D_o = 6$ ft; $\theta = 45°$; $a_o = 30$ ft; $S_o = 1{:}1\,600$; $A_o = 6 \times 30 + 6 \times 6 = 216$ sq ft; and $R_o = \dfrac{216}{30 + 2 \times 6\sqrt{2}} = 4.6$ ft. It is necesary to use a velocity equation in the form of Equation (2) in which C remains constant irrespective of R. Now, if the Manning formula is used (Equation (2), with $m = \frac{2}{3}$ and $p = \frac{1}{2}$), taking Kutter's roughness coefficient as $n = 0.020$, the mean velocity is: $V_o = \dfrac{1.486}{0.02} \times 4.6^{\frac{2}{3}} \times \dfrac{1}{\sqrt{1\,600}} = 5.15$ ft per sec. Therefore, $Q = V_o\,A_o = 5.15 \times 216 = 1\,112.4$ cu ft per sec.

If the depth of water is increased to $D_b = 30$ ft by a weir; then $y = \dfrac{D_b}{D_o} = \dfrac{30}{6} = 5$. By Example (1) of Article 6, if $\theta = 45°$ then, $a = \cot\theta = 1$; $\mu = \dfrac{a_o}{D_o} = \dfrac{30}{6} = 5$; $\dfrac{a}{\mu} = \dfrac{1}{5}$; and, $\dfrac{1 + a^2}{\mu^2} = \dfrac{1 + 1}{25} = 0.08$. It is required to find l, the distance from the weir to the section where the depth of water is 18 ft; thus, $y = \dfrac{D}{D_o} = \dfrac{18}{6} = 3$; and $m = \dfrac{2}{3}$. Hence, from Fig. 9 may be selected the values listed in Table 6(*a*); and with

TABLE 6.—ILLUSTRATIVE EXAMPLE; VALUES READ FROM CURVES

Symbol	EXAMPLE (*A*)		Symbol	EXAMPLE (*B*)	
	For depth, $D = 18$ feet	For depth, $D_b = 30$ feet		For depth, $D = 12$ feet $\left(\frac{D_o}{D} = 1.25\right)$	For depth, $D_s = 10$ feet $\left(\frac{D_o}{D_s} = 1.5\right)$
(1)	(2)	(3)	(4)	(5)	(6)
(*a*) VALUES FROM FIG. 9			(*c*) VALUES FROM FIG. 9		
y	3	5	$\frac{a}{\mu}$	0	0
s	1.31	1.36	$\frac{1+a^2}{\mu_2}$	0.25	0.25
k	0.51	0.56	s	1.0	1.0
$r - 2s$	1.07	1.07	k	0.47	0.45
r	3.69	3.79	$r - 2s$†	0.707	0.733
K	0.194*	....	r	2.707	2.733
(*b*) VALUES FROM FIG. 3			(*d*) VALUES FROM FIGS. 5 AND 6		
Φ_1	3.62	5.68	Ψ_1	1.82	1.92
Φ_2	1.80	1.80	Ψ_2	2.08	2.28

* Equation (15). † Equals $2m\,(s - k)$.

these, the integrals, Φ_1 and Φ_2, listed in Table 6(*b*) may be selected from Fig. 3. Substitution in Equation (18) then yields: $\frac{S_0\, l}{D_0} = 5.68 - 3.62 - 0.194\ (1.80 - 1.80) = 2.06$; and, therefore, $l = 2.06 \times \frac{D_0}{S_0} = 2.06 \times 6 \times 1\,600 = 19\,776$ ft. In this case the last quantity of Equation (18) (which is multiplied by K) is insignificant, but it can not be overlooked when $\frac{D_b}{D_0} < 2$.

Example (B).—Drop-Down: Case of Rectangular Channel.—Referring to Fig. 4(*b*), let $D_0 = 15$ ft; $D_s = 10$ ft; $B_0 = a_0 = 30$ ft; $S_0 = 1{:}2\,500$; $n = 0.02$; $C = \frac{1.486}{n} = 74.3$; $A_0 = 30 \times 15 = 450$ sq ft; $R_0 = \frac{450}{30 + 2 \times 15} = 7.5$ ft; and, by Equation (2) with $m = \frac{2}{3}$ and $p = \frac{1}{2}$ (the Manning formula), $V_0 = 74.3 \times 7.5^{\frac{2}{3}} \times \frac{1}{\sqrt{2\,500}} = 5.69$ ft per sec. Consequently, $Q = 450 \times 5.69 = 2\,560$ cu ft per sec; and $K = \alpha\, s\, \frac{V_0^2}{g D_0} = \frac{10}{9} \times 1 \times \frac{5.69^2}{32.2 \times 15} = 0.074$.

If D_s is equal to 10 ft (that is, if it is nearly equal to the critical depth, at the cross-section over the fall): $\mu = \frac{a_0}{D_0} = 2$; $\alpha = \cot\theta = 0$: $\frac{a}{\mu} = 0$; $s = 1$; and, $\frac{1 + a^2}{\mu^2} = 0.25$. (See Figs. 4(*b*) and 8(*b*).)

Hence, to find l, the distance from the fall in the channel to the section where $D = 12$ ft: $y_0 = \frac{D_s}{D_0} = \frac{10}{15} = \frac{2}{3}$; and $y = \frac{D}{D_0} = \frac{12}{15} = 0.8$. From Fig. 9 may be selected values listed in Table 6(*c*); and, with these, the integrals, Ψ_1, and Ψ_2, listed in Table 6(*d*) may be selected from Figs. 5 and 6.

Substitution in Equation (20) then yields $\frac{S_0\, l}{D_0} = 1.92 - 1.82 - 0.074\ (2.28 - 2.08) = 0.085$; and, therefore, $l = 0.085 \times 2\,500 \times 15 = 3\,190$ (ft).

8.—Experimental Flumes

In general, the deciding factors in establishing the shape of the back-water curve are the shape of the channel cross-section and the degree of roughness. The former is the more important and the inadequacy of previous formulas is due, in large measure, to ignoring its relative effect.

In the experiments described herein, both the cross-sectional shape and the surface roughness of the experimental channels were varied. Moreover, due to the shortness of the effective length of the flume in this experiment, it was impossible to determine the height of the water surface covering the total length of back-water limits by a single experiment. For example, when $Y = \frac{D_b}{D_0} = 2$, the back-water profile is equivalent to a curve constructed by connecting many back-water curves plotted in the ranges from: $\frac{D_b}{D_0} = 2$ to $\frac{D_b}{D_0} = 1.6$; 1.6 to 1.2; 1.2 to 1.05; etc. Hence, in the experiments reported herein, the entire back-water curve was traced by connecting several back-water curves. The curve thus obtained contains from three to nine experimental values which indicates that a considerable number of measurements is required for channels of easy slope, S_0. On the other hand, if S_0 is too steep, the velocity of the water becomes very great and the flow unsteady; in extreme cases, the water shoots ahead so violently that the bed slope up stream from the weir is necessarily fixed at 1:500 and that of the drop-down at from 1:500 to 1:2 000. In order to study the influence of roughness, two kinds of sections were devised for each type of channel section: (1) A smooth flume in which the inner surfaces were planed carefully; and (2), a rough flume in which the inner surfaces were lined with $\frac{3}{8}$-in. mesh made of No. 20 galvanized wire. In addition, the outer surfaces of the flume were submerged in water to avoid deforming the flume by alternate wetting and drying. When the flow was variable, the distance, l (from the weir to the section up stream, where the depth of water is D), was measured, and the back-water and drop-down are represented by the relative values of $\frac{S_0\, l}{D_0}$.

The typical sections of the channels studied in the writer's laboratory are shown in Fig. 13, the dimensions being as indicated. For measuring the discharge a common weir was used; and the height of the water surface was read with an ordinary engineers' level and a needle-gauge readable to the nearest 0.1 mm (0.00394 in.).

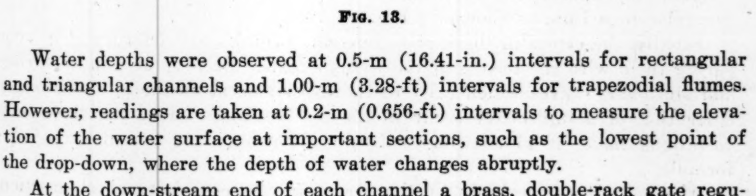

FIG. 13.

Water depths were observed at 0.5-m (16.41-in.) intervals for rectangular and triangular channels and 1.00-m (3.28-ft) intervals for trapezodial flumes. However, readings are taken at 0.2-m (0.656-ft) intervals to measure the elevation of the water surface at important sections, such as the lowest point of the drop-down, where the depth of water changes abruptly.

At the down-stream end of each channel a brass, double-rack gate regulated the water level so that it was nearly the same at the down-stream end in one set of measurements as it was at the up-stream end, in the preceding set. The regulation was effected by means of slits.

9.—The Measurement of Back-Water

Smooth Rectangular Channels.—Referring to Figs. 8(*b*) and 13(*a*), let: $B_0 = 7.874$ in.; $S_0 = 1{:}500$; $D_0 = 1.9685$ in.; $D_b = 3.937$ in.; $V_0 = 1.61$ ft per sec; and $Y = \frac{D_b}{D_0} = 2.0$.

Using Manning's formula for uniform flow, with various slopes, and assuming C to be constant, the writer found by actual measurements that the value of m was also nearly a constant, and was equal to 0.65.

The effective length of the channel was 11 m (36.09 ft). The dam at the lowest down-stream section was adjusted so that $D_b = 2\ D_0 = 3.937$ in., and the elevation of the water surface was measured at 0.5-m intervals (1.64 ft). Then the dam was re-adjusted to make $D_b = 80$ mm (3.15 in.) and the water surface elevations were measured again. This process was repeated until four series of measurements had been made for different values of D_b; then, each set was plotted and the back-water curve from 3.937 in. to 2.087 in. (the depths of water above the weir), was measured. The result thus obtained is shown by dots in Fig. 14(*a*); corresponding data pertaining to rough channels are shown.

Computation of the Ratio, $\frac{S_0\,l}{D_0}$.—In a rectangular channel such as Fig. 4(*a*), in which $s = 1.0$, the mean value of k between $Y = 2.0$ and $Y = 1.01$ may be determined as follows: $\frac{(1 + a^2)}{\mu^2} = \frac{1 + 0}{4^2} = \frac{1}{16}$; and, from Fig. 9, $k = 0.38$. Therefore, $r = 2\,s + 2\,m\,(s - k) = 2.00 + 2 \times 0.65\,(1 - 0.38) = 2.81$; $r - 2\,s = 0.81$; and, $K = a\,s\,\frac{V_0^2}{gD_0} = 0.55$.

After reading the values of Φ_1 and Φ_2 for $r = 2.81$ and $r - 2\,s = 0.81$ which correspond to various values of $y = \frac{D}{D_0}$ from Fig. 3, the values of $\frac{S_0 l}{D_0}$ can be computed by Equation (18) and arranged as in Table 7(*a*). Next, in order to compare the errors in various back-water formulas that have been used heretofore (see Table 1), the values of $\frac{S_0 l}{D_0}$ computed from these formulas are likewise tabulated, and the back-water curves are drawn, for general comparison, as shown in Fig. 14.

Finally, the errors in the various current formulas are determined by comparing them with the results of the writer's tests. Because of minute surface and stationary waves which exist in the experimental channels, variations of a fraction of a millimeter occur in the test readings. In some cases these variations make it almost impossible to determine the actual error of a formula.

Although the magnitude of the errors in the experimental observations was very small, the effects of these errors on the back-water curves for small channels were quite remarkable. In the preliminary tests the measured values were quite erratic, due to deflections in the channel structure between beam

* Value not determinable. † Different from Tables 7(*a*), 7(*b*), and 7(*c*).

supports. This condition was caused (1) by the increase in the total weight when water was impounded by the weir and absorbed to some extent by the channel; and (2) by complicating factors at the intake and outlet. Subsequently, however, these defects were mostly corrected; the experiments were conducted under almost ideal conditions; and the results coincided fairly well with the writer's calculated values.

For example, comparing the experimental and calculated values of various formulas of back-water (see Fig. 14(*a*)) for the case of a smooth rectangular flume, the Dupuit-Masoni formula is found to be the most rational, but the values of $\frac{S_0 l}{D_0}$ are a little greater, due to using the Chezy formula in which C is considered as a constant (that is, m being assumed equal to 0.5 in Equation (2)). However, this formula (Item No. 2, Table 1) agrees more nearly with experiments than any of the others.

The Dupuit-Masoni formula was adopted for a study of the relation derived by Bresse, and the section was a broad one. Errors due to these two assumptions are negative in sign and their magnitude is far greater than the positive errors due to assuming a positive value of C. Consequently, the ratios, $\frac{S_0 l}{D_0}$, by the Bresse formula are slightly too small.

The Rühlmann formula (Item No. 3, Table 1) is derived by neglecting the change in velocity head in the Bresse formula. It yields values considerably in excess of those found by the writer, using a smooth channel with a steep slope and a relatively high velocity. This is particularly true toward the up-stream end of the profile where the rise in water surface is slight and, hence, this formula is not applicable when it is desired to find the position of a point which is to be regarded as the upper limit of the back-water.

The Schaffernak formula (Item No. 5, Table 1) is based upon almost the same assumption as the Rühlmann formula. It was found to coincide somewhat better than the Rühlmann formula with experimental results, since m is equal to 0.75, C being regarded as a constant. Values of $\frac{S_0 l}{D_0}$ by this formula are assumed to be considerably greater because the rectangle is assumed to be broad and the velocity head is disregarded.

In applying the Ehrenberger formula (Item No. 6, Table 1), the rectangle is assumed to be broad, which gives rise to negative errors, but those caused by neglecting the velocity head tend to offset them so that, in general, positive errors are obtained. However, the errors were found to be relatively smaller than in the case of the Rühlmann and Schaffernak formulas.

In the Baticle formula (Item No. 7, Table 1) the velocity head is disregarded, and the irrational assumption is made that $A^2 R = z^5$, for a rectangular channel. The errors thus introduced are so great as to make this formula entirely unreliable.

The Poirée formula has no theoretical basis in hydraulics, but for a rectangular channel its errors were found to be rather less than those of some of the more complicated formulas.

The Tolkmitt formula applies to parabolic sections, and the effect of applying it to rectangular sections is to introduce serious negative errors.

Rough Rectangular Channels.—To simulate roughness, the flume was lined with wire netting. Other characteristics were (see Fig. 4(a)): $B = B_0 = 7.874$ in.; $S_0 = 1:500$; $D_0 = 1.97$ in.; $V_0 = 0.886$ ft per sec; $D_b = 3.937$ in.; and, in Equation (2), $m = 0.70$ and $s = 1.0$ in Equation 5(a). Therefore, $k = 0.38$; $r = 2.87$; and $K = 0.16$.

The back-water curves obtained by experiment and from various formulas are shown in Fig. 14(*b*), and values of $\frac{S_0 l}{D_0}$ are shown in Table 7(*b*). The back-water distance in this case is somewhat greater than that for a smooth flume.

In the velocity formula as applied to rough channel sections, $m = 0.70$ actually; but in the Dupuit-Masoni formula, $m = 0.50$ so that the errors are greater than those for smooth surfaces, and values of $\frac{S_0 l}{D_0}$ are always too large.

In the Bresse formula, errors in the ratio, $\frac{S_0 l}{D_0}$, are rather smaller than those in the preceding formula because the errors in assuming and those introduced by assuming the rectangles to be broad cancel each other.

Values computed by the Rühlmann formula agree remarkably well with laboratory tests because the degree of roughness is great and the velocity is small; hence, the effect of neglecting the velocity head is considerably less serious than in the case of smooth channels. Moreover, errors due to the illogical nature of the formula and those introduced by assuming the rectangle to be broad, cancel each other. In this case the errors are smaller in comparison with those for the smooth channel, and the calculated values agree especially well with experimental values in the lower part of the stream where the velocity is small. However, the cancellation of various errors in this manner is rather accidental and can not be expected to occur in a general case.

Smooth, Right Triangular Channel.—The characteristics of the flume for this case were: $S_0 = 1{:}500$; $D_0 = 1.97$ in; $D_b = 3.937$ in.; $V_0 = 0.866$ ft per sec; and, $Y = 2.0$. Furthermore, in case of a triangular section, $s = 2.0$; $k = 1.0$ (and both these indices are fixed); and, $m = 0.70$. Therefore, $r = 2 \times 2 + 1.4\ (2 - 1) = 5.4$; and, $r - 2\,s = 1.4$.

Back-water curves obtained by experiment and those obtained by calculations using the writer's formula, and other formulas, are shown in Fig. 15 and values of $\frac{S_0 l}{D_0}$ are shown in Table 7(*c*).

Originally, the assumption, $A^2 R = z^5$, upon which the Baticle formula is based, was considered suitable for triangular or approximately trapezodial sections, and in spite of the fact that it neglects velocity head, this formula yields results that are fairly in accord with experiment. This illustrates the predominant importance of the shape of the section.

Positive errors due to assuming a broad section are quite serious in applying the Bresse formula to smooth, triangular channels. Since the Chezy formula is also involved, introducing other positive errors, the total is quite considerable.

The Rühlmann, Schaffernak, and Ehrenberger formulas are based on the assumption of a broad section; and the velocity head is neglected, so that the errors are all positive and considerable. Serious errors, likewise, are introduced in working with the Poirée formula.

Rough Trapezoidal Channel.—The characteristics of the flume for this case (see Fig. 13(*c*)) were: a_0 = 11.81 in.; $a = \cot \theta = \cot 45° = 1$; $S_0 = 1{:}500$; D_0 = 3.937 in.; D_b = 7.874 in.; $Y = 2.0$; Q = 0.625 cu ft per sec; and V_0 = 1.453 ft per sec.

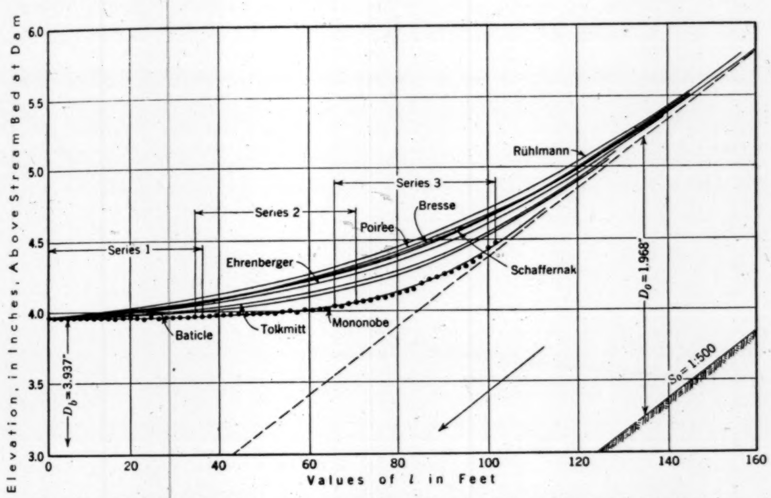

FIG. 15.—BACK-WATER MEASUREMENTS; TEST VALUES COMPARED WITH RESULTS BY VARIOUS INVESTIGATORS; SMOOTH, RIGHT-TRIANGULAR CHANNEL (SEE FIG. 8(*d*)).

The total length of the channel was 12 m (39.37 ft), but the cross-section was large in comparison with the length. The effects of the inflowing water at the up-stream end and of the latticed weir at the lower end extend quite a distance into the channel, reducing the length of a stream in which there is uniform flow, and the effective length is only about 30 ft. Moreover, in order to obtain the same ratio, $\frac{S_0\, l}{D_0}$, it was necessary that the channel be longer than a flume of less depth of water so that nine series of tests were required. Due to the skill of the operators, the results were more uniform than was expected (see Fig. 16).

In the writer's method of computation: $a = 1$; $\mu = \frac{a_0}{D_0} = 3$; $\frac{a}{\mu} = \frac{1}{3}$; and $\frac{1 + a^2}{\mu^2} = \frac{2}{9}$.

Referring to Fig. 9, the average values of s and k between the limits, $y = 1.01$ and $Y = 2.20$, are $s = 1.28$ and $k = 0.535$. In the velocity formula, m equals 0.7 so that $r = 3.60$; $r - 2\,s = 1.04$; and, $K = 0.286$.

Therefore, the integrals, Φ_1 and Φ_2, for any arbitrary values of $\frac{D}{D_0}$ may b read from the curves of Fig. 3. With given values of s and r introduced in Equations (21), the values of $\frac{S_0\, l}{D_0}$ (see Table 7(d)) can be determined easily, and such back-water curves as those shown in Fig. 16 can be plotted. For comparison the back-water curves based on various formulas are computed and these are shown by solid-line curves in Fig. 16.

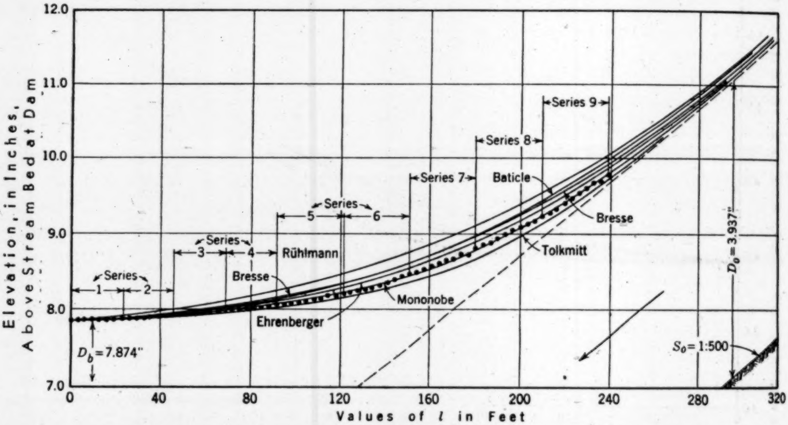

FIG. 16.—BACK-WATER MEASUREMENTS; TEST VALUES COMPARED WITH RESULTS BY VARIOUS INVESTIGATORS; ROUGH TRAPEZOIDAL CHANNEL (SEE FIG. 13(c)).

The Tolkmitt formula was derived for application to the parabolic section. Because of the analogy of this section to the cross-section of the ordinary river channel, this formula gives results that are fairly in accord with actual conditions. Positive errors are produced because $m = 0.5$ was used in the velocity formula, but errors due to the difference between sectional shapes are negative and relatively large so that the total errors are negative and are not large. In applying the Bresse formula to rough trapezoidal channels errors due to the shape of the section and the Chezy velocity formula are both positive and, therefore, fairly large.

Use of the Rühlmann formula introduces positive errors due to the shape of the section, the velocity formula, and the fact that the velocity head is neglected. The resulting errors are positive and the largest of those produced by the several formulas.

The velocity equations involved in both the Schaffernak and Ehrenberger formulas are closer to actual conditions than that in the case of the Rühlmann formula, and errors are also considerably less.

In the case of the Baticle formula, the assumption as to the shape of the cross-section is closer to actual conditions than in the case of the Rühlmann formula; but the errors are greater.

10.—MEASUREMENT OF DROP-DOWN

In the experiments to study the drop-down, the same channels were used as in the case of the back-water except that the depth of water was more shallow and the velocity and the slope of the water surface were increased. Tests were made at depths, D_0, of 3.937 in. and 5.906 in.; and the slopes were $S_0 = 1{:}500$, $1{:}1\,000$, and $1{:}2\,000$.

Smooth Rectangular Channels.—Referring to Figs. 8(*b*) and 13(*a*), $B_0 = 7.874$ in.; $D_0 = 3.937$ in.; $D_s = 2.46$ in.; $S_0 = 1{:}1\,000$; $V_0 = 1.385$ ft per sec; $Q = 0.298$ cu ft per sec; and $Z = \frac{D_0}{D_s} = 1.60$.

The height of the water surface is measured at 50-cm (1.64-ft) intervals, but near the lowest end of the channel where the slope of the water surface is steep, readings were taken at 20-cm (7.874-in.) intervals; four observations, for different values of $\frac{D_0}{D_s}$, were plotted; and the drop-down curve from $D_s = 2.461$ in. to $D = 3.839$ in. was traced.

The critical depth, D_c (the limit between jet flow and ordinary flow) was, $D_c = \sqrt[3]{\frac{Q^2}{g\,B^2}} = 2.232$ in. Therefore, in order to prevent the occurrence of the transition from ordinary flow to jet flow so as to interfere with the drop-down, the depth, D_s, at the lowest end of the channel was selected as 2.46 in.

Computation of the Ratio, $\frac{S_0\,l}{D_0}$.—In a rectangular channel, such as Fig. 4(*a*), in which $m = 0.70$; and $s = 1.0$, the average value of k between $Z = 1.60$ and $z = 1.01$ is determined from Fig. 9, as follows: $a = 0$; $\mu = \frac{B_0}{D_0} = 2$; $\frac{1 + a^2}{\mu^2} = \frac{1}{4}$; and $k = 0.47$. Therefore, $r = 2.74$, and $K = 0.202$.

The integrals, Ψ_1 and Ψ_2, for a series of z-values are read from Figs. 5, 6, and 7, for $r = 2.74$ and $s = 1.0$; the ratio, $\frac{S_0\,l}{D_0}$, is obtained by substituting these values in Equation (20); and l is computed by simple, algebraic transposition. If the curve corresponding with r and s lies between two adjacent curves of the integrals, Ψ_1 and Ψ_2, the problem is solved by interpolation.

As is evident from Figs. 6 and 7(*a*), the values of Ψ_2, expressing the effect of the change of the velocity head, are relatively quite important for drop-down measurements as compared with back-water measurements. It is only by multiplying them by the coefficient, $K<1$, that the values of Ψ_2 are made smaller than Ψ_1 which expresses the friction loss (see Figs. 5 and 7(*b*)). Consequently, it is clear that all the current drop-down formulas in which the velocity head is neglected, are entirely inadequate.

Referring to Figs. 5 and 7(*a*), the increase in Ψ_1 as compared with the increase in z is very small when z exceeds a certain value. For instance, the difference of Ψ_1 between $z = 3.0$ and $z = 2.0$ is almost equal to zero. Accordingly, the actual distance between the two sections is very small, which means that the water surface falls so considerably as to outlaw the formulas now in current use. Moreover, the application of this method of computation is limited to the part of the channel in which the flow is normal; it is not applicable to the parts of the channel shallower than D_C, such as the case in which $z \gtreqless 2$ at the lower end of the channel.

Test Measurements for the Drop-Down Curve in Smooth Rectangular Channels.—Test values for drop-down, with corresponding values derived by current formulas in use, are plotted in Fig. 17(*a*), and corresponding values of $\dfrac{S_0\, l}{D_0}$ are shown in Table 8(*a*).

* Blank spaces indicate values not determinable.

In the Kozeny formula, the velocity head is considered and $m = 0.70$ in the velocity formula, but the section is assumed to be a broad rectangle so

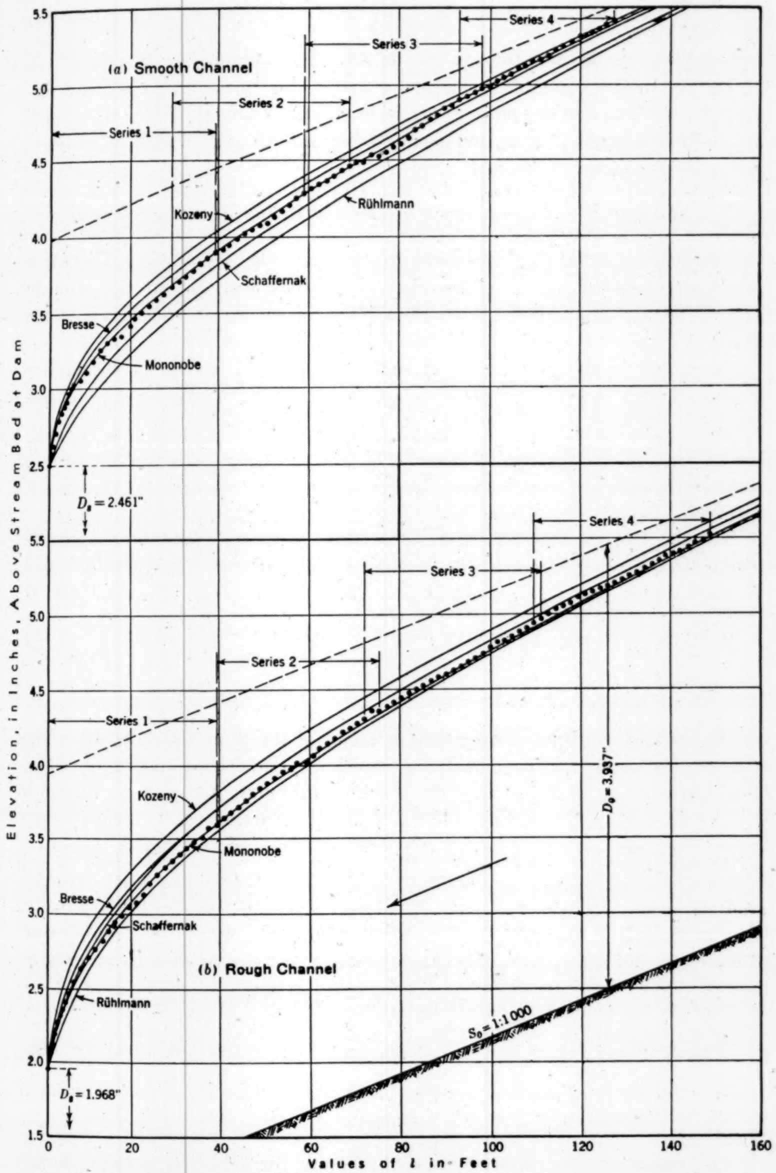

FIG. 17.—DROP-DOWN MEASUREMENTS; TEST VALUES COMPARED WITH RESULTS BY VARIOUS INVESTIGATORS; RECTANGULAR CHANNEL (SEE FIG. 4(a)).

that $\frac{S_0 l}{D_0}$ becomes very small. In other words, negative errors are produced and they become greater toward the low end of the flume.

In the Bresse formula, the negative errors due to assuming a broad rectangular section, and the positive errors due to assuming $m = 0.5$, cancel each other. The resulting errors are negative, but rather smaller than those introduced in the Kozeny formula.

The value of $\frac{S_0 l}{D_0}$ is increased considerably in the Rühlmann formula due to neglecting the velocity head and to assuming that $m = 0.5$. This error is slightly reduced by the assumption of a broad section, but the ultimate errors are very great, being more than 200% in the down-stream part of the flume.

In regard to the Schaffernak formula, $m = 0.75$ is too great a value for a channel such as that used in the experiment because the degree of roughness is relatively slight, and negative errors are produced for $\frac{S_0 l}{D_0}$, so that the resulting errors are considerably less than those involved in the Rühlmann formula.

Rough Rectangular Channel.—For this test, the smooth rectangular channel was made to simulate roughness by lining it with wire netting. Other characteristics were: $B_0 = 7.874$ in.; $D_0 = 3.937$ in.; $S_0 = 1{:}1\,000$; $Q = 0.180$ cu ft per sec; $V_0 = 0.863$ ft per sec; $D_s = 1.968$ in.; $Z = \frac{D_0}{D_s} = 2.0$; and $D_c = \sqrt[3]{\frac{Q^2}{g\,B^2}} = 0.136$ ft.

The actual depth of water at the low end of the flume was 1.67 in. which was almost equal to the calculated values of the critical depth of water. For convenience in computing the back-water curve, the section at which the depth of water, $D_s = 1.968$ in., is used as the starting point. Applying the writer's formula: $s = 1.0$; $m = 0.70$; $a = 0$; $\mu = \frac{B_0}{D_0} = 2$; $\frac{1 + a^2}{\mu^2} = \frac{1}{4}$; and the average value of k, from $Z = 2$ to $z = 1.01$, is $k = 0.46$. Finally, $r = 2.75$; and $K = 0.078$. Values of the integrals, Ψ_1 and Ψ_n, can be read directly from Figs. 5, 6, and 7. Then, similar to the case of back-water computations, it is possible to calculate the values of $\frac{S_0 l}{D_0}$ from Equation (20).

Experimental values and calculated drop-down curves obtained by using various formulas are shown in Fig. 17(b), and values of $\frac{S_0 l}{D_0}$ are given in Table 8(b).

In computing drop-down by the Rühlmann formula, the negative errors due to assuming a broad cross-section, the positive errors introduced by neglecting the velocity head, and the assumption that $m = 0.5$, cancel each other, and the errors are negligible except in the low end of the flume, but the cancellation of the errors is rather accidental.

Accidentally, the algebraic sum of the positive errors introduced by the Schaffernak formula due to neglecting the velocity head, and the negative error involved in assuming that $m = 0.75$, is almost equal to the error caused by assuming that $m = 0.5$. For this reason the result agrees well with that of the Bresse formula.

Smooth Triangular Channel.—The characteristics of the flume for this test were: $S_o = 1:1\,000$; $D_o = 3.94$ in.; $D_s = 3.03$ in.; $Z = \frac{D_o}{D_s} = 1.30$; $V_o = 1.083$ ft per sec; $Q = 0.1165$ cu ft per sec; and $D_c = \sqrt[5]{\frac{2\,Q^2}{g}} = 0.243$ in. Experimentally D_c was found to be 2.98 in., but for convenience the backwater is assumed to occur at the section where $D_s = 3.02$ in.

The computation by the writer's method is as follows: $s = 2.0$ (a constant); $k = 1.0$ (a constant); $m = 0.70$; $r = 5.4$; and $K = 0.247$.

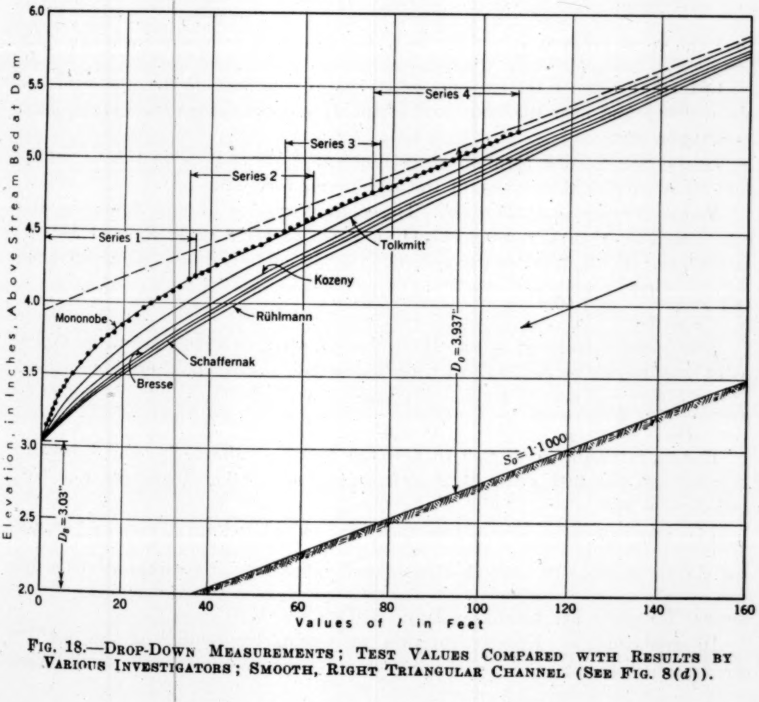

FIG. 18.—DROP-DOWN MEASUREMENTS; TEST VALUES COMPARED WITH RESULTS BY VARIOUS INVESTIGATORS; SMOOTH, RIGHT TRIANGULAR CHANNEL (SEE FIG. 8(*d*)).

As before, the integrals, Ψ_1 and Ψ_2, are read from Figs. 5, 6, and 7, and the ratios, $\frac{S_0\,l}{D_0}$, are computed by Equation (20). The experimental as well as the calculated drop-down curves based on various formulas are shown in Fig. 18 and the calculated values of $\frac{S_0\,l}{D_0}$ based on various formulas are shown in Table 8(*c*).

For the triangular channel section in general, positive errors are introduced by ignoring the velocity head, by assuming rectangular or parabolic sections, and by assuming that $m = 0.5$. Being all positive in sign these errors become quite serious.

The Kozeny formula involves the velocity head and m is assumed equal to 0.70; but the effect of assuming a broad channel section offsets the favorable conditions, and errors greater than 150 or 200% are produced. This indicates once more the importance of the shape of the cross-section in computing the drop-down.

Because of the assumption that $m = 0.5$, errors are introduced in the Bresse formula which are even greater than those in the Kozeny formula.

The Rühlmann formula applied to smooth triangular channels, involves excessive errors due to various causes, which are all positive. The result is that the total error is a serious one; for example, at the point where $\frac{D_0}{D} = 1.01$ (that is, near the extreme upper end of the drop-down), the errors are about 200% and near the lower end of the drop-down these errors are as much as 400 per cent.

In the Schaffernak formula, m is assumed equal to 0.75, so that errors are somewhat smaller than those of the Rühlmann formula.

Rough Trapezoidal Channel.—The characteristics of the flume for this case (see Fig. 13(*c*)) were: $a_0 = 11.81$ in.; $a = \cot\theta = 1$; $S_0 = 1{:}500$; $D_0 = 5.91$ in.; $V_0 = 1.837$ ft per sec; $Q = 1.338$ cu ft per sec; $D_s = 3.937$ in.; and $Z = \frac{D_0}{D_s} = 1.50$.

The critical depth of water, D_C, was computed as 4.016 in. and by experiment was found to be 3.937 in. By the writer's method, therefore, $a = 1$; $\mu = \frac{a_0}{D_0} = 2.0$; $\frac{a}{\mu} = \frac{1}{2}$; and $\frac{1 + a^2}{\mu^2} = \frac{1}{2}$.

Hence, referring to Fig. 9 to find the average values of s and k between $Z = 1.5$ and $z = 1.01$, $s = 1.31$; $k = 0.57$; and $m = 0.65$. Therefore, $r = 3.58$; and $K = 0.30$.

The test values for drop-down and those calculated from various formulas are shown in Fig. 19, and the calculated values of $\frac{S_0\,l}{D_0}$, obtained by using several formulas are found in Table 8(*d*).

In applying the Kozeny formula to rough, trapezodial flumes positive errors are introduced by assuming broad cross-sections, and small negative errors by assuming that $m = 0.70$. However, the total errors are less in this case than in the use of the other formulas, because the velocity head is taken into consideration.

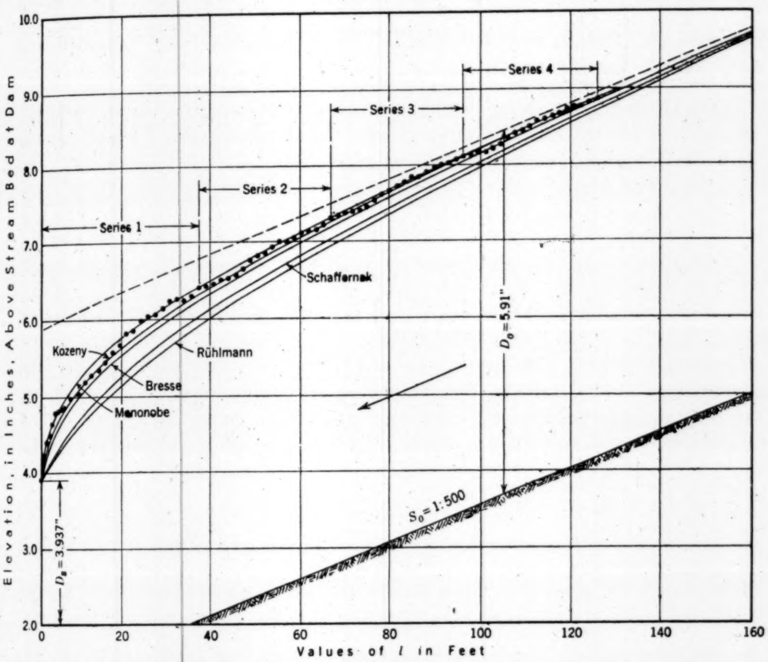

FIG. 19.—DROP-DOWN MEASUREMENTS; TEST VALUES COMPARED WITH RESULTS BY VARIOUS INVESTIGATORS; ROUGH TRAPEZOIDAL CHANNEL (SEE FIG. 13(c)).

The velocity head is considered in the Bresse formula, but since m is assumed equal to 0.5, errors are introduced which are greater than those by the Kozeny formula.

In using the Schaffernak formula, $m = 0.75$ is too great, and insignificant negative errors are introduced, but because the velocity head is ignored, the positive errors are still too great.

The total errors involved are greatest in the case of the Rühlmann formula because it introduces most of the unfavorable conditions cited.

11.—CONCLUDING REMARKS

In formulas for back-water and drop-down which are in current use the errors that enter because of illogical assumptions are:

(1) *Errors Introduced by Assuming C in the Chezy Formula as a Constant.*—

(a) In back-water computations, the actual value of C increases considerably with an increasing depth of water in a down-stream direction. Hence, if C is assumed constant and equal to its value for the original uniform flow, the computed surface slope, S, becomes steeper than the true slope. The depth of water is constant at the weir so that the computed distance, l, between the weir and the section where the depth of water is D, becomes too small. Moreover, S_0 and D_0 are fixed values so that the ratio, $\frac{S_0\, l}{D_0}$, is too small, and the error involved is negative.

(*b*) In drop-down computations the computed velocity is more than the actual if C for the case of uniform flow is used; consequently, the drop computed is too great and positive errors are introduced.

(*2*).—*Errors Created by Neglecting the Change in Velocity Head,* $\frac{d}{dx}\left(\frac{V^2}{2g}\right)$.—

(*a*) In the case of back-water, the velocity, V, decreases in a down-stream direction and the value of $\frac{d}{dx}\left(\frac{V^2}{2\,g}\right)$ is negative. Neglecting this factor, the computed slope, S, is steeper than the true slope corresponding to the fixed quantity of flow, Q. Since the depth of water at the lower end of the flume is constant, the calculated water level at points toward the upper end of the flume is too high; consequently, the elevation of the back-water is too high, so that $\frac{S_0\, l}{D_0}$ becomes too small, and negative errors are produced.

(*b*) In the case of drop-down, $\frac{d}{dx}\left(\frac{V^2}{2\,g}\right)$ is positive; and if this term is disregarded, the computed slope, S, that is necessary to maintain the flow, Q, becomes small and the drop-down in the surface becomes much too great. Positive errors greater than 100% are often introduced in the values of $\frac{S_0\, l}{D_0}$, especially near the lower end of the flume.

(*3*).—*Errors Caused by Assuming the Channel Section to Be Very Wide.*—

(*a*) In the case of back-water, the effect of assuming a wide cross-section is the same as assuming that the wetted perimeter, P, is equal to the width of the surface. That is, the hydraulic mean depth, R, is assumed to be greater than its true value. Thus, the value of S in Equation (1) becomes too small, and positive errors are introduced.

(*b*) The result of using too small a value of S, in the case of drop-down, is to make the computed water-surface slope steeper than the true surface slope and, consequently, the computed value of $\frac{S_0\, l}{D_0}$, is too great.

The foregoing conclusions, and supporting arguments, indicate that formulas for drop-down and back-water in current use, result in ratios, $\frac{S_0\, l}{D_0}$, which are either too great or too small. The effect of adopting illogical assumptions is to superpose positive and negative errors. In certain cases these errors may cancel to some extent, but more often they build up into serious discrepancies of one sign or the other. For this reason many of the old formulas have yielded data involving seriously large errors, especially in the case of drop-down.

DISCUSSION

J. C. STEVENS,[5] M. AM. SOC. C. E. (by letter).—The computation of any form of water-surface profile—on sustaining or adverse slopes, under supercritical or sub-critical flow conditions, in either rough or smooth uniform channels—may be made quickly by the simple step-by-step procedure fully described and illustrated by the writer in his discussion[6] of the paper by Arthur E. Matzke, Jun. Am. Soc. C. E.[7]

The functions set up by the author are only applicable to channels of uniform cross-section (that is, rectangle, trapezoid, triangle, etc.), whereas by far the greater number of surface profile determinations must be made for channels of irregular cross-section. For the latter case computations must be

[7] "Varied Flow in Open Channels of Adverse Slope", by Arthur E. Matzke, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 651.

made by a trial method one of which was suggested by the writer[8] in 1925. For uniform sections a simple direct computation will yield results amply accurate for all practical purposes without going through the maze of mathematical processes so laboriously set forth by the author. In fact, the simple step-by-step formula used by the writer is fundamentally more accurate than that offered by Professor Mononobe, because there are no basic assumptions and approximations entering into its composition. The only limitation is that sections shall be taken sufficiently near each other so that the surface profile may be considered a straight line between them.

Assumptions that wetted perimeters and areas are exponential monomials, and that the Chezy coefficient is constant, are not at all necessary; neither is it necessary to find neutral and critical depths and velocities. One merely fortifies himself with a table of Kutter coefficients (or Manning's, or any other set of coefficients that he prefers) and a slide-rule and performs the simple operations shown in Table 9. This table shows the calculated profile of the back-water curve under discussion for the smooth rectangular channel. The discharge is not given, but presumably may be calculated from $A_0 V_0 = 0.173$ cu ft per sec. From the neutral slope, radius, and velocity given, one may find that Kutter's $n = 0.009$. Using the formula,[6]

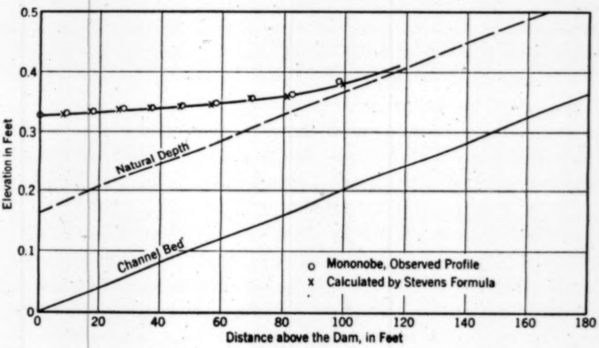

FIG. 20.—COMPARISON OF PROFILES FOR A SMOOTH RECTANGULAR CHANNEL

$$\Delta l = \frac{\Delta \epsilon}{S_f - S_0} \quad \text{.......................} (35)$$

in which Δl = the distance between adjacent depths; S_f = friction slope; S_0 = bed slope; and, $\Delta\epsilon$ = increment of specific energy between adjacent depths, or:

$$\Delta \epsilon = \left(D_1 + \frac{V^2_1}{2\,g}\right) - \left(D_2 + \frac{V^2_2}{2\,g}\right) \quad \text{.............} (36)$$

The depths given, in inches, in Table 7 were converted to feet and used in Table 9. The slope, S'_f, is the friction slope at the depth point, whereas

---

[8] *Engineering-News Record*, October 1, 1925, p. 550.

S_f is the average friction slope between depths. For such problems very little difference is found whether one averages slopes, areas, hydraulic radii, or velocities between depth points.

In the application of Equation (35) the specific energy ϵ has increasing values down stream, because the bed slope is greater than the friction slope. Therefore, values of $\Delta\epsilon$ are negative as are also values of $(S_f - S_0)$, making Δl positive up stream. Columns (14) and (15), Table 9, show how closely the calculated distances above the dam agree with the distances observed in the laboratory.

Fig. 20 shows the profile plotted from "Laboratory tests", Table 7, and the profile calculated by Equation (35). The agreement is practically perfect as such hydraulic calculations go.

CHESLEY J. POSEY,[9] JUN. AM. SOC. C. E. (by letter).—A unique method of solving the general equation of motion for steady non-uniform flow in uniform channels is presented in this paper. It is the only method yet published that takes into account the effects of changing velocity head, friction, and channel shape, without any necessity for dividing the reach into steps. The velocity head is assumed to be equal to a constant, α, times the theoretical velocity head based on the average velocity in the cross-section. At present, there is no basis for any other assumption. Consideration of the friction factor is based on an exponential type of formula; no more satisfactory formula is available. The assumption is made that the friction loss for a stream flowing at Velocity V, and Depth D, not the neutral depth, is the same as if there were neutral flow at that velocity and depth. This assumption is open to question, because of the inherent differences between convergent, parallel, and divergent flow. In uniform channels, however, the angle of divergence is not likely to be great enough for serious errors to arise from this source. Consideration of the effect of the shape of the channel is made possible by expressing the area and wetted perimeter as monomial exponential functions of the depth. Simple logarithmic plotting will demonstrate the high degree of approximation that is possible, over a wide variety of channel shapes.

Proof of the accuracy of the author's method is evidenced by the remarkable agreement obtained in the laboratory tests, reported in the paper. These tests covered as wide a range of the variables in question as could be included in a laboratory investigation without unreasonable cost. Data secured from tests in larger and longer channels would be desirable to establish a further check. Additional information might be secured as a by-product of some other investigation, and it is to be hoped that experimental workers and practicing engineers will take advantage of opportunities to secure and report further data on back-water and drop-down curves.

The author's method possesses definite advantages over those methods that require the use of steps. A vital part of the curve may be determined quickly without the tedious computation of steps intervening between it and the control point. Furthermore, theoretical curves such as those presented by the author may be used in the study of the shapes of the various possible surface curves, and in determining under what circumstances they will occur and from what feature their position along the length of the channel is fixed. The author applies his method to the two most common types of back-water curves. A complete discussion of the twelve possible types has been given[10] by Sherman M. Woodward, M. Am. Soc. C. E.

---

[9] Asst. Prof. Hydraulics and Structural Eng., State Univ. of Iowa, and Assoc. Engr., Iowa Inst. of Hydr. Research, Iowa City, Iowa.

Integration, taking into account the shape of the channel, is made possible by the author's empirical Equations (13). Before giving these formulas the author sets up Differential Equation (8), based on Equations (5) in which the hydraulic area, the wetted perimeter, the hydraulic radius, and the average velocity "are expressed most generally as functions of D, the depth of water measured from the lowest line of the channel bed." As can be seen from Equations (24), (28), (29), and (31), Equations (5) are not the most general; as approximations it is doubtful whether they are much better than Equations (13). Since neither Equation (8) nor Equation (12) is integrated, it is difficult to see why Cases 1 and 2 are included in the paper. Their presence, for which there is only a slight logical justification, makes the paper more formidable than it need be.

To determine the values of s and k, the area and wetted perimeter may be plotted logarithmically as functions of the depth, and straight lines approximating the relations over the range desired, drawn in by eye. The values of s and k are determined by the slopes of these lines. This graphical method has the advantage of enabling one to judge the closeness of fit obtained. In cases where there is no question but that a high degree of approximation will be secured, Figs. 9, 11, and 12 may be used.

The writer has been unable to check certain values from these diagrams and believes they may contain errors. For the example of the rectangular section for which the author gives $s = 1.0$ and $k = 0.38$, the writer obtains $s = 1.0$ and $k = 0.41$. For the example of the circular section, for which the author gives $s = 1.34$ and $k = 0.59$, the writer obtains $s = 1.29$ and $k = 0.65$. These results were obtained by the graphical method and can be checked by any one familiar with logarithmic plotting; for this reason it is considered unnecessary to reproduce the graphical work herein.

The author's method is simple and straightforward. It may justly be considered the culmination of the work started by Belanger and Bresse. In making the method useful to practicing engineers, it will be necessary to simplify the charts of Fig. 3, re-drawing them to a larger scale, and separating the curves for ϕ_1 and ϕ_2, as has been done with ψ_1 and ψ_2 in Figs. 5, 6, and 7.

A. A. KALINSKE,[11] ESQ. (by letter).—Undoubtedly, the most important contribution by the author is the presentation of data from certain carefully conducted experiments on back-water and drop-down curves and his discussion of the different varied-flow expressions developed by others. Although he does not go into any great detail as to experimental procedure, which is always of interest to those engaged in experimental hydraulics, his general description indicates considerable painstaking experimental and analytical effort. His "Concluding Remarks" should be of particular interest to those concerned with errors introduced by making various assumptions when setting up or using varied-flow formulas.

---

[10] Technical Repts., Miami Conservancy Dist., Pt. III.

[11] Instructor in Hydr. and San. Eng., State Univ. of Iowa, Iowa City, Iowa.

In developing his expression for back-water and drop-down surface curves the author demonstrates effectively that the most complicating item in the development of any varied-flow expression is the difficulty of obtaining a simple relation between the height of water above the channel bottom, the cross-sectional area of water flowing, and the hydraulic radius. To express A and R in terms of depth always leads to extremely complicated notations and mathematical expressions. Nearly all varied-flow expressions developed have led to such integrations that special tables and curves must be used if a problem is to be solved in any reasonable time. Furthermore, the special notations used require considerable time to master, and, frequently, the fundamental hydraulic principles are obscured. This makes it particularly difficult to present the subject of varied flow to students of hydraulics.

The author's back-water and drop-down functions are quite involved and probably will not be of great use to practicing engineers, or of great value in presenting the general subject to students. In trying to apply the various functions and also other existing varied-flow formulas to non-uniform flow in circular sewers, the writer encountered considerable difficulty, and lost much time in obtaining answers to specific problems.

The author's formulas for total length of back-water and drop-down curves (Equations (18) and (20), respectively) can be used for any length of reach as long as the relations between depth, hydraulic radius, and area remain constant and the channel slope does not vary. However, in many types of cross-sections, the constants in the type of monomial used by the author, in expressing the relation between area, hydraulic radius, and depth, vary enough so that good accuracy in outlining the surface curve can only be obtained by solving for distances between successive depths. Furthermore, if a number of points are desired on the surface curve, computation of its total length by solving for the distance between successive depths does not complicate matters, especially if the reaches need not be too short in order to obtain good precision.

A considerable number of mathematical operations and notations can be omitted without the sacrifice of any precision or lengthening of time of computation by dispensing with an expression for hydraulic radius in terms of depth (Equation (13c)). Since the hydraulic radius, relatively, changes the least from depth to depth of any of the variables, it is a convenient term to average in any reach; and in the development of the varied-flow integral from the fundamental Bernouilli equality (Equation (3)), worth while simplifications result if the velocity is the variable instead of the depth. Note that the term, $\frac{d\,(V)^2}{2\,g\,dx}$, in Equation (3), is equal to $\frac{V\,dV}{g\,dx}$. For many common types of cross-sections, whether regular or irregular, for a particular range of depths, the area and depth can be conveniently expressed in a straight-line relationship of the type, $D = a\,A + b$. Substituting $\left(\frac{Q}{V}\right)$ for A, the value of $\frac{dD}{dx}$ in Equation (3) becomes $-\frac{a\,Q\,dV}{V^2\,dx}$. The straight-line relationship is much more simple to use since the slope of the line, a, can be so easily obtained; for any given reach, it is equal to $\frac{D_1 - D_2}{A_1 - A_2}$.

Making the foregoing changes and substitutions in Equation (3), the following integral results:

$$dx = \frac{\alpha\,V\,dV}{\frac{g\,V^2}{C^2\,R^{2m}} - S_0\,g} - \frac{a\,Q\,dV}{V^2\left(\frac{V^2}{C^2\,R^{2m}} - S_0\right)} \qquad \text{(37)}$$

which, on integration, gives an expression for the distance between any two depths (or velocities):

$$L = \frac{\alpha\,C^2\,R^{2m}}{2\,g} \log_e \left(\frac{V_1^2 - V_u^2}{V_2^2 - V_u^2}\right) - \frac{a\,Q}{S_0}\left(\frac{1}{V_1} - \frac{1}{V_2}\right) - \frac{a\,Q}{2\,S_0\,V_u} \log_e \frac{\frac{V_1 - V_u}{V_1 + V_u}}{\frac{V_2 - V_u}{V_2 + V_u}} \qquad \text{(38)}$$

In Equation (38), $V_u = C\,R^m\,S_0^{0.5}$, in which R is the average value of the hydraulic radius between the depths chosen. If the surface curve in the reach approaches a straight line, R is an arithmetical average; if it is considerably concave or convex, the value of R can be slightly decreased or increased to make it approach more truly the average in the section. Using only a slide-rule and arithmetical averages of R, computations were performed on the experimental back-water and drop-down curve data given by the author (see Table 10). Equation (38) applies to either back-water or drop-down curves on sustaining slopes; V_1 is the up-stream velocity and V_2, the down-stream velocity.

TABLE 10.—COMPUTATIONS PERTAINING TO A SMOOTH RECTANGULAR CHANNEL

D-inches	*V*	*R*	*C*	Increment in *L*	VALUES OF *L*		
					Computed	Test	Mononobe
(*a*) BACK-WATER CURVES; $S_0 = 0.002$							
3.937	0.805	0.164	152	0	....	....	....
2.953	1.074	0.140	152	47.4	47.4	47.6	47.8
2.165	1.453	0.116	152	49.5	96.9	98.4	97.0
(*b*) DROP-DOWN CURVES; $S_0 = 0.001$							
2.461	2.200	0.126	155	0	....	....	....
3.030	1.790	0.143	155	13.5	13.5	12.4	12.8
3.752	1.446	0.160	155	99.0	112.5	101.0	110.0

The values for C (Table 10) were computed from data given by the author; the value of m in the back-water problem was 0.65 and in the drop-down problem, 0.70. Note that the increments used are relatively large, and the values obtained are comparable in accuracy to those of the author. Although the expression itself appears quite formidable, the computations are not tedious and can be performed very quickly on a slide-rule. It is also of advantage to be able to use the same expression for either back-water or drop-down curves instead of different functions as is done by the author.

For a rectangular section, the value of a, of course, remains constant; also, for wide trapezoidal sections, it does not change greatly in value for different ranges of depth. For circular sections, a does not change much in its value in a range of depths between 10% to 90% of the diameter. For triangular and narrow trapezoidal sections the more accurate relation between depth and area is of the type, $D = k\, A^{0.5}$.

Use of this parabolic relationship complicates the second term of the integral in Equation (37); however, direct integration is quite possible, and is not beyond the scope of the mathematical equipment of the average engineer. The straight-line and parabolic reationship will take care of all types of channels, and there seems no real necessity to complicate matters by using monomials of the type introduced by the author.

The intricate mathematical expressions presented by Professor Mononobe are perhaps justified in that they provided one means for obtaining theoretical surface curves which coincided almost exactly with the experimental results. However, it seems that the same effect could have been accomplished by much simpler methods. If, in outlining surface curves by computing distances between successive depths, there would be a loss of precision and time, then the author's functions would be of distinct help, however, since such is not the case it seems that nothing in particular is gained for any engineer or student of hydraulics to familiarize himself with the mathematics presented so that he can use the author's methods with confidence.

From the standpoint of presenting the subject of back-water and drop-down curves to those unfamiliar with the hydraulics of varied flow, the author's discussion of the fundamentals could be improved if it were pointed out how the momentum principle applies and how it can be used as a basis for the development of the fundamental equations just as readily as Bernouilli's theorem. For instance, since the acceleration (or retardation) of the water at any point is equal to $\frac{V\,dV}{dx}$, it can be readily shown that the change in velocity head with respect to distance is equal to the ratio of the water acceleration to the gravity acceleration. From Equation (3) it can be seen that this ratio is equal to the difference between friction slope and slope of the water surface. The acceleration term is very useful in indicating what must be done with eddy and turbulence losses for flow at a decreasing velocity. The writer wonders whether there was any need to take account of such extra losses in the author's experimental data on back-water. No definite mention of it is made in the discussion of the test results.

Boris A. Bakhmeteff,[12] M. Am. Soc. C. E. (by letter).—One cannot fail to be impressed by the painstaking efforts and the time which Professor Mononobe and his collaborators must have invested in the preparation of this paper. In the early stage of his studies on non-uniform flow[13] more than twenty-five years ago, studies which led to the methods subsequently developed in "Hydraulics of Open Channels",[14] the writer was confronted with the maze of the different formulas then extant and went through a process of comparison similar to that so ably presented in Professor Mononobe's work. Obviously, to make the general Bélanger formula (Equation (1)) usable for practical purposes, it must be integrated in relation to cross-sectional forms and resistance formulas as they actually occur in engineering practice. That requires, first, stepping outside the limits of the idealized broad rectangular and parabolic channel sections, as treated by the earlier pioneers, as well as doing away with the assumption of a constant Chézy factor value, C, as used by Bresse, Rühlman, and others.

Professor Mononobe correctly indicates that "monomial forms" should be used for this purpose, and recourse is taken to exponential expressions, which is in accordance with earlier suggestions of the writer, suggestions of which Professor Mononobe had no previous knowledge.

It appears to the writer, however, that the thought of giving monomial expressions separately to the area, wetted perimeter, and other elements, as suggested in Equations (13), is not so fortunate. In fact, in such general form, the assumption is somewhat misleading, and, moreover, it tends to eclipse the real significance of exponential expressions. The essence of the method lies in the fact, that any curve, $y = f(x)$, the value of which increases with x (Fig. 21), may be replaced within certain limits ($A - B$, Fig. 21), with sufficient approximation, by an exponential expression of the type, $y = a x^n$.

With reference to Equation (1), the area and the other elements do not enter singly, but in the combination,

$$A \, C \sqrt{R} = K \quad \ldots\ldots\ldots\ldots (39)$$

constituting thus a combined parameter, which connects the bottom slope with the discharge in uniform motion,

$$Q = K_0 \sqrt{S_0} \quad \ldots\ldots\ldots\ldots (40)$$

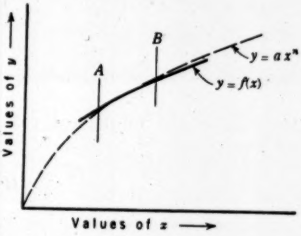

Fig. 21

and which the writer qualifies as the "carrying capacity."[15] This value, properly substituted into Equation (1), makes it,

$$S = S_0 - \frac{dD}{dx} = \frac{Q^2}{K^2} - \alpha \frac{S_0}{\sigma} \frac{K^2_0}{K^2} \frac{dD}{dx} \quad \ldots\ldots\ldots\ldots (41)$$

in which σ is the critical slope.

---

[12] New York, N. Y.

[13] "On Varied Flow of Liquids in Open Conduits" (in Russian), St. Petersburg, 1912.

[14] Engineering Society's Monograph, McGraw-Hill Co., 1932.

[15] "Hydraulics of Open Channels", Engineering Society's Mongraph, McGraw-Hill Co., 1932, p. 13.

For an open conduit, Equation (39) is a function increasing with the depth and, within certain limits, can be expressed monomially, in the sense of Fig. 21, leading to a simple relation,

$$\left(\frac{K_2}{K_1}\right)^2 = \left(\frac{D_2}{D_1}\right)^n \qquad (42)$$

with a single value of n = the hydraulic exponent.

In pursuing his course further, Professor Mononobe arrives at Equation (18), with integral functions of the type:

$$\Phi_1 = \int \frac{y^r}{y^r - 1}\, dy \qquad (43a)$$

and,

$$\Phi_2 = \int \frac{y^{(r-2S)-1}}{y^r - 1}\, dy \qquad (43b)$$

Practical application depends on knowing the numerical values of these functions and, therefore, appropriate graphical charts are given in the paper. According to Professor Mononobe, numerical evaluation of the function values in certain cases was direct, which is assumed to mean quadratures, whereas in other cases recourse had to be taken to converging series. Now, in historical retrospect, Equation (18) is generally similar in form to the relations traditionally used by Dupuit, Bresse, and subsequent investigators. With Professor Mononobe's notation the basic relation,[16] Equation (4), which is equivalent to Equation (18), and in the form used by the writer would read:

$$\frac{S_0\ l}{D_0} = \left(\frac{D_b}{D_0} - \frac{D}{D_0}\right) - (1 - \beta)\left[B\left(\frac{D_b}{D_0}\right) - B\left(\frac{D}{D_0}\right)\right] \qquad (44)$$

in which $\beta = \dfrac{S_0}{\sigma}$ is taken to be a coefficient, whereas the varied flow function, B, is the numerical value of the integral,

$$B = -\int_0^v \frac{dy}{y^n - 1} \qquad (45)$$

an expression into which Professor Mononobe's function, Φ_1, is reduced by the simple transformation,

$$\int_0^v \frac{y^r}{y^r - 1}\, dy = \int_0^v \frac{y^r - 1 + 1}{y^r - 1}\, dy = y + \int_0^v \frac{dy}{y^r - 1} \qquad (46)$$

The substantial difference between Professor Mononobe's technique and that of the previous investigators (including the writer), is that, whereas heretofore the customary manner was to present the function values in tabular form, the paper gives them graphically in chart form. Obviously, tables and charts are equivalent, the preference for one or the other being a matter of individual taste. An illuminating analogy would be to replace the customary tables of logarithms by graphical charts.

---

[16] "Hydraulics of Open Channels", p. 88.

In the light of the preceding, the writer does not quite understand in what way Professor Mononobe's approach avoids the mathematical complications supposedly inherent in earlier methods, and in what manner it simplifies computations as claimed.

With regard to details, confusion may be avoided by correcting possibly a typographical error, in using an identical symbol, *C*, in Equation (1) for the generalized Chézy factor, and for what is obviously meant to be a numerical constant in Equation (2).

The attempts of Professor Mononobe to complement his analysis with experimental work should be more than welcomed. In fact, although the varied-flow theory has been the subject of repeated treatment, scarcely any experimental data are available, the best probably being still those assembled in the classical opus by Darcy and Bazin.[17] The usual difficulty lies in the necessity of having very long flumes, and Professor Mononobe's manner of using short canals is ingenious. It is to be hoped that Professor Mononobe's experiments will once more draw attention to this much neglected field of research, and that, in particular, observations on a larger scale will become available.

P. CHARLES STEIN,[18] ESQ. (by letter).—The method for determining back-water and drop-down curves in uniform channels, described by the author, lends itself to a relatively simple routine for computing these problems. The errors introduced by the approximation that the area and the wetted perimeter are monomial functions of the depth are of small order and should be well below the range of error incident to the selection of a friction factor.

That the assumption of monomial relations between area and depth and between wetted perimeter and depth does not introduce appreciable error, even for a circular section, may be seen from Fig. 22 for the example given by Professor Mononobe (see text following Equation (32)), in which the depth in a circular conduit, 18 ft in diameter, ranged from 30% to 75% of the diameter. The heavy dashed lines in Fig. 22 show the actual variation of area and wetted perimeter and the full lines represent the monomial approximations.

It is to be noted that the range in depths of a back-water curve cannot extend across the critical depth. In practical problems, even in channels not well adapted to the monomial approximation over their entire range, the range will usually be such that the assumption of monomial variation will agree closely with the actual variation of the hydraulic elements with respect to depth.

---

[17] "Recherches Hydrauliques". Paris. 1865.

[18] Graduate Student in Hydraulics, Univ. of Iowa, Iowa City, Iowa.

Removed from its seemingly complex mathematical treatment, the author's method involves very simple reasoning and is adapted to a relatively easy computing procedure. Having expressed the area and the wetted perimeter as approximate exponential functions of depth, Professor Mononobe converts the differential equation of Bernoulli's theorem for a sloping channel (Equation (1)) into a form in which all hydraulic variables are functions of depth and, after grouping terms, integrates the resulting equation to obtain Equation (18) which defines the back-water curve in a uniform channel. A similar formula, Equation (20), defines the drop-down curve.

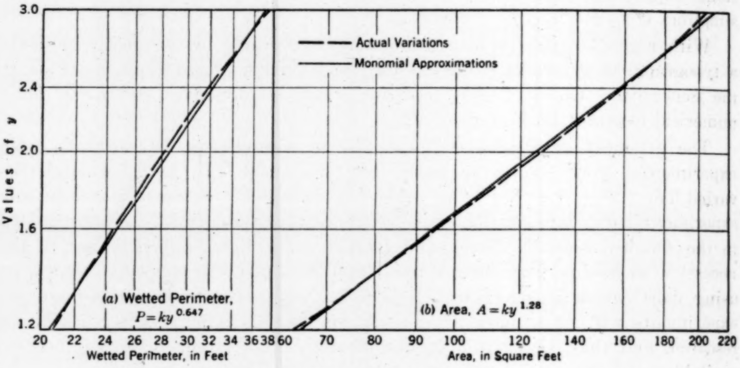

FIG. 22.—RELATION OF WETTED PERIMETER AND AREA TO DEPTH

Equations (18) and (20) are solved readily by means of the curves in Figs. 6, 7, and 8. The parameters necessary for using the charts are $\frac{D}{D_o}$, r, and s. The term, r, is defined as:

$$r = 2s + 2m\,(s - k) \qquad\qquad (47)$$

in which s is the exponent of depth in the approximate area relation; k is the exponent of depth in the wetted perimeter relation; and m is the exponent of R in the friction formula used, Equation (2). One other term, K, is necessary in solving Equations (18) and (20), and it is found from the relation:

$$K = \alpha\, s\, \frac{V_o}{g\, D_o} \qquad\qquad (48)$$

in which V_o and D_o denote the velocity and depth, respectively, which would prevail if, for the discharge under consideration, the surface slope equalled the bottom slope.

An easy method of determining the exponents, s and k, is to compute them by means of the logarithmic differences of the values at the end points of the range. Thus, in determining the area exponent in Equation (13*a*):

$$\log A_2 = \log a + s \log D_2 \text{..................} (49a)$$

and,

$$\log A_1 = \log a + s \log D_1 \text{..................} (49b)$$

Subtracting, and solving for s:

$$s = \frac{\log A_2 - \log A_1}{\log D_2 - \log D_1} \text{........................} (50)$$

For the circular conduit mentioned in the text following Equation (32): $A_2 = 204.7$; $A_1 = 64.2$; $D_2 = 13.5$; and $D_1 = 5.4$. Reading the logarithms on an ordinary slide-rule: $s = \frac{2.311 - 1.807}{1.130 - 0.732} = 1.267$. Similarly, for the wetted perimeter, this type of calculation results in: $k = 0.646$.

It is seen that the exponents thus obtained agree closely with those derived by the graphical method. In the graphical method, the eye is guided in large measure by the location of the end points.

The author's method, wherein he assumes that the average of the slopes at the ends of the range is equivalent to the slope of the straight line best approximating the curve, is open to criticism inasmuch as it may give undue weight to an extreme slope at one end of the range. The logarithmic method is simpler than the method given in the paper and is probably less subject to error.

NAGAHO MONONOBE,[19] M. AM. SOC. C. E. (by letter).—In closing this paper, the writer wishes to add nothing further to the comments so generously offered by the several discussers. The assumption may properly be made that the method yields results that are safe for practical purposes.

READJUSTMENT OF TRIANGULATION DATUM

BY JULIUS L. SPEERT,[1] JUN. AM. SOC. C. E.

SYNOPSIS

The readjustment of the basic triangulation of the United States to the 1927 North American Datum created a problem to all organizations whose surveys were built on the basic system. Complete recomputation and readjustment being out of the question because of their prohibitive cost, the United States Geological Survey investigated methods of readjusting its earlier triangulation to fit the new datum by applying corrections to the old datum values. Since the corrections are usually very small, approximate methods of determination give reasonably precise results.

Several methods of readjustment have been developed. When the subordinate triangulation is tied to the new datum through a single base only, three methods are available: (1) Analytical determination of the new positions by applying formulas for translation, rotation, and linear scale change; (2) a graphical method for determining corrections by plotting lines of equal position changes; and (3) a mechanical method requiring an easily constructed transparent rotating guide. When the subordinate triangulation is tied to the new datum at three or more points, the new positions are determined graphically by plotting lines of equal position changes. The corrections to length and azimuth of the geodetic line are determined analytically by formulas, or graphically on a nomographic chart.

The methods herein described are applicable also to the adjustment of new triangulation.

INTRODUCTION

When the United States Coast and Geodetic Survey began its readjustment of the basic triangulation system of the United States in 1927, it created a problem of major importance to practically all other surveying organizations in the country. All triangulation of lesser importance that

---

NOTE.—Published in May, 1937, *Proceedings*.

[1] Asst. Engr., Water Resources Branch, U. S. Geological Survey, Washington, D. C.

had been computed from, or based on, the arcs of the main plan, no longer fitted these arcs as they were shifted or changed by the readjustment. When the task of bringing all its accumulated triangulation data into agreement with the new 1927 North American Datum was undertaken by the United States Geological Survey, it was realized immediately that direct recomputation from the original field notes was out of the question, because neither time nor money would be available for the execution of such a huge project. To avoid the necessity of complete recomputation, various methods have been proposed and tried wherein the changes in the main control system have been studied, in order to ascertain what changes must be introduced into the subordinate triangulation to regain the harmony that had existed on the old datum, or to establish harmony where none had existed before. In dealing with changes of position, direction, and length, instead of with those quantities themselves, the magnitudes of the terms in the computations are kept so small that simplifications can be introduced readily without diminishing the accuracy of the final results.

Much of the old Geological Survey triangulation was originally adjusted as spurs from single bases. Many of these arcs have since been made parts of closed circuits by later ties to other arcs but, in most cases, the closing errors have not been distributed throughout the work. The adjustment of the closures of these circuits simultaneously with the readjustment to the 1927 North American Datum also was undertaken.

WILSON METHOD

The first rational attempt to readjust the old Geological Survey triangulation to the 1927 North American Datum by means of corrections to the previously computed values, was made by R. M. Wilson, M. Am. Soc. C. E., Chief of the Computing Section of the Survey. His method was fully and clearly described in a paper presented before the Federal Board of Surveys and Maps on April 11, 1933. The following is a brief summary of his method.

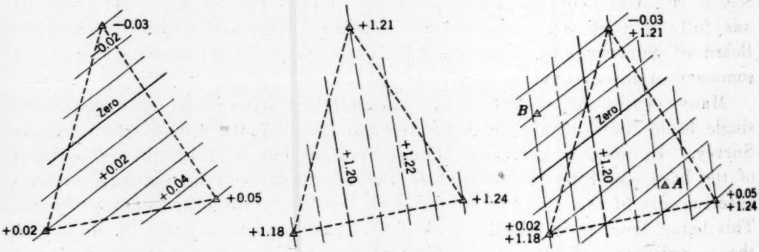
Many chains or networks of triangulation have been extended from single basic lines of higher order triangulation of the Coast and Geodetic Survey. In such a net, any change in the length, azimuth, or position of the base could be transferred to the remainder of the network without affecting any of the adjusted angles of the earlier figure adjustment within it. This being true, it is necessary only to determine the amount of change in the co-ordinates of the ends of the base, and the corresponding change in azimuth and length of the base. The entire system can be translated bodily to bring one end of the base into its new position; the system can then be rotated about this point to bring the base into its correct azimuth. If, finally, a uniform scale factor is applied to all lines of the system, the other end of the base can be brought into its correct position, and the entire system will be in harmony with the new datum. By means of formulas developed by Mr. Wilson, the translation, rotation, and scale factors may be applied to all points in the triangulation net to determine their positions on the new datum, and all lines may be corrected by the uniform azimuth and scale changes.

This method is limited in its application to those systems of triangulation that are developed from a single base and have no other ties to the new datum. In many nets, however, other ties have been made, either at the time of the original survey, or subsequently. In such nets, the values obtained by this method would fit the original base perfectly, but would be likely to show discrepancies at the other tie-points. For these conditions, other methods of treatment were found necessary.

"Isodiffs"

For those triangulation nets in which three or more ties to the new datum are available, a graphical method for the determination of the position corrections has been developed by C. L. Nelson, Assistant Topographic Engineer, U. S. Geological Survey.

On a scale map or tracing diagram of the triangulation net to be adjusted, all available ties to the new datum are indicated, and the proper corrections noted which are needed to bring the old values for latitude and longitude to the new datum. By interpolating along lines between the various ties, corrections may be obtained for intermediate points between the fixed tie-points. When enough of such values have been determined, it is possible to draw lines on the tracing representing lines of equal corrections, or of equal changes from the previous positions. This is very similar to drawing contours on a map when the elevations have been determined at a number of fixed points. It will be necessary to have one set of lines for latitudes and another set for longitudes. These lines have been named "isodiffs" (or lines of equal differences) and are also called "isolats" and "isolongs," respectively. Fig. 1 illustrates the construction of the "isodiffs" for the relatively simple case of three tie-points.



(a) ISOLATS. (b) ISOLONGS. (c) COMBINED ISODIFFS.

FIG. 1.

When the number of ties is greater than three, straight-line interpolation between tie-points sometimes leads to inconsistencies. For instance, in the illustration in Fig. 2, if an attempt were made to interpolate along both diagonals, different values might be obtained for the intersection. Under such conditions, it is advisable to assume a value for the intersection which would be a weighted mean of the values obtained from the respective diagonals, and to proceed with the interpolation from that point as if it were a tie-point.

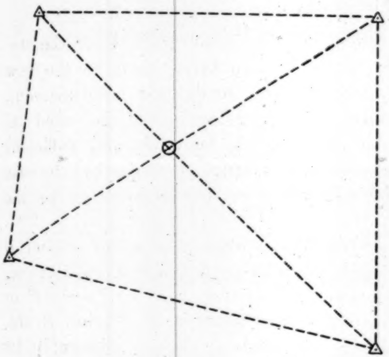


Fig. 2.

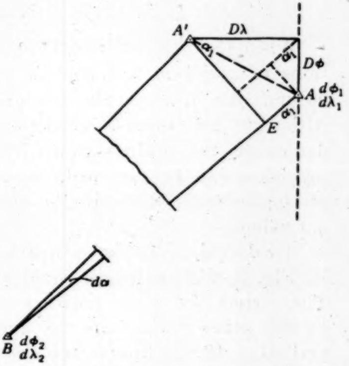

Fig. 3.

With the graph of "isodiffs" constructed on the tracing, it is necessary only to superimpose it on the plot of the triangulation plan, and the corrections to be applied to each station in the system may be read from its position on the graph, just as the elevation of any point on a contour map may be read from the contours, this being the purpose for which the graph is made.

For example, in Fig. 1(*c*), the corrections to be applied to the old co-ordinates of Station *A* in the system to be adjusted, are read as + 0.03 for latitude and + 1.22 for longitude. Similarly, the corrections to the co-ordinates of Station *B* are − 0.02 and + 1.18, respectively..

The construction and application of the "isodiff" chart will be expedited if different colors are used for the "isolats" and "isolongs," as well as to indicate the latitude and longitude corrections, respectively. For instance, red may be used for latitude corrections and "isolats," and blue for longitude corrections and "isolongs."

It will be noted that the judgment of the adjuster is an important factor in the sketching of satisfactory "isodiffs," and different men might conceivably obtain different sets of lines from the same data; but experience has shown that for practically all cases where three or more ties are available, excellent results can be obtained by this method. The "personal factor," furthermore, is not as serious a disadvantage as it might appear, since it is inherent in almost any method of adjustment in which a number of independent conditions must be satisfied. Even the application of the standard method of least squares is not altogether free from it.

The proper application of the "isodiff" graph gives corrections to be used in obtaining new values for the positions of the triangulation stations, but does not yield any new information concerning the lines connecting the stations. For this purpose, the following formulas have been developed by the writer.

NEW FORMULAS

When the required position corrections have been determined for the stations in a system and applied to the old values to bring them to the new datum, the lines connecting the stations are ready for readjustment. Although the inverse geodetic position computation could be used to determine the desired values for the lines on the new datum, sufficient precision can be obtained, at a considerable saving of time, by the use of approximate methods for the determination of the corrections to the old values.

To do this, consider a line connecting Triangulation Stations A and B in Fig. 3, with a length equal to s and azimuth at Station A equal to α_1. The corrections to the position of Station A (as determined by "isodiffs" or by any other means) are $d\phi_1$ and $d\lambda_1$ and to the position of Station B, $d\phi_2$ and $d\lambda_2$. If the line is translated by $-d\phi_2$ and $-d\lambda_2$, no change in its length or direction will take place. Then, the resulting relative changes in latitude and longitude at Station B will both be 0, and the changes at Station A will be $\delta\phi = d\phi_1 - d\phi_2$ and $\delta\lambda = d\lambda_1 - d\lambda_2$. These latter values represent the net change within the line, AB, or the relative change of one end with respect to the other, and are the values that cause whatever change there may be in the length or in the azimuth of the line.

Before they can be used in the computations, $\delta\phi$ and $\delta\lambda$ must be converted from seconds of arc to meters by the formulas:

$$D\phi = Q\ \delta\phi \qquad \text{(1a)}$$

and,

$$D\lambda = R\ \delta\lambda \qquad \text{(1b)}$$

The conversion factors, Q and R, represent the length on the earth's surface of 1" of arc of latitude and longitude, respectively. The factor, Q, varies from 30.77 m at Latitude 25°, to 30.90 m at Latitude 50°, and a mean value of 30.83 m has been assumed as sufficiently precise for all points in the United States. The value of R varies more rapidly (see Table 1).

If $D\phi$ and $D\lambda$ are plotted at Station A to an enlarged scale, Point A' (Fig. 3), represents the new position of Station A with respect to Station B (to the distorted scale), and the total displacement of the station is represented by AA'. If this is projected on AB, then AE represents the linear change in AB (to the scale of the plot) and $A'E$ is a measure of the rotation of the line. The angular rotation at Station B (to bring BA to BA') $= -d\alpha = \dfrac{\overline{A'E}}{\overline{A'B}\sin 1''}$, approximately, $= \dfrac{\overline{A'E}}{s \sin 1''}$, approximately;

but $\overline{A'E} = D\phi \sin \alpha_1 + D\lambda \cos \alpha_1$. Therefore,

$$d\alpha = -\frac{1}{s \sin 1''} (D\phi \sin \alpha_1 + D\lambda \cos \alpha_1)$$

or,

$$d\alpha = -K (D\phi \sin \alpha_1 + D\lambda \cos \alpha_1) \ldots\ldots\ldots\ldots\ldots (2)$$

in which $K = \frac{1}{s \sin 1''}$. It is readily apparent that practically the same rotational change occurs at both ends of the line, and $d\alpha$ must be applied to α_1 as well as to α_2.

Line *AE*, Fig. 3, represents, in meters, the change in the length of the line, *AB*. If this is multiplied by a factor, *C*, which is the tabular difference (in units of the last place) in logarithms per meter of *s*, then the change in $\log s = d (\log s) = - C \times \overline{AE}$; but $\overline{AE} = D\lambda \sin \alpha_1 - D\phi \cos \alpha_1$, and therefore:

$$d (\log s) = C (D\phi \cos \alpha_1 - D\lambda \sin \alpha_1) \ldots\ldots\ldots\ldots\ldots (3)$$

For 6-place logarithms, $C = \frac{10^6 \log e}{s}$. Values of Factors *C* and *K* may be read from Table 2.

When the total latitude correction to both ends of the line is appreciable (as is the case between some of the old astronomic datums in the West and the 1927 North American Datum), and the difference in longitude between the ends of the line is large, another term must be added to the length correction to allow for convergence of meridians. This need becomes apparent when one considers that the distance between meridians decreases rapidly with an increase in latitude. For instance, if two points at the same latitude, but on different meridians, were shifted north by the same amount, the differential change between them would be zero in latitude and zero in longitude; but since the movements of the points were not parallel, the distance between them would be decreased appreciably, whereas the azimuth would remain practically unchanged.

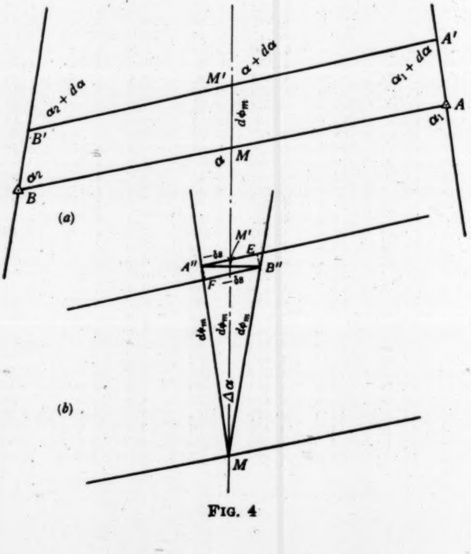

FIG. 4

To determine the change in length due to convergence, consider Fig. 4(*a*). Points A and B are moved northward along different meridians to A' and B', respectively. If M is the mid-point of the line, $\overline{AB}$, $\overline{MM'} = d\phi_m$, or the mean change in latitude of Stations A and B. In meters, $\overline{MM'} = Q \times d\phi_m$.

The next step will be clearer if the line is assumed to be broken at M, and the two halves are moved separately as shown in Fig. 4(*b*), so that MB'' is parallel to BB' and equal to $d\phi_m$, and MA'' is parallel to AA' and equal to $d\phi_m$. For the small angles involved, the arc, $A''\,M'B''$, may be treated as a straight line. Then, $\overline{B'B''} = \overline{BM}$; $\overline{A'A''} = \overline{AM}$; and, $\overline{AB} = \overline{A'A''} + \overline{B'B''}$. The shortening of the original line would then be the distance by which the two halves overlap, or, $-\ \delta s = \overline{A''E} = \overline{B''F} = \overline{A''B''} \sin (\alpha + d\alpha)$; but $\overline{A''B''}$ (in meters) $= Q\ d\phi_m\ \Delta\alpha$ arc 1′. Since $d\alpha$ will usually be very small compared to α, $\sin \alpha$ may be substituted for $\sin (\alpha + d\alpha)$ with negligible error. Therefore,

$$-\ \delta s = Q \text{ arc } 1'\ d\phi_m\ \Delta\alpha \sin \alpha \qquad (4)$$

By substituting Q arc $1' = 0.009$, approximately, and noting that $\Delta\alpha \sin \alpha$ will always be negative, the correction becomes,

$$\delta s = 0.009\ d\phi_m\ \Delta\alpha \sin \alpha \qquad (5)$$

Since δs has been derived in meters, it should be applied to the change in length of s (Equation (3)) to give:

$$d(\log s) = C\ (D\phi \cos \alpha_1 - D\lambda \sin \alpha_1 + 0.009\ d\phi_m\ \Delta\alpha \sin \alpha) \qquad (6)$$

Although the original formulas were derived on the basis of a differential change at Station A, the same might have been done, instead, for the change at Station B, or preferably at the mid-point, M, and the results determined in the same form. It seems reasonable, therefore, to use the mean azimuth of the line instead of that at either end, and the final formulas for the corrections become:

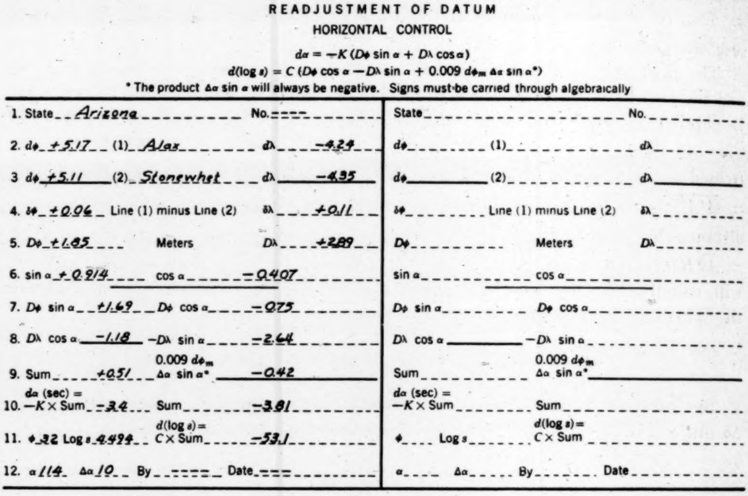
$$d\alpha = -\ K\ (D\phi \sin \alpha + D\lambda \cos \alpha) \qquad (7)$$

and,

$$d(\log s) = C\ (D\phi \cos \alpha - D\lambda \sin \alpha + 0.009\ d\phi_m\ \Delta\alpha \sin \alpha) \qquad (8)$$

in which $D\phi = 30.83\ \delta\phi$; $\delta\phi = d\phi_1 - d\phi_2$; $D\lambda = R\ \delta\lambda$; $\delta\lambda = d\lambda_1 - d\lambda_2$; $d\phi$, $d\lambda$, $d\alpha$, and $d(\log s)$ = corrections to old datum values for latitude, longitude, azimuth, and log meters, respectively; $d\phi_m$ = the mean of $d\phi_1$ and $d\phi_2$; α = the mean azimuth of the line between Points (1) to (2), (or between Points A and B) $= \alpha_1 + \dfrac{\Delta\alpha}{2}$; and, $\Delta\alpha$ = the convergence of meridians, in minutes of arc, $= \alpha_2 - \alpha_1 \pm 180°$.

To facilitate the computations, the form in Fig. 5 has been prepared. It is arranged to hold the computations for four geodetic lines (an example is shown in Fig. 5), which may be performed conveniently in the following order, using a slide-rule for all multiplications:



READJUSTMENT OF DATUM
HORIZONTAL CONTROL

$d\alpha = -K\,(D\phi \sin\alpha + D\lambda \cos\alpha)$

$d(\log s) = C\,(D\phi \cos\alpha - D\lambda \sin\alpha + 0.009\, d\phi_m\, \Delta\alpha \sin\alpha^*)$

* The product $\Delta\alpha \sin\alpha$ will always be negative. Signs must be carried through algebraically

FIG. 5.—SAMPLE FORM FOR COMPUTATIONS. (COMPLETE FORM PRINTS COMPUTATIONS FOR FOUR GEODETIC LINES).

The State in which the line occurs and the reference number of the computation are entered on Line 1 of the form; the names of the stations involved, together with their respective latitude and longitude corrections, on Lines 2 and 3; and the mean latitude and azimuth, log distance, and convergence, on Lines 11 and 12, as indicated. All these values may be taken by inspection from the available records for the two stations involved. For third-order triangulation, with positions given to the nearest 0.01″ of latitude and longitude, azimuth to the nearest second, and log s to six decimal places, it is sufficient to use ϕ and α to the nearest degree, log s to three decimal places, and $\Delta\alpha$ to the nearest minute on the form.

Next, $\delta\phi$ and $\delta\lambda$ are determined by algebraic subtraction and entered on Line 4, and $D\phi$ and $D\lambda$ are computed and entered on Line 5. Note that R is taken from Table 1, using ϕ as the argument; sin α and cos α are taken from tables, using α as the argument, and are entered on Line 6.

With $D\phi$ set on the slide-rule, $D\phi$ sin α and $D\phi$ cos α are determined and entered on Line 7. Similarly, $D\lambda$ cos α and $- D\lambda$ sin α are entered on Line 8; $d\phi_m$ is determined by inspection from Lines 2 and 3; and the term, $0.009\, d\phi_m\, \Delta\alpha \sin\alpha$ is entered on Line 9.

The sums on Lines 9 and 10, Fig. 5, are obtained algebraically as indicated; Factors C and K are taken from Table 2, using log s as the argument, and applied to the sums as indicated to obtain $d\alpha$ and $d(\log s)$ on Lines 10 and 11, respectively. The initials of the computer and the date are entered on Line 12.

Since C and K are direct functions of $\frac{1}{s}$, to find either, for a line for which the value of log s is beyond the limits of Table 2, find the value desired for the log s in the table with the same mantissa, and multiply or divide by the proper power of 10; for instance, C and K for $\log s = 2.200$ are 100 times C and K for $\log s = 4.200$, respectively; and for $\log s = 5.200$, the values are 0.1 times those for $\log s = 4.200$, respectively. In other words:

When log s has a characteristic of:	Multiply Factors C and K, Table 2, by:
2	100
3	10
5	0.1

Table 2 gives C for 6-place logarithms. For each additional place, multiply the tabular value by 10; for each place less than 6, divide by 10. Table 2 is arranged for intervals of 0.2 for C and 0.095 for K.

With all the necessary information before him, the average computer should be able to determine the corrections for a geodetic line in from 3 to 5 min. The work can be speeded considerably by setting up a number of geodetic lines on the forms and computing them together, completing each operation on the entire group before proceeding with the next. If a colored pencil is used for recording the last step in the computations, namely, $d\alpha$ and $d(\log s)$, these values will stand forth conspicuously, and may be found more readily when needed.

NOMOGRAPHIC CHART

In order to check the values of $d\alpha$ and $d(\log s)$ computed by the formulas, the nomographic chart of Fig. 6 has been prepared, on which the same corrections may be determined graphically. It has scales for $\delta\phi$ (the differential change in latitude within the line); $\delta\lambda$ (the differential change in longitude at the various latitudes); sin α; cos α; log s; and the desired corrections, $d\alpha$ and $d(\log s)'$. In addition, there is an auxiliary chart (Fig. 7) for the determination of the supplementary correction to $d(\log s)'$, due to the convergence of meridians.

To use Fig. 6, proceed as follows: To determine $d\alpha$, mark on the proper scales, $\delta\phi$ (Point a), $\delta\lambda$ (Point b) for the proper latitude, sin α (Point c), cos α (Point d), and log s (Point e). On the $\delta\lambda$-scale, project the intersection of the horizontal line for ϕ and the curved line for $\delta\lambda$ to the main horizontal line (Point g), using as a guide the fine vertical lines.

Connect log s with sin α (Line ce) and draw a parallel line (ah) through $\delta\phi$ to intersect the vertical index line containing the sin and cos scales. Call this intersection Point (h). Connect log s with cos α (Line de) and draw a parallel line through $\delta\lambda$ (Line gk) to intersect the vertical index line on the right half of the chart. Call this intersection Point (k). The line joining Points (h) and (k) intersects the $d\alpha$-scale *at* Point l, indicating the value of $d\alpha$.

To determine d(log s), the markings for $\delta\lambda$ (Point g), sin α (Point d), and cos α (Point c) are the same as before: $\delta\phi$ (Point a) must be set off on the opposite side of the $\delta\phi$-scale, and log s (Point e) must be marked on the lower log s-scale.

Connect log s and cos α (Line ec) and draw a parallel line (ah) through $\delta\phi$, intersecting the left index line as before. Call this intersection Point (h). Connect log s and sin α (Line de), and draw a parallel line (gk) through $\delta\lambda$, intersecting the right index line as before. Call this intersection Point (k). The line joining Points (h) and (k) intersects the d(log s)$'$-scale at the preliminary value for d(log s) Point (l).

Fig. 7, an auxiliary chart for the convergence term, has scales for log s, α, $\Delta\alpha$, $d\phi_m$ (the mean latitude correction), and d(log s)$''$. To use this chart, draw a line (ab) connecting log s with $\Delta\alpha$. Through the intersection of this line with the diagonal, draw a line from $d\phi_m$ (Point c), to intersect the right vertical index (Point d). Through this intersection and α (Point e) on the diagonal scale, draw a line (def) to meet the left scale at d(log s)$''$, which will always be opposite in sign to $d\phi_m$. This value for d(log s)$''$ should be added to the preliminary value, d(log s)$'$, obtained from Fig. 6, to derive the final value of d(log s).

For use in the office, the nomographic chart has been drawn on a double-mounted plane-table sheet, 18 by 24 in. in size, and covered with a sheet of transparent cellulose acetate. All marks and lines for each problem are drawn in pencil on this cover, from which they may be easily removed later with a soft eraser, leaving the chart clean for the beginning of another problem. Parallel lines are drawn by the usual methods, using a parallel rule or a pair of triangles.

A complete problem (determination of $d\alpha$ and d(log s)) can be solved in about 2 min by one familiar with the charts.

Two-Point "Isodiffs"

Examination of the Wilson method indicates that two tie-points are sufficient to control the adjustment of a triangulation net if no others are available. Since this is true, it should be possible to draw "isodiffs" to give, graphically, the same adjustment that would be obtained by the application of the Wilson formulas. Interpolation along the line between the two tie-points, however, gives only the spacing of the "isodiffs", but no indication of their directions. It should be possible to compute, by the formulas, the position changes of one additional point on the system, and

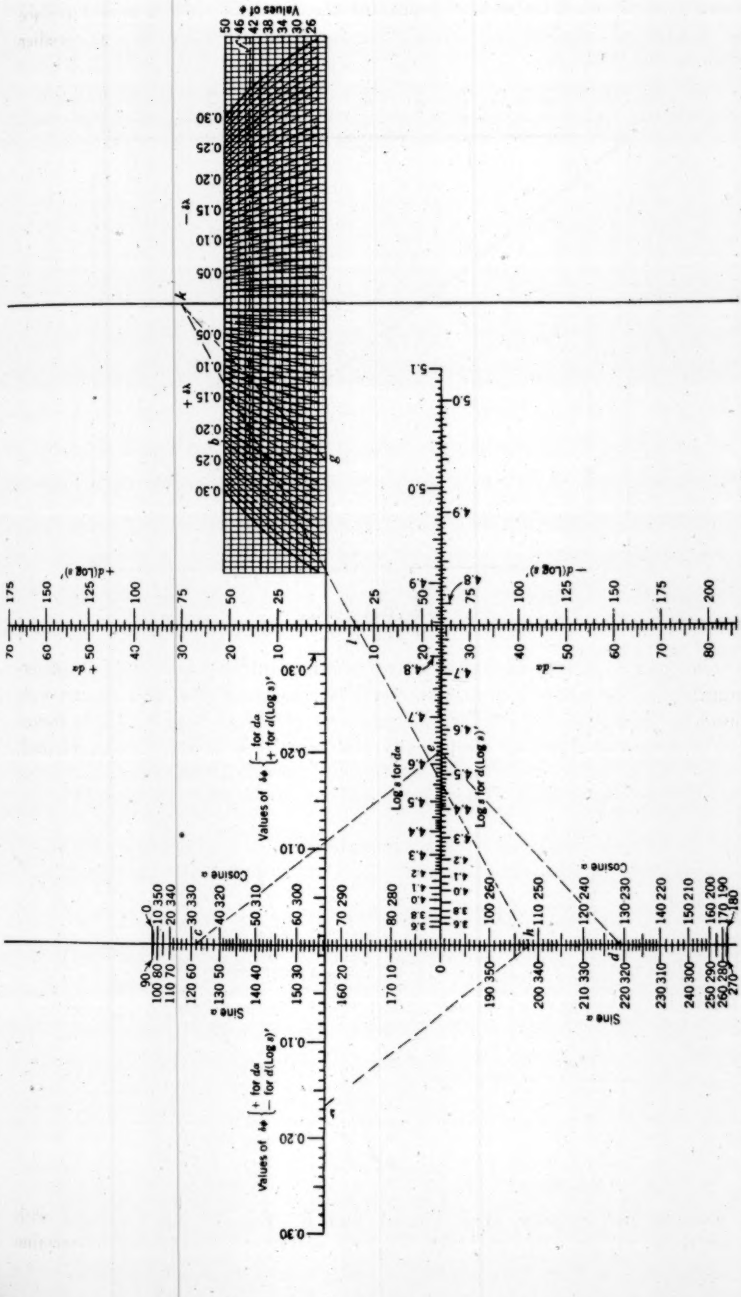

FIG. 6.—NOMOGRAPHIC CHART FOR THE DETERMINATION OF THE SWING AND CHANGE IN LENGTH OF A LINE RESULTING FROM THE SHIFTING OF ITS ENDS.

to use that as the third control point for the "isodiffs". This would replace the analytical method for computing position changes by a speedier graphical method.

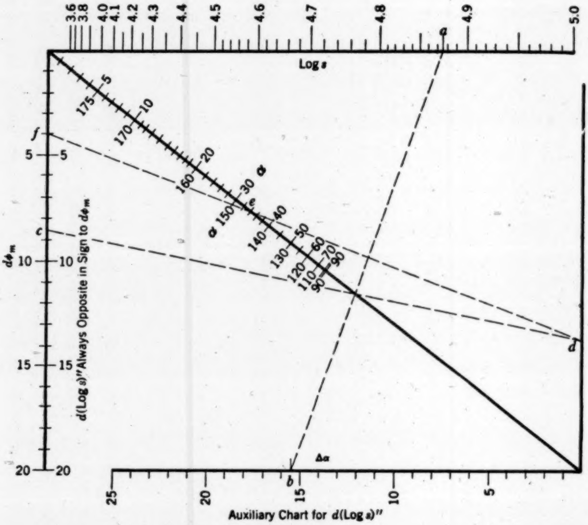

FIG. 7.

The computation of the third control point, requiring, as it does, the determination of the various constants, could be dispensed with if a means were found to draw the "isodiffs" from only two points as a base. This means can be found by applying graphically the principles of the Wilson method.

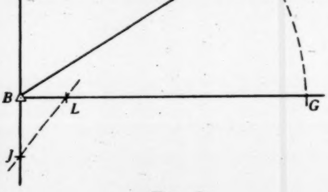

FIG. 8.

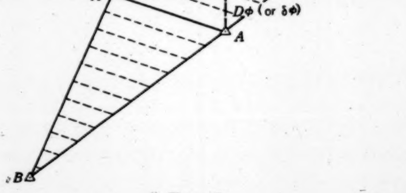

FIG. 9.

Assume, for instance, that Ties A and B (Fig. 8), are available with corrections of $d\phi_1$, $d\lambda_1$ and $d\phi_2$ $d\lambda_2$, respectively. As before, determine

$\delta\phi$, $\delta\lambda$, $D\phi$, and $D\lambda$. If $D\phi$ and $D\lambda$ are plotted at A to an enlarged scale as before, Point A' becomes the new relative position of Station A, and Point E the projection of Point A' on Line AB. Then, AE represents the change in length of AB and $A'E$ is a measure of the rotation of the base. Since the entire system must receive the same treatment as the base, all lines must be swung by the same amount, $K \times \overline{A'E}$, around Station B as a pivot, and reduced (or expanded) by the same ratio, $\frac{\overline{AE}}{s}$.

For convenience, consider Point F on the same meridian and Point G on the same parallel as Station B, so that $\overline{BF} = \overline{BG} = s$. At Point F the relative change in latitude is produced by the scale change only and equals $\frac{-\overline{AE}}{Q}$, and the spacing of "isolats" along Line BF equals $-\frac{sQ}{\overline{AE}} = m_\phi$. At Point G the relative change in latitude is produced by the rotation factor, $A'E$, only, and equals $\frac{\overline{A'E}}{Q}$, and the spacing of "isolats" along Line BG equals $\frac{sQ}{\overline{A'E}} = p_\phi$. Then, $\frac{m_\phi}{p_\phi} = -\frac{sQ}{\overline{AE}} \times \frac{\overline{A'E}}{sQ} = -\frac{\overline{A'E}}{\overline{AE}}$. It is now possible to draw the "isolats" by either of two methods; (1) By interpolation along Lines BF and BG, using the intersections on Line AB as a check; or (2) by the simpler method of interpolating along AB and using the directions, indicated by the slope ratio, $\frac{m_\phi}{p_\phi} = -\frac{\overline{A'E}}{\overline{AE}}$. The "isolats" will be straight, parallel lines, uniformly spaced.

Similarly, the relative longitude change at Point F is produced by $A'E$ only, and equals $\frac{\overline{A'E}}{R}$, and the spacing of the "isolongs" along BF equals $\frac{sR}{\overline{A'E}} = m_\lambda$; also, the relative longitude change at Point G is produced by AE only, and equals $\frac{\overline{AE}}{R}$, and the spacing of the "isolongs" along Line BG equals $\frac{sR}{\overline{AE}} = p_\lambda$. Then, $\frac{m_\lambda}{p_\lambda} = \frac{sR}{\overline{A'E}} \times \frac{\overline{AE}}{sR} = \frac{\overline{AE}}{\overline{A'E}}$. The "isolongs" may be drawn by the same methods as those used for the "isolats", and they, also, will be straight, parallel lines, uniformly spaced.

It will be noted that the slope of the "isolongs" is the negative reciprocal of the slope of the "isolats", which, by the principles of analytical geometry, shows them to be perpendicular to each other. By similar triangles it may be shown that the normal spacing of the "isolats" is $\frac{sQ}{\overline{AA'}}$, and that of the "isolongs", $\frac{sR}{\overline{AA'}}$. Therefore, the normal spacing of "isolats" is to the normal spacings of "isolongs" as $\frac{sQ}{\overline{AA'}}$ is to $\frac{sR}{\overline{AA'}}$ or as Q is to R.

Special attention may now be called to certain fundamental features of the "isodiff" diagram. Whenever a net of triangulation is shifted so that no change occurs in any of the previously adjusted angles of the net, the following conditions must result:

(*a*) The "isolats" will be straight, parallel lines, uniformly spaced;

(*b*) The "isolongs" also will be straight, parallel lines, uniformly spaced, and they will be perpendicular to the "isolats"; and,

(*c*) The normal spacing of the "isolats" will be to the normal spacing of the "isolongs" as Q is to R for the mean latitude of the project.

Conversely, it would appear that, when a graph of "isodiffs" satisfies Conditions (*a*), (*b*), and (*c*), the shape of the triangulation net being adjusted is not changed or warped. In other words, the net may have been shifted, rotated, and expanded (or contracted), but the angles have not been altered. This will be true if one other condition is satisfied; namely, if the direction of increasing values of the "isolats" is taken as north, the values of the "isolongs" should increase to the westward. If this pattern is kept in mind when drawing "isodiffs" for the general problem of several tie-points, an effort can be made to adhere to it as far as possible, in order to prevent or to minimize distortion in the system that is being adjusted.

To summarize the simpler construction for "isodiffs" when only two ties are available for a system: At Station A, plot $D\phi$ and $D\lambda$ to locate Point A'. Measure Lines AE and $A'E$. Along the meridian through Station B (BF), lay off $BJ = -A'E$. Along the parallel through Station B(BG), lay off $BL = AE$. Interpolating along AB for the "isolat" intersections, draw "isolats" parallel to JL. Interpolating along AB for the "isolong" intersections, draw "isolongs" perpendicular to JL. These "isodiffs" may be extended beyond Points A and B, respectively, by continuing the same spacings. As a partial check on the work, it may be noted that the normal distance between "isolats" is to the normal distance between "isolongs" as Q is to R.

From these "isodiffs" the same position corrections should be obtained as by the Wilson formulas; and the uniform azimuth and distance corrections may be applied to all lines in the same manner.

ROTATING GUIDE

Another method has been developed by Mr. Nelson for the graphical application of the principles proposed by Mr. Wilson. On a stiff transparent medium, such as celluloid or cellulose acetate, lay off Line AB (Fig. 9). At Station A, plot $D\phi$ and $D\lambda$ to locate Point A'. Then, AA' represents the actual movement (to the distorted scale) of Point A. With the system pivoted about Station B, all points on the system will receive the same relative movement with respect to B, the magnitude of the movements varying only with the distance of each point from the pivot. If BA and BA' are extended indefinitely, any point the original position of which is on BA would fall on BA' after adjustment, and the path of its movement would be parallel to AA'.

To use the adjustment guide, pass a pin or thumb-tack through Point B on the guide and Point B on the map, so that the guide is free to pivot about that point. Rotate the guide about the pivot so that each station to be adjusted will, in turn, fall on BA, extended. Project the station to BA' by a line parallel to AA'. Measure the differences in latitude and longitude for each station to the scale of the guide, and divide by Q and R, respectively, to obtain $(d\phi)'$ and $(d\lambda)'$. The projection to BA' may be made by eye if a number of lines are ruled on the guide parallel to AA'.

When a number of stations are to be adjusted by this method, time can be saved if scales for $(d\phi)'$ and $(d\lambda)'$ for the mean latitude of the project, are prepared in which one unit of $(d\phi)'$ is to one unit of $(d\lambda)'$ as Q is to R. With the aid of these auxiliary scales, $\delta\phi$ and $\delta\lambda$, for Point A, may be plotted directly on the guide without first converting them to meters, and $(d\phi)'$ and $(d\lambda)'$ may be scaled in seconds instead of in meters. Of course, the corrections at Station B must be added to those obtained by the use of the guide, in order to secure the final corrections for each station being adjusted. The uniform azimuth and distance corrections may be applied to each line in the proper manner.

CONCLUSION

It is readily apparent that all the methods of adjustment herein described are based on approximations of varying degrees. However, since the actual quantities considered are so small, they may be determined only approximately and still be well within the accuracy of the original survey. The mathematical computations will seldom require more than three significant figures, and a 10-in. slide-rule will usually be found ample; for the graphical work, ordinary plotting precision will satisfy most requirements.

The weakest link in the entire chain of readjustment would appear to be the construction of the "isodiffs" when several ties are available. Moreover, these methods do not correct errors or inaccuracies that may exist in the original computations. In the readjustment of good field work that has been rigidly adjusted to a good datum, the change of datum will not be likely to distort the originally adjusted figure to any great extent, so that the "isodiffs" should be sketched with little difficulty and will be fairly regular lines, well spaced. For such work there should be little question about the suitability of readjustment by "isodiffs".

If the field work itself contains appreciable discrepancies, or if it was not properly adjusted, or adjusted to a poor datum, the corrections at the tie-points might not be expected to be consistent. The "isodiffs" for such a readjustment might be badly curved and poorly spaced, but the readjustment based on them would probably be no worse than the original work and would make the survey available on the new datum, whereas its usefulness might otherwise be lost completely.

These methods, furthermore, permit the closing of circuits that formerly consisted of independent links tying to common stations, but with different co-ordinates. In some problems of this type, it is a simple matter to sketch the "isodiffs" between the fixed ties, making due allowance for the break.

Another method that sometimes gives good results is to assume as a position for each common station a weighted mean of its positions on the respective triangulation nets tying to it, the weight depending on the strength of the respective nets and the distance of the common station from each of the fixed tie-points. The common station may then be used as a fixed tie-point in the adjustment.

A third method, somewhat longer than either of the foregoing but, perhaps, more rigid, involves a partial preliminary adjustment. Each link in the circuit is, in turn, adjusted to the datum of any one of the links, regardless of the fixed tie-points. When the entire circuit has been reduced to a single unified datum it may be adjusted to the final datum through the fixed tie-points.

Other appropriate methods will doubtless suggest themselves to the computer, according to the specific problems on hand.

The use of these methods for readjustment of old work suggests an application to new work that might warrant the consideration of the computer. If a chain of quadrilaterals (or other suitable figures) is extended from one fixed base to close on another, it should be possible to begin with the fixed positions at one end of the chain and compute through individually adjusted figures to obtain new values for the fixed positions at the other end. The necessary corrections to bring the closing stations to their proper positions may then be determined, and "isodiffs" drawn for the chain, using the corrections determined for the closing end and zero corrections for the other end. Then, all intermediate positions could be corrected by the indicated amounts, and all lines corrected for azimuth and scale by the formulas. By this means, latitude and longitude conditions, as well as length and azimuth conditions, would be satisfied for both bases. Although the results might not agree perfectly with those of a complete, rigid least-squares adjustment, it is believed the differences would be very slight unless the strength of the chain varies appreciably within its length.

The choice of methods for readjustment of datum may be summarized briefly, as follows:

(*a*) When two ties to the new datum are available, determine position corrections by: (1) The Wilson formulas; (2) the rotating adjustment guide; or (3) the two-point "isodiffs". Apply uniform azimuth and length corrections to all lines.

(*b*) When three or more ties are available, construct an "isodiff" graph for the determination of position changes. Determine azimuth and length corrections by the formulas or by the nomographic chart; or use both for a check.

STRUCTURAL ANALYSIS BASED UPON PRINCIPLES PERTAINING TO UNLOADED MODELS

BY OTTO GOTTSCHALK,[1] ESQ.

WITH DISCUSSION BY MESSRS. L. J. MENSCH, FREDERICK SHAPIRO, JAMES R. GRIFFITH, CAMILLO WEISS, F. B. FARQUHARSON, A. A. EREMIN, DAVID M. MACALPINE, AND OTTO GOTTSCHALK.

SYNOPSIS

When the stresses in a structure are investigated by the use of unloaded models, known deformations are produced at a section at which the stresses are desired, and the corresponding displacements are measured at the point at which the load is applied in the actual structure. The ratios between the latter and the former deformations give the required stresses for a unit load, and when the original deformation is taken as unity, the model forms the influence line of stress. To obtain a moment, a known or unit rotation is produced at the section at which the stress is required; a normal displacement is produced to obtain a shear or a reaction; and an axial displacement is produced to obtain a direct tension or compression. The geometrical analysis of these operations without the actual use of models leads to fundamental simplifications, and it is the purpose of this paper to establish the few simple equations necessary for the use of this method of analyzing statically indeterminate structures.

DEFINITIONS AND NOTATION

The fundamental beam with a constant moment of inertia used in this analysis is the member, *AB*, shown in the several illustrations. The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials,[2] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

a = a definite value of x; $a' = L - a$ = a definite value of x'; a'' = distances measured along a cantilever from the support;

f = the intercept at End A of the tangent to the elastic curve, at End $B = \alpha_{BA} L$; similarly, $f' = \alpha_{AB} L$;

NOTE.—Published in January, 1937, *Proceedings*.

[1] Buenos Aires, Argentine Republic.

[2] A.S.A.—*Z10a*—1932.

I = moment of inertia;

K_A = the sum of the relative stiffness values of the ends of all members meeting at a joint; and, therefore, $K_A = S + S_A$; and, $K_B = S' + S_B$;

k = stiffness of a member $= \frac{I}{L}$;

L = span length;

M = bending moment; M_{AB} = moment at End A of Beam AB; M_{BA} = moments at End B of Beam AB; and are positive in the same directions as their corresponding rotations (α);

m = ratio of end rotations; for rotations at Ends A and B, respectively: $m = \frac{\alpha_{BA}}{\alpha_{AB}} = \frac{f}{f'}$; and, $m' = \frac{\alpha_{AB}}{\alpha_{BA}} = \frac{f'}{f}$; for rotations originating at A and B, respectively;

N = a substitution factor (see Equation (18));

P = total concentrated load applied at any point of the actual structure;

R = a ratio $= \frac{\Delta}{L}$;

S = relative stiffness value $= (1 - 0.5\ m)\, k$ = the resistance to rotation of the left end of a member; $S' = (1 - 0.5\ m')\, k$ = the resistance to rotation of the right end of a member; S_A = the sum of the relative stiffness values of all the members meeting the left end of a member at a joint, but not including the end of the member in question. Since the right ends of the members connect with the left end of a member under consideration, $S_A = S'_1 + S'_2 + S'_3 + \ldots +$, etc.; S_B is a quantity similar to S_A, for the right end of a member, and, correspondingly, $S_B = S_1 + S_2 + S_3 + \ldots +$, etc.;

V = total shear;

W = total uniform load on a beam;

x = variable abscissa of the influence line, measured from the left support; $x' = L - x$;

y = variable ordinate of the influence line; y_c = the ordinate at the center of the beam; y_m = the mean value of y for any influence line;

α = the angular rotation of the end of a member relative to the final direction of the axis. It is positive when the rotation is such that tension is produced in the "upper" fibers. As will be seen from the analysis all members have a "left" and a "right" end, both of which are definitely determined; therefore, the terms "upper" and "lower" are also definitely determined;

Δ = the deflection of the left end of a member relative to the right end and is positive when the left end is "raised" relative to the right end;

ϵ = energy; internal work exerted against the work involved in the diminishing reaction (see Equation (26));

θ = the angular rotation of the end of a member relative to the original direction of its axis, and is positive in the same direction as α.

INTRODUCTION

In hypothetical models, as in actual models, the deformations are assumed to be indefinitely small, so that the projection of any deformed member or part of it on its original axis is equal to its original length; that is, in Fig. 1, the distance, *A-B*, remains unchanged after rotation at Point *E*.

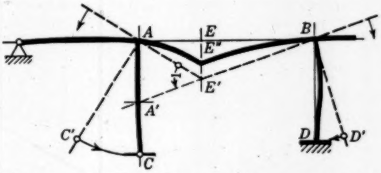

FIG. 1.—A RIGID FRAME; INFLUENCE LINE FOR MOMENT AT POINT *E*.

The present analysis will be limited to skeletons or frames with vertical columns and horizontal beams, each of constant moment of inertia and all of the same homogeneous material, with constant modulus of elasticity. As in other, similar methods of analysis, the structure is first restrained against side-sway. The structure is then released, the effect of side-sway computed, and the stresses are corrected. For example, let *AB* be a beam within the typical skeleton shown in Fig. 1 in which the bending moment, M_E, at Point *E* is required. If the skeleton were merely simply supported at Points *A* and *B*, a unit rotation at Point *E* would produce the deformation, $C' A E' B D'$, in the model as shown in broken lines, in Fig. 1. Then (with the angles between members fixed at all joints, but with the joints free to rotate) Points C' and D' and the ends of all other beams and columns, are returned to their original position. The shape of the frame ($C A E'' B D$), will then represent the final influence line for bending moment.

It will be seen from Fig. 1 that all branches of the influence line for M_E are simple geometrical curves, produced by the rotation of the broken ends at Point *E* and by the restraint at the far ends, except $A E'' B$, which is a combination of the triangle, $A E' B$, corresponding to free supports at *A* and *B* and the eventual restraint at Points *A* and *B*. These rotations, restraints, and displacements produce typical bending moments in the several parts of the model, which admit of an easy analysis of the curves formed. It should be kept in mind, however, that influence lines may be considered as geometrical curves which can be obtained by geometrical methods. Equations (1) to (21) which follow, have been obtained experimentally by applying visible displacements and unit rotations to models composed of elastic splines. The resulting curves have been analyzed in Appendix II. The basic theory of unloaded models is derived in Appendix I.

FUNDAMENTAL EQUATIONS OF SIMPLE INFLUENCE LINES

When an elastic spline (see Fig. 2(*a*)), pin-connected at Points *A* and *B*, is rotated about Point *A* through an angle equal to $\frac{f'}{L}$, the corresponding rotation at Point *B* is equal to $\frac{f}{L} = \frac{f'}{2\,L}$; or $m = \frac{f}{f'} = 0.5$. This experiment may be checked by abstract theory: Rotation at Point *A* produces a bending moment in the spline which is a maximum at Point *A* and which decreases uniformly to zero at Point *B*. At Point *A*, the reaction of the beam, loaded with that triangular moment area, is twice that at Point *B* and, because the inclination of the tangents to the elastic line are proportional to the reactions of this moment area, $f' = 2f$.

FIG. 2.—SIMPLE INFLUENCE LINES

However, when other members join at Point *B* to create a total relative stiffness, S_B, the rotation of the spline is restrained proportionately as shown by Line *BA'* (Fig. 2(*a*)) and, therefore:

$$m = \frac{f}{f'} = \frac{0.5\,k}{S_B + k} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Similarly, rotating the spline about Point *B* and restraining it at Point *A* (see Fig. 2(*b*)):

$$m' = \frac{f'}{f} = \frac{0.5\,k}{S_A + k} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Referring back to Fig. 2(*a*), when the spline is released at Point *B* so that the value of *f* increases, the strain on the spline at Point *A* is reduced by one-half the corresponding increase; and since, when Point *B* is fixed and cannot rotate, $S = k$ (for $f = 0$ and $m = 0$):

$$\frac{S}{k} = 1 - \frac{m}{2} \qquad (3a)$$

and, similarly,

$$\frac{S'}{k} = 1 - \frac{m'}{2} \qquad (3b)$$

The curves shown in Figs. 2(*a*) and 2(*b*) are typical simple influence lines; they are obtained by applying to the spline, *AB*, bending moments at Points *A* and *B* and, consequently, may be analyzed as the moment lines of Beam *AB* loaded by areas of moments that change uniformly from:

$M_A = 4K\theta_A - 2K\theta_B$

$$\frac{M_A}{E\,I} = \frac{2\,(2\,f' - f)}{L^2} \qquad (4a)$$

at Point *A*, to:

$$\frac{M_B}{E\,I} = \frac{2\,(2\,f - f')}{L^2} \qquad (4b)$$

at Point *B* (see Fig. 2(*c*)). Thus, one may derive the very simple equation for general influence lines in terms of end rotations:

$$y = \frac{x\ x'}{L^3}\,(x\,f + x'\,f') \qquad (5)$$

At the center of the beam:

$$y_c = \frac{1}{8}\,(f + f') \qquad (6a)$$

and the mean value is:

a parabola approx.

$$y_m = \frac{2\,y_c}{3} = \frac{f + f'}{12} \qquad (6b)$$

When the beam, *AB*, is simply supported or pin-connected at Point *B*: $m = 0.5$; $S = 0.75\,k$;

$$y_c = \frac{3\,f'}{16} \qquad (7a)$$

$$y_m = \frac{f'}{8} \qquad (7b)$$

and,

$$y = \frac{x\,x'\,f'}{L^3}\left(\frac{x}{2} + x'\right) \qquad (7c)$$

and when End B is fixed: $m = 0$; $S = k$;

$$y_c = \frac{f'}{8} \quad \text{.........................} (8a)$$

$$y_m = \frac{f'}{12} \quad \text{.........................} (8b)$$

and,

$$y = \frac{x\,(x')^2\,f'}{L^3} \quad \text{.........................} (8c)$$

Similarly, when End A is simply supported: $m' = 0.5$; $S' = 0.75\,k$;

$$y_c = \frac{3f}{16} \quad \text{.........................} (9a)$$

$$y_m = \frac{f}{8} \quad \text{.........................} (9b)$$

and,

$$y = \frac{x\,x'\,f}{L^3}\left(x + \frac{x'}{2}\right) \quad \text{.........................} (9c)$$

When End A is fixed: $m' = 0$; $S' = k$;

$$y_c = \frac{f}{8} \quad \text{.........................} (10a)$$

$$y_m = \frac{f}{12} \quad \text{.........................} (10b)$$

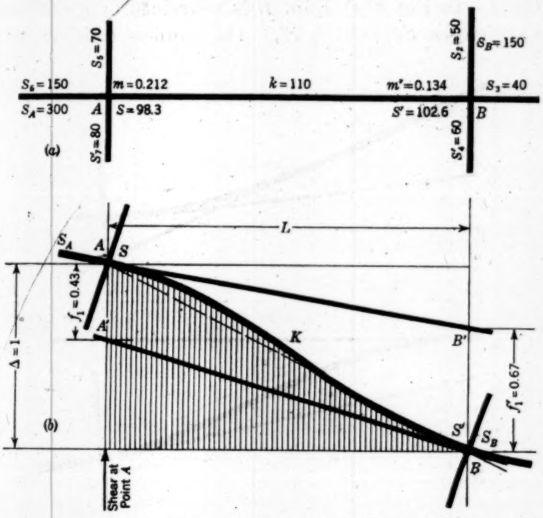
and,

$$y = \frac{x^2\,x'\,f}{L^3} \quad \text{.........................} (10c)$$

Equations (1) to (10) are the fundamentals required for analyzing frames. They apply to all classes of influence lines and lead to new and useful analytical and graphical interpretations of these curves. Of special interest is the fact that the relative stiffness of end panels can be easily calculated from Equations (8) and (10) and that, therefore, the statical indeterminancy due to restraint at the support need no longer be a serious factor in computations. Side-sway is not taken into account in these equations, but the necessary correction can be made easily.

LINEAR DISPLACEMENT

Fig. 3(a) shows a beam or column in its normal, unstrained position. If End A, with all of the part of the structure to the left, is translated vertically upward a distance, Δ, Beam AB will deform as shown in Fig. 3(b). The members to the left of Point A are considered to be restrained so that they cannot move parallel to the original position of Member *AB*, but are free to move perpendicular to that axis, except that all members move the same distance, Δ. All members are considered free to rotate as much as their relative stiffnesses, *S*, will permit.



$S_5=70$
$S_B=150$
$S_2=50$

Shear at Point A

FIG. 3.—LINEAR DISPLACEMENT IN A RIGID FRAME

Joints *A* and *B*, then, tend to resist rotation and exert a counter rotation as shown in Fig. 3(*b*), so that the algebraic sums of the deformations are:

$$\frac{f}{\Delta} = -\frac{S_B}{K_B} + \frac{m\ S_A}{K_A} \qquad \text{(11)}$$

and,

$$\frac{f'}{\Delta} = \frac{S_A}{K_A} - \frac{m'\ S_B}{K_B} \qquad \text{(12)}$$

For example (referring to Fig. 3), let $k = 110$; $S_A = 70 + 150 + 80 = 300$; and $S_B = 50 + 40 + 60 = 150$. If Joint *A* is displaced vertically a distance, $\Delta = 1$, the rotations are: At Joint *A*, $\frac{f'}{L}$; and, at Joint *B*, $\frac{f}{L}$. The influence line for shear at End *A* of Beam *AB*, then will be determined as follows: $m = \frac{0.5 \times 110}{110 + 150} = 0.212$; $S = 110\left(1 - \frac{0.212}{2}\right) = 98.3$; $m' = \frac{0.5 \times 110}{110 + 300} = 0.134$; $S' = 110\left(1 - \frac{0.134}{2}\right) = 102.6$; $K_A = 98.3 + 300 = 398.3$; and $K_B = 102.6 + 150 = 252.6$. The net rotation, therefore, will be: At Joint B, $-\dfrac{f}{\Delta} = \dfrac{150}{252.6} - \dfrac{0.212 \times 300}{398.3} = 0.434$; and, at Joint A, $\dfrac{f'}{\Delta} = \dfrac{300}{398.3} - \dfrac{0.134 \times 150}{252.6} = 0.674$.

Special Cases.—In Fig. 4(a) Joint B is restrained by a stiffness, S_B, composed of the stiffnesses, $S_2 + S_3 + S'_4$. The stiffness ratio, $K_B = S'_1 + S_B$.

FIG. 4.—INFLUENCE LINES FOR THE REACTION, R_A, AT THE EXTERIOR SUPPORT, A.

If End A is the outside simple support, for $\Delta = 1$: $S_A = 0$; $m' = 0.5$; $S_1' = 0.75\,k$; and, $K_B = 0.75\,k_1 + S_B$. Substituting in Equations (10) and (11):

$$-f = \frac{S_B}{K_B} \qquad \text{(13a)}$$

and,

$$f' = -\frac{S_B}{2\,K_B} \qquad \text{(13b)}$$

On the other hand, if Point A is fixed (see Fig. 4(b)), for $\Delta = 1$: $S_A = \infty$; $\dfrac{S_A}{K_A} = 1$; $m = \dfrac{k_1}{2\,K_B}$; and $m' = 0$, substituting these values in Equations (10) and (11):

$$-f = \frac{S_B}{K_B} - \frac{k_1}{2\,K_B} = 1 - \frac{3\,k_1}{2\,K_B} \qquad \text{(14a)}$$

and,

$$f' = 1 \qquad \text{(14b)}$$

Equations (13) and (14) may also be obtained from Fig. 4 without reference to Equations (11) and (12); for example, in Fig. 4(*b*) if Support *B* were free, an upward displacement, Δ, at End *A* would rotate *AB* at Joint *B* through an angle, $\frac{3\,\Delta}{2\,L}$. If the resisting stiffness of the remaining three members meeting at Joint *B* is then applied, a counter rotation occurs, equal to $\frac{3\,\Delta\,S'_1}{2\,L K_B}$. Finally, for $\Delta = 1$ and $S'_1 = k_1$: $-f = 1 - \frac{3\,k_1}{2\,K_B}$ (see Equation (14)).

TRANSVERSE FORCES

The force necessary to produce a given linear displacement of Support *A* with respect to Joint *B* of the unloaded beam, *AB*, or the shear at the supports, corresponding to known bending moments at the joints, is $P = \frac{M_A - M_B}{L}$ in which, according to Fig 2(*c*), $M_A = \frac{2\,E\,k_1\,(2f' - f)}{L}$; and, $M_B = \frac{2\,E\,k_1\,(2f - f')}{L}$. Making the necessary substitutions and simplifying:

$$P = \frac{6\,E\,k_1\,(f' - f)}{L^2} \qquad (15)$$

INFLUENCE LINES FOR BENDING MOMENTS

The influence line for bending moment at any section, *E*, of a beam, *AB* (see Fig. 5), is obtained by applying a unit rotation at Point *E*. When Joints *A* and *B* are simply supported the unit rotation deforms the member, *AB*, as shown in Fig. 5(*a*), producing the broken beam, *AE′B*, so that $\Delta = a$ and $\Delta' = a'$.

The restraining stiffness of the connecting members of the two joints, however, exerts a counter rotation, producing the curve with end rotations, $a - f$ and $a' - f'$, shown in Fig. 5(*b*), so that, finally, in Fig 5(*c*):

$$f = a\,\frac{S_B}{K_B} - m\,a'\,\frac{S_A}{K_A} \qquad (16a)$$

and,

$$f' = a'\,\frac{S_A}{K_A} - m'\,a\,\frac{S_B}{K_B} \qquad (16b)$$

General Ordinate and Mean Ordinate.—For $x < a$:

$$y = \frac{a'\,x}{L} - N \qquad (17a)$$

and, for $x > a$:

$$y = \frac{a\,x'}{L} - N \qquad (17b)$$

in which,

$$N = \frac{x\,x'}{L^3}\left[\,(a - f)\,x + (a' - f')\,x'\,\right] \quad \ldots\ldots\ldots\ldots\ldots(18)$$

In general, the mean ordinate is expressed by,

$$y_m = \frac{a\,a'}{2\,L} - \frac{L - f - f'}{12} \quad \ldots\ldots\ldots\ldots\ldots(19)$$

FIG. 5.—INFLUENCE LINES FOR BENDING MOMENTS, OBTAINED GEOMETRICALLY

When $a = a' = 0.5\,L$, the ordinate at the center, y_c, and the mean ordinate, y_m, are respectively:

$$y_c = \frac{L + f + f'}{8} \quad \ldots\ldots\ldots\ldots\ldots(20a)$$

and,

$$y_m = \frac{2\,y_c}{3} - \frac{L}{24} \quad \ldots\ldots\ldots\ldots\ldots(20b)$$

For $x = a$:

$$y = \frac{a\,a'}{L^3}\,(2\,a\,a' + a\,f + a'\,f') \quad \ldots\ldots\ldots\ldots\ldots(21)$$

Here again it is demonstrated that influence lines, considered as purely geometric curves, can be derived by geometric methods alone. For example, the ordinate of Fig. 5(*b*) may be deducted from corresponding ordinates of Fig. 5(*a*) to secure the final curve of Fig. 5(*c*), without becoming involved in the theory of stresses or in stress functions. When $a = L$ and $a' = 0$, the result is an influence line for the end moment, M_B (see Fig. 6), for which the corresponding end rotations are:

FIG. 7.—INFLUENCE LINE FOR BENDING MOMENT AT POINT C OF A SIMPLE BEAM

Example 1.—Fig. 7(*a*) represents a beam simply supported at Points *A* and *B*, with a cantilever extension beyond Point *B*. The bending moment M_c is required. Breaking the hypothetical beam at Point *C* and rotating one of the parts with respect to the other through an angle equal to $\frac{a'}{\Delta} = 1$ (see Fig. 7(*b*)), produces the influence line for M_c, $A C' B$, with major ordinates of: $y_1 = \frac{a\,a'}{L}$; $y_m = \frac{y_1}{2} = \frac{a\,a'}{2\,L}$; and $y_2 = -\frac{a\,a''}{L}$. Consequently,

$$M_C = \frac{W\,a\,a'}{2\,L} + \frac{P_1\,a\,a'}{L} - \frac{P_2\,a\,a''}{L} \quad \ldots\ldots\ldots\ldots\ldots (23)$$

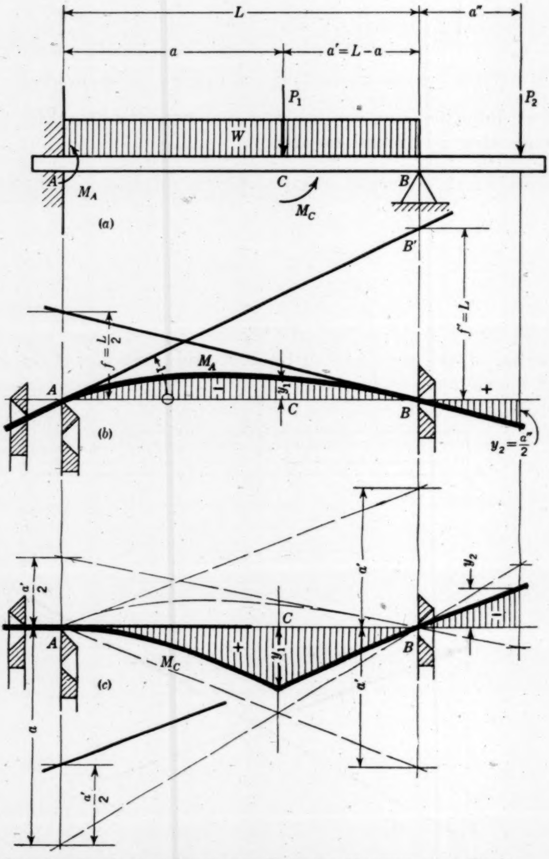

FIG. 8.—INFLUENCE LINES FOR BENDING MOMENT IN A BEAM FIXED AT ONE END

Example 2.—In Fig. 8(*a*), the beam in Example 1 has been fixed at End *A*. The bending moment M_A is required. Rotating the beam at Point *A* through an angle, $\frac{f'}{L} = 1$ (see Fig. 8(*b*)) and then translating Point *B'* back to its original position at Point *B*, $f = \frac{f'}{2} = \frac{L}{2}$ Then, from Equation (7); $y_m = \frac{L}{8}$; $y_1 = \frac{a\,a'\,(0.5a + a')}{L^2}$; $y_2 = \frac{f\,a''}{L} = \frac{a''}{2}$; and,

$$M_A = -\frac{W\,L}{8} - \frac{P_1\,a\,a'\,(0.5\,a + a')}{L^2} + \frac{P_2\,a''}{2} \quad \text{..........} (24)$$

Example 3.—To determine the influence line for the moment, M_C, at any Point *C*, Fig. 8(*a*), the beam is broken at Point *C* and rotated through an angle of $\frac{a'}{\Delta} = 1$, as in Example 1. End *A* is then rotated back until it is once more horizontal, and for this operation considered separately, the hypothetical beam has the form shown by the dotted curved line shown above *AB* in Fig. 8(*c*), ($f' = +\,a'$ and $f = +\,0.5\,a'$), for which Equation (7) gives the ordinates. For the first operation the ordinates are the same as in Example 1. The final ordinates are the differences between corresponding ordinates in each of the two steps, thus: $y_m = \frac{a\,a'}{2\,L} - \frac{a'}{8}$; $y_1 = \frac{a\,a'}{L} - \frac{a\,(a')^2\,(0.5\,a + a')}{L^3} = \frac{a^2\,a'\,(3\,L - a)}{2\,L^3}$; $y_2 = \frac{-\,a\,a''}{L} + \frac{a'\,a''}{2\,L} = \frac{-\,a''\,(3\,a - L)}{2\,L}$; and, finally,

$$M_C = W\,y_m + P_1\,y_1 + P_2\,y_2 \quad \text{.................} (25)$$

It is to be noted that the ordinates in Equation (25) can be obtained directly by means of Equations (16) to (22).

It is to be noted also that the effect of the load on the cantilever section is to produce positive bending moment in Member *AB* when $a < \frac{L}{3}$.

Example 4.—Consider the continuous beam in Fig. 9 for which M_B is required. This beam is elastically determinate, with: $S_1 = k_1 = 80$; $S_2 = 0.75\,k_2 = 45$; $k_B = 80 + 45 = 125$; $\frac{S'_1}{k_B} = \frac{80}{125} = \frac{16}{25}$; and, $\frac{S_2}{k_B} = \frac{45}{125} = \frac{9}{25}$. Referring to Fig. 9(*b*), break the beam at Point *B*; rotate one part through an angle of 1; and holding the angle between the two ends at this joint at 1, return End *C* back to a pin connection in its original position. According to Equation (22*a*), the result is that End *B* of Beam *AB* yields through an angle measured by $f_1 = \frac{20 \times 9}{25} = 7.2$, and (since the beam is fixed at Point *A*) $f' = 0$; $f'_2 = \frac{16 \times 16}{25} = 10.24$; and (since *BC* is simply supported at Point C), $f_2 = \frac{10.24}{2} = 5.12$. From Equation (10): $y_{m1} = \frac{f_1}{12} = 0.6$; and, $y_1 = \frac{14^2 \times 6 \times 7.2}{20^3} = 1.06$. Also, from Equations (7): $y_{m2} = \frac{10.24}{8} = 1.28$. Finally, $y_2 = \frac{-5.1 \times 5.0}{16} = -1.6$; and, therefore, $M_B = 12 \times 0.6 + 15 \times 1.06 + 8 \times 1.28 - 5 \times 1.6 = 25.32$.

FIG. 9.—INFLUENCE LINES FOR A CONTINUOUS BEAM

Example 5.—The influence line for the reaction, R_A, in the beam shown in Fig. 9 may be determined by reference to Fig. 9(c). First, deflect End A upward a distance, $\Delta = 1$, without permitting it to rotate. Following the procedure demonstrated in connection with Fig. 4(b) and from Equations (14): $-f_1 = 1 - \frac{3 \times 80}{250} = 0.04$; $f'_1 = 1$; $-f'_2 = \frac{0.96 \times 16}{20} = 0.77$; $f_2 = \frac{f'_2}{2} = 0.385$; $y_{m1} = \frac{1}{2} + \frac{1 - 0.04}{12} = 0.58$; $y_1 = \frac{6}{20} + 14 \times 6 \times \left(\frac{-14 \times 0.04 + 6 \times 1}{20^3}\right) = 0.36$; $y_{m2} = -\frac{0.77}{8} = -0.096$; $y_2 = \frac{0.385 \times 5}{16} = 0.12$; and, $R_A = 12 \times 0.58 + 15 \times 0.36 - 8 \times 0.096 + 5 \times 0.12 = 12.2$.

Example 6.—Consider an unsymmetrical portal frame, loaded by a horizontal force as shown in Fig. 10(*a*). The values, H_A and H_D are required. The stiffness, S, of Columns AB and DC is equal to k, and, therefore, $S'_1 = 20$;

FIG. 10.—INFLUENCE LINE FOR SIDE-SWAY IN A RIGID FRAME

and $S'_3 = 10$, respectively. In Beam BC, at Point B: $m_2 = \dfrac{30}{2\,(30 + 10)} = \frac{3}{8}$; and $S_2 = 30\left(1 - \dfrac{3}{16}\right) = 24.4$; and, at Point C: $m'_2 = \dfrac{30}{2\,(30 + 20)} = 0.3$; and, $S'_2 = 30\left(1 - \dfrac{0.3}{2}\right) = 25.5$. If the effect of the horizontal force, P, is to deflect the frame sidewise any distance, Δ, with respect to Points A and D (assuming Joints B and C as pin-connected), the next step is similar to that shown in Fig. 3(*b*), with the result that, $f' = \Delta = 1$ and $f = -\dfrac{\Delta}{2} = -\,0.5$. Restoring the rigidity in the joints by applying counter-rotations: $1 - f_1 = \dfrac{3 \times 20}{2(20 + 24.4)} = 0.676$; and $1 - f_3 = \dfrac{3 \times 10}{2\,(10 \times 25.5)} = 0.423$, the adjustment being in the ratio of $m'_2 = 0.3$, and $m_2 = 0.375$. Consequently, $f_1 = 1 - 0.676 + 0.3 \times 0.423 \times \frac{15}{10} = 0.514$; $f_3 = 1 - 0.423 + 0.375 \times 0.676 \times \frac{10}{15} = 0.746$; $f_1 + f'_1 = 0.514 + 1 = 1.514$; and, $f_3 + f'_3 = 0.746 + 1 = 1{,}746$. Therefore, $\frac{H_A}{H_D} = \frac{20}{10} \times \frac{1.514}{1.746} \times \frac{10^2}{15^2} = 0.77$; $\frac{H_A}{P} = \frac{0.77}{1.77} = 0.435$; and, $\frac{H_D}{P} = \frac{1.0}{1.77} = 0.565$.

CONCLUSIONS

When analyzing structures the relative stiffnesses, S and S', of the members are computed first, beginning at the end panels where $S = 0.75\,k$ when the end is free to rotate and $S = k$ when it is fixed. Then, imposing an imaginary displacement or rotation, the rotations at the joints are obtained in the simple manner shown, which at each load give the ordinate by which it must be multiplied to obtain the stress that is sought. Side-sway must be computed by Equation (15) and analyzed as demonstrated by Fig. 10. Until the designer becomes accustomed to this method of analysis it is suggested that the deformations of the hypothetical models be sketched as shown in Figs. 7 to 10.

Some of the fundamental advantages of this method of structural analysis are:

(1) Results are obtained from the diagram by a simple process that eliminates complicated equations;

(2) Results are exact for any load or change of load;

(3) The stress at any section may be computed independently without knowing the moment, shear, etc., at any other section; and,

(4) As a consequence of Conclusion (3) numerical errors at one section do not affect the results of other sections.

ACKNOWLEDGMENTS

Acknowledgment is freely given to Bernard L. Weiner, Assoc. M. Am. Soc. C. E., for a meticulously careful examination of this paper before publication. Mr. Weiner offered numerous important suggestions for clarifying the ideas contained, and the authorship of Appendices I and II is his entirely, except, as noted, that Appendix I is based on theory developed by Henry G. Babcock, Assoc. M. Am. Soc. C. E.

APPENDIX I

THEORY OF THE ANALYSIS OF "UNLOADED MODELS"

Models used for the analysis of structures may be divided roughly into two classes: "Loaded Models" and "Unloaded Models." The first type is simply a small-scale reproduction of the full-sized structure to which loads are applied which are proportional to the loads that will presumably be carried by the actual structure. No loads are applied to the second type of model, but, instead, a known deformation is introduced at one point of the model and the deflection at some other point is measured. The stresses are obtained from the ratio of these two deformations as will be shown subsequently.

The two types of models differ in the manner in which the required information is obtained. In the first case, the action of the real structure is reproduced in the model and the data are obtained by direct measurement of the quantities involved. In the second case, the manipulation to which the model is subjected has no direct counterpart in the actual structure and the results are obtained by a mathematical relationship which exists between the deformations and the loads acting in the prototype A well known example of this latter type is that developed by George E. Beggs, M. Am. Soc. C. E.[3]

The derivation[4] which follows was developed by Henry G. Babcock, Assoc. M. Am. Soc. C. E., as a proof of the validity of the Beggs method, but it applies equally well to any other type of model, or to an imaginary model as is the case in this paper.

Let P (Fig. 11) be a load acting at any point, C, of a structure, in any direction whatever; let R be the component, in any assumed direction, of the reaction of Point A due to P; let R be gradually diminished to zero; let the point of application, A, of R be constrained to move in the line of action of R; let Δ_1 be the deflection of Point A when $R = 0$; and, let Δ_2 equal the component of that part of the deflection of Point C in the direction of P which is due to the removal of the reaction, R (thus, Δ_2 does not include the deflection of Point C due to the application of P while Point A is fixed).

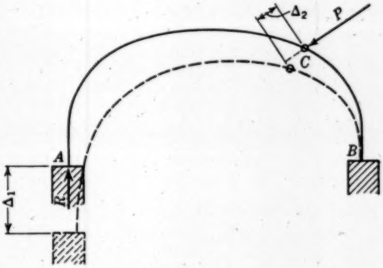

FIG. 11.

As Point C moves through the distance, Δ_2, in the direction of P, the total work done is $P\,\Delta_2$. Part of this work is done against the diminishing reaction, R, and the remainder, ϵ, is the internal work done on the structure. Evidently,

$$P\,\Delta_2 = \frac{R\,\Delta_1}{2} + \epsilon \qquad \text{......................(26)}$$

To evaluate ϵ, remove P and permit Point A to return to its original position. Now, apply a force at Point A, gradually increasing it from zero to $-R$; that is, in a direction opposite to that of $+R$. Since every force produces its own characteristic deflections at every point of a structure, independently of any other forces acting, it follows that the load, $-R$, acting alone will produce the same deflections, Δ_1, at Point A as was produced by the removal of $+R$ when P was acting. It will also produce the same deflections at every other point of the structure and, hence, the same internal work, ϵ; but, without P acting, $\frac{R\,\Delta_1}{2}$ is the total external work and ϵ the total internal. Therefore,

---

[3] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1208.

[4] Not previously published.

$$\epsilon = \frac{R\,\Delta_1}{2} \qquad \text{.........................(27)}$$

Substituting in Equation (26), $P\,\Delta_2 = \frac{R\,\Delta_1}{2} + \frac{R\,\Delta_1}{2}$; and,

$$R = P\,\frac{\Delta_2}{\Delta_1} \qquad \text{.........................(28)}$$

Since the ratio, $\frac{\Delta_2}{\Delta_1}$, is independent of the value of P, it may be determined by moving Point A through any arbitrary known distance in the direction of R and measuring the corresponding component of the deflection at Point C in the direction of P.

The preceding derivation can be extended to include moments as well as forces. If a rotation, α_1, is substituted for Δ_1, and a moment, M, for the reaction, R, other symbols remaining the same:

$$M = \frac{P\,\Delta_2}{\alpha_1} \qquad \text{.........................(29)}$$

in which α_1 is in circular measure.

The preceding theory was developed for a reaction, but it can be easily shown that it applies also to the moment, thrust, or shear at any point of a structure. If a model is cut at any section and the two cut ends are moved apart by translation (or rotation) a known amount relative to each other, Δ_1 (or α_1), and Δ_2 (or α_2) measured as before, Equations (28) and (29) still remain true. The moment, thrust, and shear can thus be found directly at any point of a structure. Finding reactions is, therefore, only a special case of finding the stresses at any point in general.

APPLICATION

The theory presented in this paper can be derived without reference to models. The usual theories deal directly with the loads and their reactions and stresses. Here, an indirect method based on the deflections of a model is used, and simplifications result. If instead of discussing more or less abstract deflections, a model is imagined to be manipulated in the same manner as a physical model is deformed by gages, and the relationship between the deflections established mathematically instead of by measurement as in a actual model, the understanding of the theory is simplified.

In the derivations which follow, the customary theories are used only in so far as they are necessary to develop the equations for the deflections. Once these relations are established, stresses are obtained by "model analysis."

APPENDIX II

ANALYTICAL DERIVATION OF EQUATIONS

Fig. 12 shows a simply supported beam subjected to a typical deformation, which forms a simple influence line. It can be easily shown, by the usual methods,

that: $\alpha_A = \frac{M_A}{3\ E\ k} + \frac{M_B}{6\ E\ k}$; and, $\alpha_B = \frac{M_A}{6\ E\ k} + \frac{M_B}{3\ E\ k}$; whence, $\theta_A = \frac{M_A}{3\ E\ k} + \frac{M_B}{6\ E\ k} - R$; and, $\theta_B = \frac{M_A}{6\ E\ k} + \frac{M_B}{3\ E\ k} + R$. Solving for M_A and M_B:

$$M_A = 2\ E\ k\ (2\ \theta_A - \theta_B + 3\ R) \quad \text{.................}(30a)$$

and,

$$M_B = 2\ E\ k\ (-\ \theta_A + 2\ \theta_B - 3\ R) \quad \text{...............}(30b)$$

Equations (30) are for the fundamental deformed beam used in the development of the "slope deflection method" and will be found in any standard text on statically indeterminate structures. The system of signs used herein, however, is different from that generally used in these texts.

FIG. 13.

Fig. 13(*a*) shows a typical member, *AB*, with all the members joining the beam at Point *B* removed from the remainder of the structure. If the End *A* is rotated through an angle, θ_{AB}, this part of the structure will deform as shown. The relation between θ_{AB} and θ_{BA} will now be found (side-sway being prevented so that $\theta = \alpha$) from Equations (30) and Fig. 14 as follows:

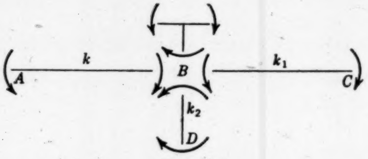

FIG. 14.

$$M_{BA} = E\,(4\,k\,\theta_{BA} - 2\,k\,\theta_{AB}) \,..(31a)$$

$$M_{BC} = E\,(4\,k_1\,\theta_{BC} - 2\,k_1\,\theta_{CB}) \,..(31b)$$

and,

$$M_{BD} = E\,(4\,k_2\,\theta_{BD} - 2\,k_2\,\theta_{DB}) \,..(31c)$$

Since $M = 0$ about any joint:

$$M_{BA} = M_{BC} + M_{BD} \quad \ldots\ldots\ldots\ldots\ldots\ldots (31d)$$

Since the rotation at a joint is the same at the ends of all members meeting at the joint:

$$\theta_{BC} = \theta_{BD} = -\,\theta_{BA} \quad \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

and,

$$(k + k_1 + k_2)\,\theta_{BA} + 0.5k_1\,\theta_{CB} + 0.5k_2\,\theta_{DB} = 0.5k\,\theta_{AB} \quad \ldots\ldots (33)$$

By definition, since $\theta = \alpha$ for this case, $\dfrac{\theta_{BA}}{\theta_{AB}} = m$; $\dfrac{\theta_{CB}}{\theta_{BC}} = \dfrac{\theta_{CB}}{\theta_{BA}} = m_1$; and, $\dfrac{\theta_{DB}}{\theta_{BD}} = \dfrac{\theta_{DB}}{\theta_{BC}} = m_2$. . Consequently, it follows that:

$$m = \frac{\theta_{BA}}{\theta_{AB}} = \frac{0.5\,k}{k + \left(1 - \dfrac{m_1}{2}\right)k_1 + \left(1 - \dfrac{m_2}{2}\right)k_2} \quad \ldots\ldots (34a)$$

By definition, $S_1 = \left(1 - \dfrac{m_1}{2}\right)k_1$ (see Equation (3a)); $S_1 = \left(1 - \dfrac{m_2}{2}\right)k_2$ (see Equation (3b)); and $S_B = S_1 + S_2 + \ldots +$, etc. Therefore:

$$m = \frac{\theta_{BA}}{\theta_{AB}} = \frac{0.5\ k}{k + S_B} \quad \ldots\ldots\ldots\ldots\ldots\ldots (34b)$$

Similarly, when AB is removed, with all members joining Beam AB at End A, (Fig. 13(b)), and when Joint B is rotated through an angle, θ_{BA}:

$$m' = \frac{\theta_{AB}}{\theta_{BA}} = \frac{0.5\ k}{k + S_A} \quad \ldots\ldots\ldots\ldots\ldots\ldots (34c)$$

From Fig. (15):

$$E\,I\,\frac{d^2y}{dx^2} = M_A - \frac{M_A - M_B}{L}\,x \quad \ldots\ldots\ldots\ldots\ldots (35)$$

Integrating twice and remembering that $y = 0$ when $x = 0$ and $x = L$, and substituting the values of M_A and M_B from Equations (30):

$$y = \frac{x\,x'}{L^3}\,(x\,f + x'\,f') \qquad \text{.......................(36)}$$

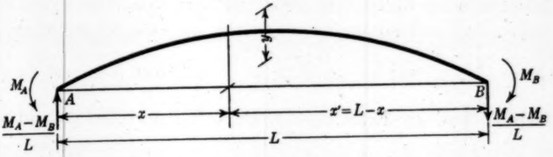

FIG. 15

Equation (36) is the formula of the elastic curve in terms of the end rotations.

Fig. 16 shows two beams, AB and BC, joined at Point B and rotated with respect to each other through an angle of 1, to produce the influence line, M_B. In this case, $\theta_{BA} + \theta_{BC} = \theta = 1$; and, $M_{BA} = M_{BC}$.

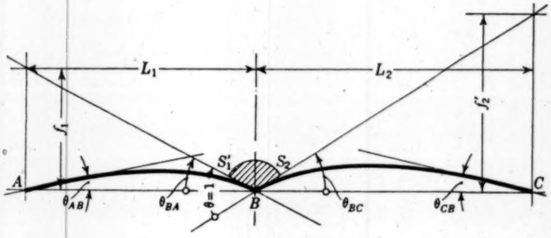

FIG. 16

Writing the values for $M_{BA} + M_{BC}$ from Equations (30), and equating the resulting expressions:

$$k_1\,(2\,\theta_{BA} - \theta_{AB}) = k_2\,(2\,\theta_{BC} - \theta_{CB})$$

or,

$$k_1\left(1 - \frac{\theta_{AB}}{2\,\theta_{BA}}\right)\theta_{BA} = k_2\left(1 - \frac{\theta_{CB}}{\theta_{BC}}\right)\theta_{BC}$$

Since $\frac{\theta_{AB}}{\theta_{BA}} = m'_1$; $\frac{\theta_{CB}}{\theta_{BC}} = m_2$; $\left(1 - \frac{m'_1}{2}\right) k_1 = S'_1$; and $\left(1 - \frac{m_2}{2}\right) k_2 = S_2$:

$$S'_1\,\theta_{BA} = S_2\,\theta_{BC}$$

Since $\theta_{BA} + \theta_{BC} = \theta = 1$:

$$\theta_{BA} = \frac{S_2}{S'_1 + S_2} = \frac{S_2}{K_B} \qquad \text{....................(37a)}$$

and,

$$\theta_{BC} = \frac{S'_1}{K_B} \quad \text{.......................... (37b)}$$

The following equations for side-sway are derived in a manner similar to that used for obtaining Equations (34). Referring to Fig. 3(*b*), using Equations (30) once more and remembering that $R = 0$ for all members except AB, for which $R = \frac{\Delta}{L}$, it follows from $\Sigma M = 0$ about Joint B (repeating the operations which lead to Equations (32), (33), and (34*a*) and (34*b*), that the last equations take the following forms when $R = \frac{\Delta}{L}$ instead of zero:

$$(k + S_B)\,\theta_{BA} - 0.5\,k\,\theta_{AB} = 1.5\,k\,R \quad \text{............. (38a)}$$

and,

$$0.5\,k\,\theta_{BA} - (k + S_A)\,\theta_{AB} = 1.5\,k\,R \quad \text{............. (38b)}$$

Solving these two equations simultaneously for θ_{BA}:

$$\theta_{BA} = 1.5\,k\,R\,\frac{0.5\,k + S_A}{(k + S_A)\,(k + S_B) - 0.25\,k^2} \quad \text{.......... (39)}$$

Subtracting R from both sides of the equation and then dividing by R, simplifying and re-arranging:

$$\frac{(\theta_{BA} - R)\,L}{R\,L} = \frac{\dfrac{0.5\,k}{k + S_B}\,S_A}{k + S_A - 0.5\,k\left(\dfrac{0.5\,k}{k + S_B}\right)} - \frac{S_B}{k + S_B - 0.5\,k\left(\dfrac{0.5\,k}{k + S_A}\right)} \quad \text{. (40)}$$

and,

$$\frac{f}{\Delta} = \frac{m\,S_A}{S_A + k - 0.5\,m\,k} - \frac{S_B}{S_B + k - 0.5\,m'\,k} = \frac{m\,S_A}{S_A + S} - \frac{S_B}{S_B + S'}$$

$$= -\frac{S_B}{K_B} + \frac{m\,S_A}{K_A} \quad \text{.................... (41a)}$$

Similarly,

$$\frac{f'}{\Delta} = \frac{S_A}{K_A} - \frac{m'\,S_B}{K_B} \quad \text{..................... (41b)}$$

The force, P_A, necessary to displace Point A in Figs. 3 and 4 is easily derived. Referring to Fig. 12, $P_A = \frac{(M_A - M_B)}{L}$. Substituting the values of M_A and M_B from Equations (30):

$$P_A = \frac{6\,E\,k}{L}\,(\theta_A - \theta_B + 2\,R) = \frac{6\,E\,k}{L}\,[(\theta_A + R) - (\theta_B - R)]$$

$$= \frac{6\,E\,k}{L}\,(\alpha_A - \alpha_B) \quad \text{...................... (42)}$$

and,

$$\frac{P}{E} = \frac{6\,k}{L^2}\,(-f + f') \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

Equation (43) can also be used to obtain the correction for side-sway.

INFLUENCE LINES FOR BENDING MOMENTS

Fig. 17 shows a typical member, AB, broken at Point G and rotated through an angle, θ, by means of the gage. The forces acting at Point G must be the moment, M, and a shear, V, shown in Fig. 18.

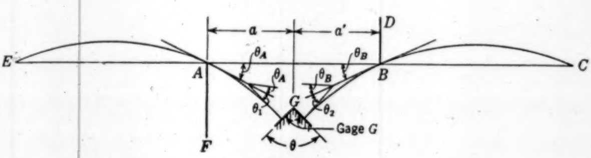

FIG. 17

From Fig. 17, the angle of the gage is:

$$\theta_A + \theta_1 + \theta_B + \theta_2 = \theta \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

Furthermore, the deflection normal to AB at Point G, must be the same for both broken members, AG and BG.

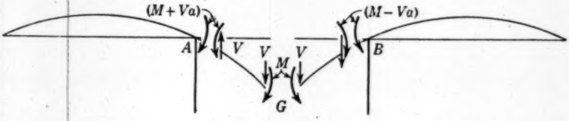

FIG. 18

Using Equations (30), once more and writing $M + V\,a$ for M_A, and $M - V\,a'$ for M_B, the resulting equations can be easily transformed to the following form:

$$M + V\,a = 4\,E\,S_A\,\theta_A \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (45a)$$

and,

$$M - V\,a' = 4\,E\,S_B\,\theta_B \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (45b)$$

or,

$$\frac{M\,L}{E} = 4\,(a'\,S_A\,\theta_A + a\,S_B\,\theta_B) \quad \ldots\ldots\ldots\ldots\ldots\ldots (46a)$$

and,

$$\frac{V\,L}{E} = 4\,(S_A\,\theta_A - S_B\,\theta_B) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (46b)$$

The equations for the angular and linear deflections at Point G, are:

$$\theta_A + \frac{M\,a}{E\,I} + \frac{V\,a^2}{2\,E\,I} + \theta_B + \frac{M\,a'}{E\,I} - \frac{V\,(a')^2}{2\,E\,I} = \theta \;\ldots\ldots\ldots (47)$$

and,

$$a\,\theta_A + \frac{M\,(a')^2}{2\,E\,I} + \frac{V\,a^3}{3\,E\,I} = a'\,\theta_B + \frac{M\,(a')^2}{2\,E\,I} - \frac{V\,(a')^3}{3\,E\,I} \;\ldots\ldots\ldots (48)$$

Substituting Equation (46) in Equations (47) and (48):

$$(k + 2\,S_A)\,\theta_A + (k + 2\,S_B)\,\theta_B = k\,\theta \;\ldots\ldots\ldots\ldots\ldots (49)$$

and,

$$3\,k\,a'\,\theta_A + 2\,(2\,a - a')\,S_A\,\theta_A = 3\,k\,a'\,\theta_B - 2\,(a - 2\,a')\,S_B\,\theta_B \;\ldots (50)$$

Solving Equations (49) and (50) for θ_A and θ_B, and remembering that $a' + a = L$; $L\,\theta_B = f$; $L\,\theta_A = f'$; $S = \dfrac{0.75\,k + S_A}{k + S_A}$; $K_A = S + S_A$; etc., the resulting equations can be put into the form given in Equations (16*a*) and (16*b*).

DISCUSSION

L. J. Mensch,[5] M. Am. Soc. C. E. (by letter).—The many papers on rigid-frame analysis that have been published by the Society have evidently intrigued the author, an engineer of exceptional ability in the art of the design of hyperstatic structures and of extended experience, to contribute his share to the excitement, or "talk-fest", on the subject of rigid-frame analysis.

The honor of having first simplified the analysis of continuous structures belongs to Clapeyron[6]. For the development of his famous formulas, Clapeyron used a method which in the United States has lately been called the "slope-deflection theory." These "slope-deflection formulas", are in common use for all kinds of problems in the well known textbook of Dr. F. Grashof[7], and in many textbooks issued before and afterward.

Professor Grashof treats[8] the problem of a girder, $A B$, partly fixed at the supports by the moments, M_A and M_B, having the slopes, α and β, of the elastic line at A and B, and affected by an uniform load, W, and a concentrated load, P, distant a and b from the ends, A and B, and gives the following formulas:

For moment:

$$M_A = -\frac{P a b^2}{L^2} - \frac{W L}{12} + \frac{2 E I}{L} (2 \alpha - \beta) \quad \ldots\ldots\ldots\ldots (51a)$$

and,

$$M_B = -\frac{P a^2 b}{L^2} - \frac{W L}{12} + \frac{2 E I}{L} (- \alpha + 2 \beta) \quad \ldots\ldots\ldots (51b)$$

and, for shear:

$$V_A = \frac{P (3 a + b)}{L^3} b^2 + \frac{W}{2} + \frac{6 E I}{L} (- \alpha + \beta) \quad \ldots\ldots\ldots (52a)$$

and,

$$V_B = \frac{P (3 b + a)}{L^3} a^2 + \frac{W}{2} + \frac{6 E I}{L} (\alpha - \beta) \quad \ldots\ldots\ldots\ldots (52b)$$

He shows[9] that α and β must be replaced by $\theta_A - R$ and $R - \theta_B$, when Point A is lifted a distance, $R L$, over Point B during the deformation of the girder. He also shows[10] that, when $M_B = 0$, Equation (51b) becomes:

$$E I \beta = \frac{P a^2 b}{4 L} + \frac{W L^2}{48} + \frac{E I \alpha}{2} \quad \ldots\ldots\ldots\ldots\ldots (53a)$$

---

[5] Civ. Engr. and Constructor, Chicago, Ill.

[6] *Comptes Rendus*, Vol. 45, Paris, 1857.

[7] "Theorie der Elasticität und Festigkeit," Second Edition, Berlin, 1878.

[8] *Loc. cit.*, p. 78.

[9] *Loc. cit.*, p. 101.

[10] *Loc. cit.* p. 83.

and, from Equation (51*a*):

$$E\,I\,\alpha = M_A + \frac{P\,a\,b\,(b + 0.5\,a)}{3\,L^2} + \frac{W\,L^2}{24} \quad\text{..........(53}b\text{)}$$

When both M_A and M_B are zero, Equations (51) yield the well known formulas:

$$E\,I\,\alpha = \frac{P\,a\,b\,(a + 2\,b)}{6\,L} + \frac{W\,L^2}{24} \quad\text{................(54}a\text{)}$$

and,

$$E\,I\,\beta = \frac{P\,a\,b\,(b + 2\,a)}{6\,L} + \frac{W\,L^2}{24} \quad\text{................(54}b\text{)}$$

Girders of varying section are also treated in this textbook.

In addition to Grashof, there is at least one other old elementary textbook, that of Wilhelm Keck[11], in which may be found all the slope-deflection formulas in use for the solution of continuous structures. The first textbook which the writer can now remember to have treated rigid-frame, multiple-storied structures is that of Professor E. Winkler[12] in which the "slope-deflection" formulas were freely used.

After this revelation of the status of the "slope deflection theory", it is to be hoped that enthusiasts will not further clutter up American literature with the incorrect statement that the "slope deflection theory" is an American development, improvement, or invention, except in so far as the coinage of the phrase, "slope deflection," is concerned.

How did it come about that these important and simple earlier methods have been nearly forgotten by American and European engineers? It seems to the writer that teachers on any subject, in order to acquire at least a quasi-reputation, must produce something new, even if it is not better than the old art, and their students spread the new "light", and, presto, a new philosophy is in fashion. So it was with Mohr's principle of virtual velocities which was soon put out of fashion by Manebrea's and Castigliano's principle of least work (originally invented by Daniel Bernouilli in the Eighteenth Century) which principle found an enthusiastic and able propagandist in Professor Müller-Breslau and, through him, came to be used all over the world. Not so many years passed, however, before it was discovered that this intriguing method was practical only for comparatively simple problems, and could not be used by busy men for highly hyperstatic structures, and the pendulum (but not the habit, so easily) swung backward again and various types of "slope deflection" methods were re-invented.

One of these is the principle of fixed or conjugate points, so well treated by W. Ritter[13] and greatly elaborated for framed continuous structures, consisting of straight and arched members, by A. Strassner[14]. The author's paper is nothing but a variation from Strassner's treatment of this subject. Strassner uses the angles, whereas the author uses the intercepts of the tangents on the verticals at the opposite support, an unnecessary complication. The author has treated only the simplest cases in Strassner's work and has not made the slightest improvement in the formulas or in their derivation. Like Clapeyron, Ritter, and Strassner, he proposes to analyze a structure by beginning at one end and going over its entire length in order to determine the relative angle changes that are necessary for the computation of the unknown bending moments. This is clearly too large and entirely too impractical a task for the large structures that American engineers must design so often, and further simplifications are absolutely necessary so that engineers may be able to arrive at more precise results with comparatively little effort. Strassner gives a hint in one of his examples of an attempt at simplification, but does not go far enough as he has still to go through the entire structure in order to solve that part of it which may require more precise treatment.

[12] "Vorträge über Brückenbau," Wien, C. Gerold, 1875.

[13] "Graphische Statik," Zurich, 1900.

[14] "Neuere Methoden", Berlin, 1916.

How to solve any girder or column in a large structure quickly and with sufficient accuracy, the writer has shown elsewhere[15]. He obtained a sufficiently close estimate of the values of α and β in Equations (51) by setting,

$$\alpha = \frac{-M_A}{\Sigma m_A E K_A} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (55a)$$

and,

$$\beta = \frac{-M_B}{\Sigma m_B E K_B} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (55b)$$

in which m_A and m_B are certain factors (given in that discussion) and K_A equals the ratio of $\frac{I}{L}$ for each member adjoining A, except $A\,B$.

The solution of Equation (51) after the values of α and β from Equations (55) are introduced in them, gives the two simple formulas for a girder with an uniform load, W:

$$M_A = -\frac{W\,L}{4}\,\frac{1 + 2\,N_B}{4\,(1 + N_A)\,(1 + N_B) - 1} \quad \ldots\ldots\ldots\ldots (56a)$$

and,

$$M_B = -\frac{W\,L}{4}\,\frac{1 + 2\,N_A}{4\,(1 + N_A)\,(1 + N_B) - 1} \quad \ldots\ldots\ldots\ldots (56b)$$

in which,

$$N_A = \frac{3\,K}{\Sigma\,m_A\,K_A} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57a)$$

and,

$$N_B = \frac{3\,K}{\Sigma\,m_B\,K_B} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57b)$$

---

[15] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 1050.

The author's treatment of linear displacement is not as simple as that of Strassner and contains the same limitation in the sense that it is strictly applicable only to one-story structures, or to frames which remain vertical in the stories above and below the story which has been displaced, a case that never occurred in the writer's experience. The actual problem is to find the restraint at *A* and *B* when the entire structure is deformed as a girder due to the horizontal load acting at *A*, which is really a difficult problem; possibly, the author may be able to reveal some simplifying suggestions by experimentation. The problem of side-sway in a non-symmetrical single-story bent of two columns can be more easily solved by Strassner's method, which is really only a variation of Clapeyron's method.

The writer has heard engineers state that a method of analyzing highly hyperstatic structures which gives the unknown bending moments within 5% to 10% of their ideal values is necessary. No method, however laborious, known to-day can give such a close result. First, girders and columns have dimensions of from 6% to 20% and more of the spans and story heights, and not enough tests have been made to establish how near the designer guesses when he uses clear spans instead of theoretical spans. Although Strassner shows how to consider the shortening of columns by girders, he uses theoretical spans in his examples.

Another serious disturbance is the variation of the modulus of elasticity, *E*, under high or long-continued loadings. After all, the final intent of these analyses should be the establishment of the factor of safety of designs against failure or undue deformations. All formulas are derived by the assumption of a constant value of *E*.

Under intense loadings the modulus of elasticity of the highly stressed part of the member decreases rapidly, and if it is the end part of a restrained beam, for example, this diminution of *E* will have the effect of decreasing restraint and will modify the moments both in the center of the span and at the ends. The center moment will be increased and the end moments decreased. No clear-cut tests have been made to estimate readily, the decrease of restraint. A very able treatment of this phase of the subject has been offered[16] by E. Mirabelli, M. Am. Soc. C. E.

That much has yet to be learned about the deviation of Hooke's law in such a standard material as structural steel is made evident by tests reported by the National Bureau of Standards[17]. A unit load of 31 000 lb per sq in. was imposed on two heavy stiff columns, 159 sq in. in cross-section and 24 ft long. The shortening was found to be 0.0016 in. per in.; and, therefore, the secant modulus of elasticity was only $\frac{31\,000}{0.0016} = 19\,000\,000$ lb per sq in. The moduli of elasticity decreased when stresses increased beyond 24 000 lb per sq in. It would have been of great importance to know what they would have been had the load remained for a month or a year.

[16] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 1397.

[17] *Journal of Research*, National Bureau of Standards, *Research Paper 873*, March, 1936.

That the deviation of E in reinforced concrete members plays an important rôle was shown by the tests to destruction of Mikishe Abe, M. Am. Soc. C. E.[18], on rigid-framed structures. The ultimate strengths were at least 10% larger than those computed by current analysis when clear spans were used. For this reason highly complicated formulas or processes which require long study will be of limited value in this field.

FREDERICK SHAPIRO,[19] JUN. AM. SOC. C. E. (by letter).—The method of analysis presented in this paper is an excellent variation of the moment-distribution principle. The underlying theory is the same as that of moment distribution, although the problem is viewed from a different angle. When one part of a frame is rotated and the effects of this motion are traced by multiplying the original rotation by factors the values of which depend upon the rotation resistance of the constituents of the frame, the method of moment distribution is being used, even if angular changes instead of bending moments are involved.

The formulas of the paper may readily be converted into more useful ones. Following the notation of the paper,

$$C = \frac{1 - 2\,m}{2 - m} \qquad \text{.........................(58)}$$

and instead of giving the ratio of the angular rotations of the ends of unloaded spans, Equation (58) gives the ratio of the end moments, in which C is the transmission coefficient introduced by R. C. Brumfield, M. Am. Soc. C. E., who developed an analysis of statically indeterminate structures based upon it.[20] It is a very useful value for computing end moments, even for loaded spans, and may be found from the formula:

$$C = \frac{Q}{2\,Q + F_r} \qquad \text{.........................(59)}$$

in which $Q = \frac{1}{k} = \frac{L}{I}$, and F_r is a term called a restraint factor, and is equal to $\frac{1.5}{K_B}$. It is given by,

$$F_r = \frac{1}{\frac{1}{Q_1\,(2 - C_1)} + \frac{1}{Q_2\,(2 - C_2)} + \frac{1}{Q_3\,(2 - C_3)} + \ldots\ldots} \qquad \text{....(60)}$$

A term of the form, $Q\ (2 - C)$, is called a stiffness index. Obviously, each end of a beam has its own transmission coefficient, restraint factor, and stiffness index $\left(= \frac{2}{3\ S_1} \text{ or } \frac{2}{3\,S'_1}\right)$. The stiffness indices found in the denominator of Equation (60) are those for the ends of all the beams meeting at a joint, except that of the beam end for which the restraint factor is to be found.

[18] *Bulletin 107*, Eng. Experiment Station, Univ. of Illinois, 1918.

[19] Draftsman, Gibbs & Hill, Inc., New York, N. Y.

[20] "The Analysis of Monolithic Structures by Transmission Coefficients", by Frederick Shapiro, *Concrete*, May, June, July, and August, 1936; see, also, "Moving Loads on Beams with Restrained Ends", by R. C. Brumfield, M. Am. Soc. C. E. (Complete manuscript filed for reference in Engineering Societies Library, 33 West 39th Street, New York, N. Y.)

The transmission coefficient varies from zero for pin-ended beams to one-half for fixed-end beams of constant moment of inertia. In the interior of interlocking frames it may be approximated by the following method: Compute the ratio of the sum of the $\frac{I}{L}$-values for the other members at the joint to twice the sum of the $\frac{I}{L}$-values of all the members at the joint. If this value is between zero and 0.35, add 0.02; if it is between 0.36 and 0.43, add 0.01; and if it is greater than 0.43, add nothing to obtain the coefficient with less than 1% error. This value may be corrected later.

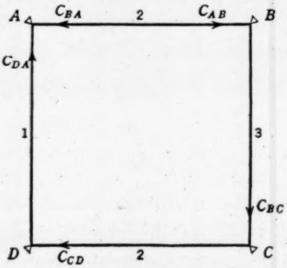

FIG. 19

For example, C_{AB}, in Fig. 19, will be computed. The large numbers on the spans are Q-values or $\frac{L}{I}$-values. Approximately, C_{AB}

$$= \frac{K_{BC}}{2\,(K_{AB} + K_{BC})} + (?) = \frac{\frac{1}{3}}{\left(\frac{1}{2} + \frac{1}{3}\right)}$$

$+ (?) = 0.20 + 0.02 = 0.22$. Using Equation (59) $C_{DA} = \dfrac{Q_{DA}}{2\,Q_{DA} + Q_{AB}\,(2 - C_{AB})} = \dfrac{1}{2 \times 1 + 2\,(2 - 0.22)} = 0.180$; C_{CD}

$$= \frac{2}{2 \times 2 + 1\,(2 - 0.180)} = 0.343; \; C_{BC} = \frac{3}{2 \times 3 + 2\,(2 - 0.343)} = 0.322;$$

and, finally, $C_{AB} = \dfrac{2}{2 \times 2 + 3\,(2 - 0.322)} = 0.222$, which is correct to three decimal places. The change in C_{DA} would be indistinguishable on a slide-rule.

If a bending moment of 1 000 ft-lb were introduced at Point A, it would flow around the frame, becoming 1 000 C_{AB} at Point B, or 222 ft-lb; $222 \times 0.322 = 71$ ft-lb at Point C; $71 \times 0.343 = 24$ ft-lb at Point D; and, $24 \times 0.180 = 4$ ft-lb at Point A, and would continue around the frame again in the same manner.

In computing end moments for loaded spans, the transmission coefficients receive their greatest use. Formulas have been derived for end moments[20] and these involve only constants dependent upon the type of loading, the position of the load on the span, and the transmission coefficients for the span.

The writer and Professor Brumfield have developed charts to give transmission coefficients, restraint factors, and torque splits and moment splits at joints. They have arranged tables to reduce computations to a minimum and to simplify the work. Professor Brumfield has derived formulas for locating loads to produce maximum moment at any given point in a span or under any given load. He has also modified his formulas for use with clear spans and generalized them to include beams of variable moment of inertia, providing the neutral axis may be considered to be a straight line.

The writer has deduced mechanical methods for the determination of transmission coefficients, comparable to those for finding the carry-over factors in the method of distributing fixed-end moments by successive approximations. It might be noted here that the transmission coefficients, summing up by formula the converging series of the Cross method,[21] do in one step what the fixed-end method does by successive approximation. Many short-cuts have been found that may be applied without restricting the generality of Professor Brumfield's formulas. A method of checking computations for continuity, besides the obvious check at each joint for $\Sigma M = 0$, has also been developed[22] by the writer.

The usefulness of direct moment distribution cannot be denied. Although Dr. Gottschalk has presented a method in which the underlying theory is based on a simple conception, its practical application is very limited compared to the system of analysis evolved by Professor Brumfield.

JAMES R. GRIFFITH,[23] M. AM. SOC. C. E. (by letter).—A valuable contribution to the subject of unloaded models is contained in this paper. The principles involved in the determination of influence lines by unit displacements of a model have been somewhat difficult for some engineers to accept. This is particularly true of the influence lines for moment. The mathematical proof in Appendices I and II alone is worthy of consideration. As a mathematical means of computing the numerical value of moment, shear, or thrust at any section of a structure independent of values obtained at any other section, the method is of additional note. When the loads are few and stationary, such a mathematical solution might be more economical in some cases than a solution by model.

In the design of the catenary structures for the terminal electrification of the Illinois Central System, at Chicago, Ill., the writer was one of the first users of the unloaded model. Since that time he has never lost his enthusiasm for the method. As a means of helping students to visualize the action of an indeterminate structure, the method is far superior to any other known to the writer. It has had one serious objection, however, in that the cost of commercial sets for utilizing such models has been prohibitive for the average individual and the smaller offices. The writer has long experimented with various materials and equipment, with cost and availability as the principal objectives.

Anders Bull, M. Am. Soc. C. E., made a real contribution when he described the use of both loaded and unloaded models fabricated of "brass drill rod."[24] The writer has been unable as yet to locate any local supply of this material. Bronze welding rod, of the various materials tried, has thus far best fulfilled the qualifications. It is available in almost every shop equipped to do gas-welding, and the cost is scarcely worth mentioning. Scraps of tin, push pins, and a welding iron are the only other equipment needed.

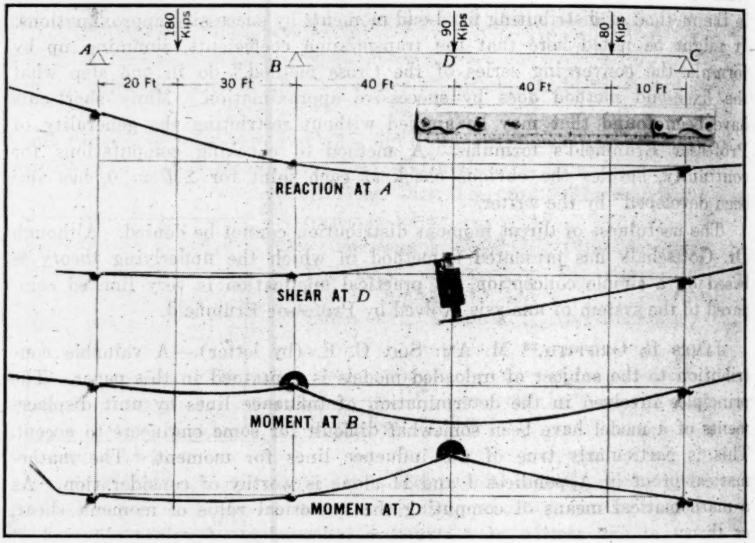

FIG. 20

Fig. 20 shows a series of influence lines constructed by welding wire for the beam of constant section shown. The shear clamp is the development suggested by Ray de Lancey, Jun. Am. Soc. C. E. It is adjustable within a reasonable range of accuracy and is fabricated entirely of tin. The necessary rotation for moment at interior sections is obtained by a tin clamp as shown, which, as in the case of the sheer clamp, can be removed quickly from the wire. Since it was found impossible to fabricate the moment clamps to a predetermined angle within the required accuracy, it was necessary to calibrate them after fabrication.

Theoretically, as the author indicates, the deformation of a model must be very small to avoid error. Practically, even with relatively large deformations, the writer feels that results are obtained well within the limits warranted by the present knowledge of reactions, elastic properties of the finished structure, and rigidity of connections.

CAMILLO WEISS,[25] M. AM. SOC. C. E. (by letter).—Apart from its usefulness, this is an extremely interesting and stimulating paper. By virtue of Appendices I and II, this method may be considered as an ingenious combination of Maxwell's theorem with the slope deflection theory, and it may be permissible to compare it with the latter. Such a comparison is also helpful in appraising the merits of the proposed method and to show under what circumstances it is particularly useful.

---

[24] *Engineering News-Record*, December 8, 1927, p. 920.

[25] Structural Engr., Fabricated Steel Constr., Eng. Dept., Bethlehem Steel Co., Bethlehem, Pa.

The author was wise in selecting simple problems to illustrate his method; but because he did so he has not really done his method full justice. Furthermore, the method has certain drawbacks which are not apparent in simple problems.

In Conclusion (3) the author states: "The stress at any section may be computed independently without knowing the moment, shear, etc., at any other section." This is indeed a great advantage. On the other hand, the word, "may", in this Conclusion could be written "must"; and this fact may be a disadvantage at times.

In general, the proposed method will prove most valuable when the loads are movable; when stresses are wanted at only a few points; and when the number of loaded members is comparatively small. For example, in Fig. 21(*a*) all joints are assumed to be free to rotate but are fixed against translation. Suppose that only the moment, M_{AB}, at End *A* of Member *AB*, is desired. To obtain the answer by the slope deflection method, twelve unknown slopes and forty-two unknown moments must

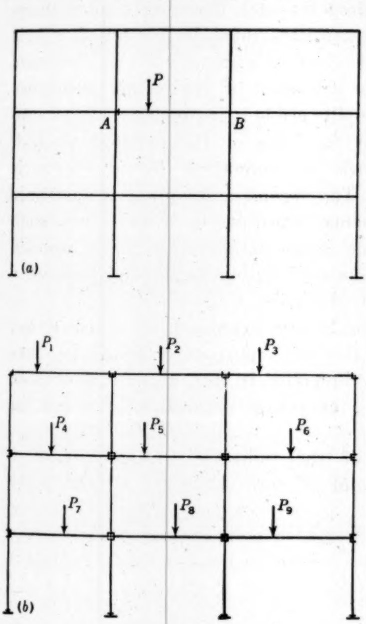

FIG. 21.

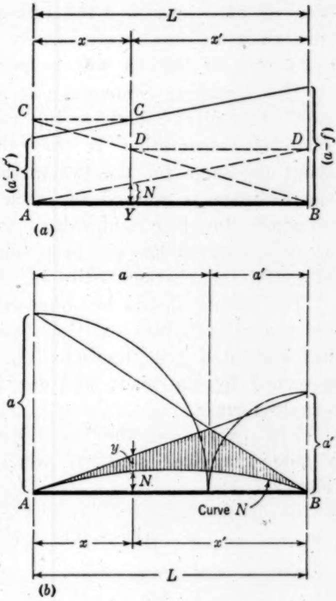

FIG. 22.

be introduced and twelve simultaneous equations must be solved. To obtain the answer by the proposed method, two unknown tangential intercepts and the ordinate of one influence line are the only variables. These three unknown quantities are obtainable from three equations, two of them independent of each other. If Load P is moving along Member $A\,B$, one new ordinate of the influence line is all that is required for each position.

The slope deflection method would necessitate solving a set of twelve simultaneous equations for each position of the load. Therefore, this problem is obviously one for which the proposed method may well be considered superior.

Fig. 21(b) represents the same frame, except that in this case every panel is loaded and the moments at the end of every member (forty-two moments in all) are wanted. To obtain the answer by the slope deflection method again involves fifty-four unknowns and requires the solution of twelve simultaneous equations. To obtain the answer by the proposed method eighteen tangential intercepts and nine ordinates of influence lines (twenty-seven variables), are required for each moment; a total, therefore, of 27 × 42 = 1 134 unknown quantities must be computed. It is true, these unknowns are largely independent of each other. In this case, the choice of method will be primarily a matter of individual preference.

The foregoing comparison is admittedly crude. It implies at least two tacit assumptions, both erring probably in favor of the proposed method. The first assumption is that the work of computing the constants is about the same for the two methods. The second assumption is that only one ordinate is wanted for each influence line; or, in other words, each influence line is considered as only one unknown quantity. The example herein presented has not been selected as typical, but is presented in order to reveal the characteristics of the two methods.

The author should be commended for having expressed, in simple terms, the mutual relations existing between the coefficients of stiffness; for having separated the functions that are inherent in the frame from those governed by the load; and for having expressed these functions, too, in simple form.

The expression for the ordinate of the influence line admits of a simple graphical solution when f and f' are known. Referring to Fig. 22(a):

$$\overline{AC'} = \overline{YC} = (a - f)\,\frac{x}{L} + (a' - f')\,\frac{x'}{L} \quad \text{..........} \quad (61a)$$

$$\overline{BD'} = \overline{YD} = \overline{AC'}\,\frac{x'}{L} \quad \text{..................} \quad (61b)$$

and,

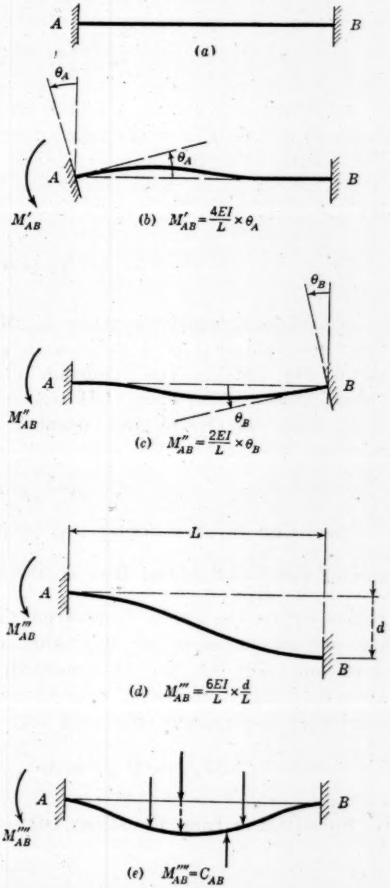
$$N = \overline{BD'}\,\frac{x}{L} \quad \text{........................} \quad (61c)$$

Substituting Equations 61(a) and 61(b) in Equation 61(c), the result is expressed by the author as Equation (18). To construct any point on the curve of this formula, lay off $(a - f)$ above End B, Fig. 22(a), and $(a' - f')$ above End A. The closing line intersects the vertical, Y, at Point C. Projecting Point C horizontally to Point C', Line $C'B$ intersects the vertical through Point Y at Point D. Projecting D to D', Line $D'A$ intercepts the required ordinate, N, on the vertical, Y. Proof of the construction can be obtained from the similarity of triangles. In this manner, Curve N of Fig. 22(b) can be constructed. The remainder of the construction of the influence line in Fig. 22(b) is self-explanatory.

Similar construction will furnish the ordinates of the elastic curve, Equation (5), if the intercept f, is substituted for $(a - f)$ and f' for $(a' - f')$ in Fig. 22(a) and if proper consideration is given to the signs of f and f'.

Appendix II.—Referring to Appendix II, Equations (30) are stated to be the formulas used in the slope deflection method, but "the system of signs is different from that generally used." The signs are not in agreement with the "Notation", nor is it stated, what convention has been adopted. The enlightening derivation of the fundamental formulas, as presented in Appendix II, is an essential part of the paper and the absence of a sign convention may be somewhat confusing. Perhaps the following comments will be of service.

Assume that all slopes, deflections, and moments are absolute numerical quantities. As in arithmetic, a plus sign means "add" and a minus sign means "subtract." Fig. 23(a) represents a restrained but unloaded member, AB. Suppose, it is desired to produce a contra-clockwise restraining moment, M_{AB}, at End A. Apart from temperature stresses, this can be done in any of four (and only four)



(b) $M'_{AB} = \frac{4EI}{L} \times \theta_A$

(c) $M''_{AB} = \frac{2EI}{L} \times \theta_B$

(d) $M'''_{AB} = \frac{6EI}{L} \times \frac{d}{L}$

(e) $M''''_{AB} = C_{AB}$

FIG. 23.

different ways illustrated in Figs. 23(*b*), 23(*c*), 23(*d*), and 23(*e*), and in any combination of these four ways.

A contra-clockwise restraining moment at A can be obtained by:

(*a*) Rotating End A counter-clockwise through an angle, θ_A, as in Fig. 23(*b*). Quantitatively, this moment is:

$$M'_{AB} = \frac{4\,E\,I\,\theta_A}{L} \quad \text{.....................(62a)}$$

(*b*) Rotating End B counter-clockwise through an angle, θ_B, as in Fig. 23(*c*). Quantitatively, this moment is:

$$M''_{AB} = \frac{2\,E\,I\,\theta_B}{L} \quad \text{.....................(62b)}$$

(*c*) Displacing Points A and B with respect to each other so that Point B seems to move in a clockwise direction around Point A. Referring to Fig. 23(*d*), it is immaterial whether Point B was moved down or Point A was moved up, or both points were moved. Quantitatively, this moment is:

$$M'''_{AB} = 6\,E\,\frac{I}{L}\,\frac{d}{L} \quad \text{.....................(62c)}$$

(*d*) Placing transverse loads on Member $A\,B$, so that the moment of their resultant will tend to turn in a clockwise direction about Point A, as in Fig. 23(*e*). The condition illustrated in Fig. 23(*e*) is termed a "beam fixed at both ends." If C_{AB} is the end moment at A for the given load, then the restraining moment is numerically equal to this end moment, or,

$$M''''_{AB} = C_{AB} \quad \text{.....................(62d)}$$

Equations (62*a*) to (62*c*) can be derived from two well-known properties of the $\dfrac{M}{EI}$ -diagram; that is, the principles that the area between two points equals the angle, θ, between the tangents at these points and that the statical moment of this area equals the corresponding tangential deviation. By the law of superposition these four methods of creating a contra-clockwise resisting moment at A are additive, therefore, if all four conditions are present, the total is:

$$M_{AB} = M'_{AB} + M''_{AB} + M'''_{AB} + M''''_{AB} \quad \text{...........(63)}$$

Substituting from Equations (62) and writing K for $\dfrac{I}{L}$ and R for $\dfrac{d}{L}$:

$$M_{AB} = 2\,E\,K\,(2\,\theta_A + \theta_B + 3\,R) + C_{AB} \quad \text{............(64)}$$

Obviously, if any of the four methods of inducing a contra-clockwise restraining moment at A acts in a direction opposite to the direction shown in Figs. 23(b) to 23(e), the corresponding moment must be subtracted instead of being added. For instance, if End B is rotated clockwise, instead of contra-clockwise, and if there are no transverse loads:

$$M_{AB} = 2\,E\,K\,(2\,\theta_A - \theta_B + 3\,R) \qquad (65)$$

Equation (65) corresponds to the condition shown in Fig. 12, as expressed by Equation (30a), and indicates that the foregoing method of treating slopes and deflections as purely numerical quantities, is apparently the convention adopted in Appendix II. This convention is well suited to the author's proposed method, when deformations of known direction are applied.

It might be mentioned that this convention, although admirably adapted to the purposes of the author, is not convenient when the slopes and deflections are unknown in direction. This is why, in the slope deflection method, it is usual to assume that all rotations and deflections are in the same direction (clockwise), and only the known constant, C_{AB}, is treated as an absolute numerical quantity. When, after computation, certain slopes and deflections are found to be negative quantities, it means that their directions are in reality opposite to the direction assumed.

In effect, Equation (64) is the slope deflection equation, without the use of a sign convention. Introducing the convention that clockwise rotation is to be indicated by a "plus" sign, and contra-clockwise rotation by a "minus" sign, and referring again to Figs. 23(b) to 23(e):

$$-M'_{AB} = -4\,E\,K\,\theta_A \qquad (66a)$$

$$-M''_{AB} = -2\,E\,K\,\theta_B \qquad (66b)$$

$$-M'''_{AB} = +6\,E\,K\,R \qquad (66c)$$

and,

$$-M''''_{AB} = +C_{AB} \qquad (66d)$$

Adding Equations (66), $-M_{AB} = -M'_{AB} - M''_{AB} - M'''_{AB} - M''''_{AB}$; $-M_{AB} = -2\,E\,K\,(2\,\theta_A + \theta_B - 3\,R) + C_{AB}$; or,

$$M_{AB} = 2\,E\,K\,(2\,\theta_A + \theta_B - 3\,R) - C_{AB} \qquad (67)$$

which is the conventional form of the slope deflection equation.

F. B. FARQUHARSON,[26] ASSOC. M. AM. SOC. C. E. (by letter).—The writer views this paper as a contribution to the field of analysis of structures by models and from this vantage point suggests that it provides a real contribution in a field that receives altogether too little attention from the practicing structural engineer. It has been the writer's experience that the influence line in general takes on no real and lasting significance until experienced and handled in the form of a model. After working with several model methods for a number of years, the re-thinking necessary in reading this paper has served a valuable function in bringing Maxwell's theorem slope-deflection principles, influence lines, and the model and its prototype into a more harmonious relationship.

---

[26] Associate Prof. of Civ. Eng., Univ. of Washington, Seattle, Wash.

It is undoubtedly true that the fact that models may only be studied in connection with an existing tangible model, has led many engineers to neglect this approach in favor of one of the many methods requiring only pencil, paper, and a slide-rule as adjuncts to fundamental thinking. Thus, it is probable that the majority of efforts along model lines have been confined to university laboratories and a few of the larger engineering offices.

It is unfortunate that this condition exists since it does not follow that the model method requires the use of an expensive set of equipment. Indeed, it has been the practice of the writer to accompany the discussion of influence lines by practical demonstrations on the blackboard, making use of a long wooden spline and half a dozen small steel pins inserted in holes in the blackboard. In this manner, using a sharp piece of chalk and a meter stick for measurement, influence line results are obtained on fairly complex structures which check theoretical computations to within 15 per cent. Of course, the general usefulness of the model method is much extended by the availability of accurate and more elaborate equipment offered commercially for this purpose.

It has been the writer's experience that much of the indifference to the use of models arises through engineers who have never tried the method. It is suggested that even so complex a problem as that illustrated in Fig. 1 of the paper might be solved with an accuracy within 10% or 15%, through the use of a few carefully selected wooden splines, a dab of glue, and a few brads. The model can be constructed and mounted in an hour. A minute or two will suffice to trace off the influence line from which the moment at Point *E* is observed directly for any single concentrated load and obtained with ease for any load distribution whatever. To be sure, a check solution yielding the exact theoretical influence line may occupy several evenings, but the result is likely to be an enthusiasm for the model as an adjunct to structural analysis.

A. A. Eremin,[27] Assoc. M. Am. Soc. C. E. (by letter).—An interesting method of computing bending moments and shear stresses in rigid frames, based on the Mohr principle, which has been cited by the writer elsewhere,[28] is developed by Mr. Gottschalk. His method has merit, but, it is regrettable that he failed to extend it to the computation of stresses in rigid frames with variable sections. The advantage of rigid frames and continuous beams with variable sections is evident and it is a serious limitation of the method that it can be applied only to structures with constant sections.

---

[27] Associate Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[28] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 21.

The computations may be divided into two steps: (1) Computing the stiffness factors, S, at each end of members in the frame; and (2) computing the factors, f. The stiffening factors express the elastic properties of a frame and do not vary with loads on the frame. The factors, f, computed in Step (2), however, vary with the manner of loading and the location of a section in the frame at which analysis of stresses is desired. The final bending moments and shear stresses in the frame are determined by the algebraic expressions involving the Factors f and the loading. The method may be extended to determine stresses in rigid frames with variable sections. Computation of the stiffening factors, S, and loading factors, f, for variable sections may be simplified by preparing tables of constants for the elastic properties of members in frames. However, the final algebraic expression for bending moment and shear stress in members with variable sections, involving the factors, f, will be lengthy and difficult of solution for practical purposes.

In rigid frames more than one story in height the value of S, cannot be obtained by direct computations. It must be assumed, and true values are determined by repeated trial computations. Therefore, the labor required for computing the values of S varies with the experience acquired in deciding on an initial trial value.

A direct computation of shear stresses by Equations (11) and (12) can scarcely be considered a saving of time. In rigid frames, shear stresses at ends of members are generally determined by the formula:

$$V = V_0 + \frac{M_1 - M_2}{l} \qquad \text{.....................} (68)$$

in which V_0 = shear stress at one end of a member assuming both ends freely supported; M_1 and M_2 = the restraining bending moments at the ends of a member; and l = span length of the member. Evidently, the time and effort required for computing Factor f and the shear stresses is not less than that required for computing the restraining bending moments, M_2 and M_1, and shear stress, V_0, in Equation (68).

The author's method is convenient in the construction of influence lines for bending moments and shear stresses in rigid frames. Likewise, it may be used conveniently in the analysis of stresses in rigid frames and continuous beams that have a single statically indeterminate reaction. However, in computing bending moments and shear stresses for each member of a multiple-span rigid frame the method involves lengthy computations and cannot be considered as a time saver.

DAVID M. MACALPINE,[29] ASSOC. M. AM. SOC. C. E. (by letter).—In so far as the author has introduced the little used idea of f, this paper is an interesting one. It is unfortunate, however, that he has chosen an unfamiliar sign convention. For the paper to realize its greatest value to the profession it is imperative that this convention be clearly stated in the closing discussion. It will then be possible to transform the formulas developed to more familiar ones.

---

[29] Instructor, Coll. of the City of New York, School of Technology, New York, N. Y.

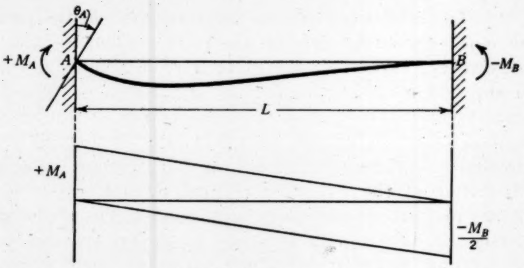


FIG. 24.

There appears to be no need of abandoning any of the several rather widely accepted and publicized sign conventions. One wonders why all these conventions were discarded. If the author had accepted the rather common convention of tension on the bottom fiber being caused by positive moment, Equation (36) would not have been changed. A derivation of this formula, without recourse to the slope-deflection equation, follows: Holding End *B* fixed (see Fig. 24) and rotating End *A* so as to produce tension in the bottom fiber:

$$M = -M_A + \frac{3}{2} M_A \frac{x}{L} \qquad \text{(69a)}$$

and,

$$E\,I \frac{dy_1}{dx} = -M_A\,x + \frac{3}{4} M_A \frac{x^2}{L} + C_1 \qquad \text{(69b)}$$

When $x = L$: $\frac{dy_1}{dx} = 0$; and, $C_1 = \frac{M_A\,L}{4}$:

$$E\,I\,y_1 = -\frac{M_A\,x^2}{2} + \frac{M_A\,x^3}{4\,L} + \frac{M_A\,L\,x}{4} + C_2 \qquad \text{(69c)}$$

When $y_1 = 0$: $x = 0$; and, $C_2 = 0$:

$$y_1 = \frac{M_A\,x\,(x - L)^2}{4\,E\,I\,L} = \frac{M_A\,x\,(x')^2}{4\,E\,I\,L} \qquad \text{(69d)}$$

When $x = 0$: $E\,I \frac{dy_1}{dx} = E\,I\,\theta_A = \frac{M_A\,L}{4}$; $\theta_A = \frac{M_A\,L}{4\,E\,I}$; and $f' = \theta_A\,L$; $\frac{M_A}{4\,E\,I} = \frac{f'}{L^2}$; and,

$$y_1 = \frac{f'\,x\,(x')^2}{L^3} \qquad \text{(70a)}$$

Holding End A fixed and rotating End B so as to obtain tension in the bottom fiber:

$$y_2 = \frac{f\, x^2\, x'}{L^3} \qquad \text{(70b)}$$

Adding Equations (70*a*) and (70*b*), the result is identical with Equation (36) of the paper.

On the other hand, the beam convention is very inconvenient to apply to the slope-deflection equation. A sign convention must fit some definite system if it is to be used from a practical, as well as from a mathematical, standpoint. Such a convention would require that positive angles be measured by counter-clockwise rotation, that distances, forces, and displacements be positive upward and to the right from the origin, and that moments capable of being represented by a positive vector be positive; that is, counter-clockwise external moments in the plane of the paper are positive. In this case positive moments are increasing positive angles. No great harm is done, however, if any other consistent convention is used.

In this convention, the familiar slope-deflection equations are:

$$M_{AB} = M_{F\,AB} + \frac{2\,E\,I}{L} (2\,\theta_A + \theta_B - 3\,R_{AB}) \qquad \text{(71a)}$$

and,

$$M_{BA} = M_{F\,BA} + \frac{2\,E\,I}{L} (2\,\theta_B + \theta_A - 3\,R_{BA}) \qquad \text{(71b)}$$

Ordinarily, $M_{F\,BA}$ is arithmetically negative but should carry a positive sign in the formula. Using Equations (71) and deriving formulas similar to Equations (34*b*) and (34*c*):

$$m = \frac{-\,0.5\,k}{k + S_B} \qquad \text{(72a)}$$

and,

$$m' = \frac{-\,0.5\,k}{k + S_A} \qquad \text{(72b)}$$

These expressions are in accordance with the geometric facts, θ_A being opposite in direction to θ_B. Equations (37*a*) and (37*b*) become, respectively,

$$\theta_{BA} = -\,\frac{S_2}{K_B} \qquad \text{(73a)}$$

and,

$$\theta_{BC} = \frac{S_1'}{K_B} \qquad \text{(73b)}$$

Equations (73) are also in accord with the geometry of the figure. The remainder of the equations follow directly, differing from the author's formulas only in sign.

Referring further to signs, the author has failed to state that he assumes L to be negative when measured to the left of his origin. This is necessary in order to obtain Equation (16) in its present form. This assumption, however, introduces an interesting incongruity in Fig. 2(*a*). For example, both θ_A and θ_B are positive by the author's sign convention. The values of f and f' are then positive and negative, respectively, thereby violating the sign convention as adopted for the paper for L. It is necessary to assume L as positive when measured to the right for θ_A and to the left for θ_B; otherwise, f' is positive when measured upward and f is positive when measured downward.

Referring to Line 2 following Equation (2), the use of the word, "strain," rather than "moment," is open to question. It would seem that "moment" is the more exact term.

The derivation given in Appendix I does not seem to be as satisfactory as the many other derivations of Maxwell's theorem to be found in any text or reference book on the subject. The theorem is so well known and widely publicized that there is some question as to the necessity of a derivation unless a new and better proof is given.

The derivation of the slope-deflection equations, using any of the accepted sign conventions, is also familiar and Appendix II only serves to illustrate the breakdown of the author's sign system (see Fig. 14).

There is a definite need for the establishment of a mathematically consistent, and practical, sign convention, as well as notation, in both the beam theory and stress analysis. Any sign convention that is not self-consistent tends to confusion and delays the establishment and acceptance of a correct one.

Otto Gottschalk,[30] Esq. (by letter).—Interesting suggestions have been presented in the discussion of this paper. The writer's methods have been derived from unloaded model analysis on a primarily geometrical basis, establishing the fundamental relations which make it possible to analyze structures directly, the same as in models, by using the simple stiffness values of the members instead of equations containing abstract stress symbols or a series of numbers.

In contrast with other branches of applied science, structural analysis has lacked that sound, experimental procedure which is characteristic of model analysis (especially models with visible deformations). It has required its own austere development entirely separate from current abstract conception. The fact that one of the discussers considers the geometrical process explained in the paper as only a variation of that by Strassner, and another discusser, a variation of the Cross method, proves the impossibility of judging a new conception merely from appearances, even to those who are most conversant with current theories.

Mr. Mensch contributes an inspiring anthology of former methods and offers suggestions of greatest practical interest. However, in his comments on the paper, he is fundamentally at variance with the writer, probably due to lack of examples in the original presentation. The paper is not a variation of any abstract treatment and does not require one to "analyze a structure by beginning at one end and going over its entire length." On the contrary, a fifth conclusion may properly be added to those cited in the paper: "(5) The analysis may be limited to the structural member under consideration and a few adjacent members." The examples given subsequently herein should satisfy Mr. Mensch that the writer's methods fit the requirements he so clearly establishes.

---

[30] Buenos Aires, Argentine Republic.

Mr. Shapiro presents a really interesting example of the rapid convergence of transmission coefficients, which are an essential part of the advantage inherent in Conclusion (5). Thus far, the writer has not encountered the limits in practical application of his geometrical methods which Mr. Shapiro suspects; there is a need, however, for perfecting the application of methods of analytical geometry, especially the evolution of curves, so that the writer's method can be used more easily for curved structures.

Professor Griffith contributes experiences of his own in the handling of models and confirms the writer's experiences which make it possible to deal accurately with visible deformations. In Fig. 20, for example, the angle of the moment clamps at Point *B* is different from that at Point *D*. The necessarily high cost of working commercial sets should make it a habit, where the expense is not warranted, to use the equipment available at the nearest college, just as one would consult its library.

Mr. Weiss deserves sincere acknowledgment for his encouraging comments. His suggestions are of positive value and have been used in the preparation of this closing discussion. In principle, the writer avoids obtaining stresses by equations with unknowns. Special attention should be called to Mr. Weiss' graphical solution for the ordinates of influence lines as demonstrated by Fig. 22.

In a few words, Professor Farquharson shows how the experimentation is indispensable as a guide to intuition in solving problems in statics and his recommendations for teaching influence lines deserve widest acceptance. As a first step students should be taught the habit of having handy wooden or metal splines, in order to check all their results.

Mr. Eremin rightly desires the extension of the geometrical methods shown in the paper to variable sections. These were omitted to simplify the presentation; but they offer no difficulties.[31] Mr. Eremin is incorrect in assuming that the manner of loading has any bearing on the factors, *f*, and that values of *S* cannot be obtained directly in rigid frames more than one story high. Furthermore, contrary to his assumptions, the number of so-called statically indeterminate reactions does not complicate the computations in any respect, and the time saved becomes more marked the more equations there are to be solved by current methods.

Mr. MacAlpine offers an interesting derivation of the general equation of influence lines (Equation (5)) and makes valuable suggestions with regard to the question of signs. The latter cannot be settled entirely satisfactorily within the scope of the paper.

In general derivations, the complications imposed by rotation signs can be avoided by working with *f* and *f'* directly as has been done herein under the heading, "General Influence Lines."

---

Examples to Clarify Questions Raised in Discussion.—An excellent opportunity to apply the writer's method is afforded by the interesting example of the continuous four-span beam shown in Fig. 25(*a*).[32]

(*b*) SOLUTION FOR M_c BY STRUCTURAL ANALYSIS

6 $M_c = W_{ym} = 28.8 \times 0.44 = 12.66$ Kip · Ft $\quad -21.6 \times 1.77 = 25.16 \quad -12.0 \times 0.41 = -4.92 \quad 12.0 \times 0.102 = 1.22$

7 $M_c = Py = \quad -10.0 \times 0.61 = -6.10 \quad 6.0 \times 0.118 = 0.71$

8 Total $M_c = 12.66 - 25.16 - 4.92 - 6.10 + 1.22 + 0.71 = 14.59 - 36.18 = -21.59$ Kip · Ft

(*c*) COMPUTATION OF M_c FOR LOADS W AND P

FIG. 25.—MULTIPLE-SPAN CONTINUOUS BEAM

For the elastic determination (namely, the computation of stiffness values) the analysis may start at one end because of the small number of spans. Line 1, Fig. 25(*a*), shows the stiffness factors, $k = \frac{I}{L}$. In Span *A B*, the coefficient, $m_1' = 0.5$ (see Line 2) and, therefore, $S_1' = (1 - 0.25)\,k_1 = 6.25$ (see Line 3); similarly, in Span *B C*, $m_2' = \frac{0.5\,k_2}{(k_2 + S_1')} = 0.235$; and, $S_2' = k_2\left(1 - \frac{0.235}{2}\right) = 4.91$, etc. Likewise, beginning at the fixed end, *E*: $m_4 = 0$; $S_4 = k_4 = 5$; etc., all of which may be written in the diagram directly from slide-rule readings.

The structure, thus made elastically determinate, may be analyzed now for any stress, M_C (Fig. 25(*b*)), by rotating *C B* and *C D* one unit with respect to each other. Then, $K_C = S_2' + S_3 = 4.91 + 8.33 = 13.24$ and, consequently, for Span *C B*, $\theta_2' = \theta_{CB} = \frac{8.33}{13.24} = 0.63$; and for Span *C D*, $\theta_3 = \theta_{CD} = \frac{4.91}{13.24} = 0.37$. The rotation at Point *B* then is $\theta_2 = \theta_2'\,m_2' = 0.63$

---

[32] "Continuous-Beam Analysis by Direct Distribution," by John C. Schulze and William A. Rose, *Engineering News-Record*, December 20, 1934; with discussions in *Civil Engineers' Digest*, June, 1935, by J. D. Gedo, Ben Moreell, Odd Albert, Members, Am. Soc. C. E., F. E. Turneaure, Hon. M. Am. Soc. C. E., and Messrs. Otto Gottschalk, and John C. Schulze.

× 0.235 = 0.148; and at Point D, $\theta_3' = \theta_3\, m_3 = 0.37 \times 0.333 = 0.123$. This is the complete analysis of the structure for M_C.

Line 4, Fig. 25(b), indicates the average ordinates, y_m, with which the uniformly distributed loads must be multiplied. Equation (6b) may be rewritten for spans to the left of Point C:

$$y_m = \frac{\theta' L (1 + m')}{12} \qquad \text{(74a)}$$

and to the right of Point C:

$$y_m = \frac{\theta L (1 + m)}{12} \qquad \text{(74b)}$$

Line 5, Fig. 25(b), shows the y-values for concentrated loads; and Lines 6, 7, and 8, show $M_C = W\, y_m$; $M_C = P\, y$; and the total M_C, respectively.

* Minimum. † Maximum. ‡ Total. § 1 kip = 1 000 lb.

Although the explanation, in detail, occupies some space, the analysis shown gives the exact result in only a fraction of the time and work required for any other method now current. If moments at the other supports are needed also, the analysis may be arranged as shown in Table 1.

The superiority of the model method becomes even more marked when the continuous beam in Fig. 25 is supported on columns, forming the irregular frame shown in Fig. 26. The stiffness factors, k, of the columns and beams, are underlined. The stiffness, S, of the columns is $S = k$, when the base is fixed and $S = 0.75\, k$ when it is hinged. The computation of m and S to the left, and m' and S' to the right, of the several spans of the beam is shown at the top of Fig. 26(a). The m-values are smaller, and the S-values larger, than those in Fig. 25.

Fig. 26(b) demonstrates the analysis of the structure for M_C, obtaining the influence line of M_{CB} by unit rotation at End C of Span $C\,B$ to which Spans $C\,D$ and $C\,G$ offer resistance. On the left of End C: $\theta_2' = 0.697$; and to the right of End C: $\theta_3 = 0.303$. Therefore, because of rotation at Point B:

$\theta_2 = \theta_2' \, m_2' = 0.131$; and because of rotation at Point D: $\theta_3' = \theta_3 \, m_3 = 0.087$. The values of y_m for uniformly distributed loads, and of y at concentrated loads, are then computed in the same manner as in Fig. 25. With the structure thus analyzed, M_{CB} (see Fig. 26(*c*)) is the sum of the several loads multiplied with y_m and y, respectively; and $M_{CB} = 12.69 - 35.57 = -22.88$ kip-ft.

(*c*) COMPUTATION OF M_c FOR LOADS W AND P IN FIG 25

FIG. 26.—UNSYMMETRICAL MULTIPLE-SPAN FRAME

Analysis is begun at the section for which the stress is wanted (see Fig. 26(*b*)), instead of complicating it by beginning at supports; beyond two spans on either side of the section ordinates of influence lines generally become small and may be neglected. Similarly, the elastic determination does not need to start farther away, as is illustrated in Fig. 27. If the support at End A were fixed, the value of S_3' at Point D would be 8.62, exactly the same as if End A

were hinged as in Fig. 26. Assuming, then, at the most two spans away a value of S is wanted: Roughly, by inspection, $\frac{S}{k}$ equals between 0.8 and 0.95. If an interior span is considered, the value will be exact for adjacent spans.

In Fig. 26(a), if Beam $A\ B\ C\ D\ E$ could move freely in a horizontal direction, the influence line for side-sway can be obtained by sliding the beam a unit distance with respect to the column base, as shown in Fig. 10, computing the horizontal thrust at the column base, and deducting the bending moments determined in Fig. 26(c). The analysis is similar to that in Fig. 28(a) except

(b) DEFORMATION OF COLUMN BF, FIXED AT POINT F

(c) DEFORMATION OF COLUMN CG, HINGED AT POINT C

(d) DEFORMATION OF COLUMN DH, HINGED AT POINT H

Fig. 28.—Stresses Due to Uniform Changes of Temperature in Beam $A\ B\ C\ D\ E$

that it is simpler because the side-sway is equal at the column tops; the horizontal thrust added at the column bases F, G, and H, respectively, is $0.44 + 0.34 + 0.42 = 1.20$ kips and $M_{CB} = -22.88 + 1.31 = -21.57$ kip-ft.

A further question of practical interest in the case of the unsymmetrical frame in Fig. 26(*a*), is that concerned with the stresses produced by a uniform change of temperature in Beam $A\ B\ C\ D\ E$ of, say, $t = 60°$ F. The coefficient of expansion is assumed equal to $\epsilon = 5.5 \times 10^{-6}$; and the modulus of elasticity is equal to $E = 3 \times 10^6$ lb per sq in. Not considering the microscopic shortening caused by compression in the beam, the side-sway of the ends of any beam is proportional to its distance from End E; or, $10'\,\epsilon\,t$ at Point D; $20'\,\epsilon\,t$ at Point C; and $38'\,\epsilon\,t$ at Point B as shown in Figs. 28(*b*), 28(*c*), and 28(*d*), respectively.

If the column is hinged at Point B, Fig. 28(*b*), the column top, B, will rotate through an angle, $\theta_{BF} = 1.5\,\epsilon\,t\,\frac{38'}{15'}$; but due to its rigid connection with the beams the rotation at Joint B is $\theta_B = 0.795\,\epsilon\,t$, this rotation being transmitted to Points C and D in relation to $-m_2$ and $m_2\,m_3$, respectively. If the column top at Point C is hinged: $\theta_{CG} = \frac{20'\,\epsilon\,t}{10'}$; due to the rigid connection with the beams the rotation at Point C will be $\theta_C = 0.362\,\epsilon\,t$, which is transmitted to Points B and D in proportion to their respective values of $-m_2'$ and $-m_3$. The sum of those partial rotations makes it possible to compute the intercepts of Tangents f and f', the Thrust P at the foot of each column (by Equation (15)) and, finally, the points of inflection of each beam (by Equation (91)), all as demonstrated in Fig. 28.

The horizontal thrusts at Points F, G, and H are, as shown in Fig. 28: 0.432 kips, 0.182 kips, and 0.113 kips, which would seem rather small if the structure were of reinforced concrete. However, the k-values are only proportional to each other and, in practice, all of them would be, say, five times the indicated values, increasing the thrusts to 2.16 kips, 0.91 kips, and 0.56 kips, respectively.

Turning to the subject of multiple-story skeletons mentioned by Mr. Mensch: For the skeleton frame shown in Fig. 21, Mr. Weiss derives 1 134 unknown quantities for the moments, which must be computed. This is not only an interesting statement, but also a timely warning against adopting current complicating methods based on abstract conceptions which do not show clearly the effect of each member on every other member. For example, in Fig. 29 (a reinforced concrete frame) the bending resistance of Beam $A\ B$ is desired. It is generally sufficient to compute the necessary resistance at the center, bending convenient parts of the reinforcement and extending it over the supports.

Elsewhere,[33] the writer has demonstrated the principles of mechanical analysis (a concise expression first introduced to the writer by Hale Sutherland, M. Am. Soc. C. E.) by the physical deformation of models. For present purposes Fig. 30 may be used to illustrate the method of determining M_C at the center Point C of Beam $A\ B$, by this method. The model is composed of steel splines—those for columns reproducing the combined k-values of the upper and lower columns, the lengths of spans of the beams being modified in proportion to their several values of $k = \frac{I}{L}$. The far ends of the column splines are held at the original distance from each other, and at the proper angles, by clamps mounted on a rod which, in turn, is supported on rollers that permit horizontal sliding without friction. In Fig. 30, a unit rotation has been exerted at Point C by means of a special clamp and the experiment has shown that, even where the relative stiffness of structural parts meeting at Points A and B differ extremely, the rolling rod will not sway when a unit rotation is applied at Point C (or even outside of Point C, within the middle-fourth, or even the middle-third of the span). This demonstrates that bending moments may be analyzed at these sections as if the frame did not sway, and that the values of m and S may be computed as shown previously herein for structures fixed against horizontal movement.

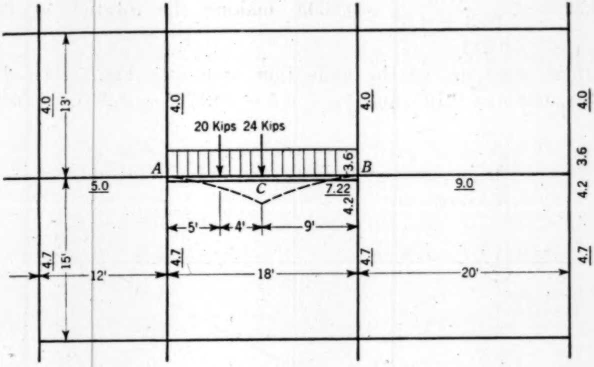

FIG. 29.—TYPICAL REINFORCED CONCRETE FRAME

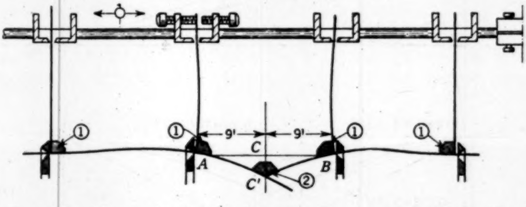

FIG. 30.—MODEL ANALYSIS FOR THE DETERMINATION OF M_C

The structural analysis for M_C is shown in Fig. 31. In a simple beam, $A\ B$, the unit rotation at Point C would rotate Beam $A\ B$ at Points A and B through an angle, 0.5, resulting in the dotted line, $A\ C'\ B$ (Fig. 31(*a*)). To compute the restraint at Point A (Fig. 31(*b*)) assume the beam, $A\ B$, to be free at Point B, making $m = 0.5$ and $S = 7.22\left(1 - \frac{0.5}{2}\right) = 5.41$. Since $S_A = 13.0$, the rotation, $\theta_{AB} = 0.5 \times \frac{13.0}{(13.0 + 5.41)} = 0.363$; and, at the free end, *B*, $\theta_{BA} = 0.5 \times 0.353 = 0.1765$. At End *B*, therefore, the rotation is $0.5 - 0.1765 = 0.3235$ = (Fig. 31(*c*)). Once again, making Beam *A B* fixed at Point *B*, and with m', S', and S_B as computed in Fig. 31(*a*), the rotation, θ_{BA} (see Fig. 31(*c*)) equals $0.3235 \times \frac{16.3}{16.3 + 6.58} = 0.2305$, making the rotation at Point *A*, $\theta_{AB} = \theta_{BA}\, m' = 0.041$.

The total rotations at the ends then, are (see Fig. 31(*d*)) $\theta_A = 0.5 - (0.353 + 0.041) = 0.106$; and, $\theta_B = 0.5 - (0.1765 + 0.2305) = 0.093$, producing the influence line, *A C″ B*. By Equation (20*a*), the ordinate at the center is: $y_c = \frac{L\,(1 + \theta_A + \theta_B)}{8} = 2.70$ ft; the medium ordinate (Equation 20(*b*)) is $y_m = \frac{2\,y_c}{3} - \frac{L}{24} = 1.05$ ft, and, at $x = 5.0$ ft from End *A* (see Equa-

FIG. 31.—GEOMETRICAL ANALYSIS FOR M_C

tion (17*a*)): $y = 1.05$. Consequently, with the loads indicated in Fig. 29: $M_C = 20 \times 1.05 + 24 \times 2.7 + 18 \times 1.05 = 104.7$ kip-ft.

The solution of Fig. 31, starting either at Point *A* or at Point *B*, is recommended as a means of becoming familiar with the working of geometrical curves; for practical application M_C may be analyzed directly from the *m* and *S* values computed in Fig. 31(*a*). At Point *A*: $\frac{0.5 \times 13.0}{13.0 + 6.67} = 0.330$ and at Point *B*: $\frac{0.5 \times 16.3}{16.3 + 6.58} = 0.356$; and, therefore, the total rotations are, at *A*, $0.330 + 0.179 \times 0.356 = 0.394$; and, at *B*, $0.356 + 0.153 \times 0.330 = 0.407$, leaving $\theta_A = 0.5 - 0.394 = 0.106$ and $\theta_B = 0.5 - 0.407 = 0.093$, the same as was obtained before according to Fig. 31(*d*).

General Influence Lines.—Development of Equations (5) to (10*c*) beyond the form given in the paper, leads to conclusions that should be vitally useful in drafting and in understanding influence lines. The typical influence curve (see Fig. 2) is fully determined by the rotations, $\frac{f}{L} = \theta_B$ and $\frac{f'}{L} = \theta_A$, and may be expressed (see Fig. 32) as,

$$(f, f') = (f, 0) + (0, f') \ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

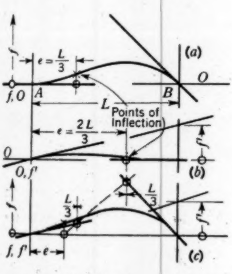

FIG. 32.—GENERAL INFLUENCE LINE

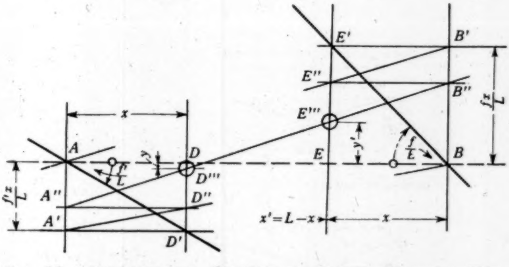

FIG. 33.—SYMMETRICAL ORDINATES, y AND y', FROM END TANGENTS, OR END TANGENTS FROM SYMMETRICAL ORDINATES, y AND y'

which is the sum of one curve rotated through $\frac{f}{L}$ at Point *B* and fixed at Point *A*, and another curve fixed at Point *B* and rotated through $\frac{f'}{L}$ at Point *A*.

The ordinates are found as follows: For the beam fixed at Point *A* $(f, 0)$, use Equation (10*c*); for the beam fixed at Point *B* $(0, f')$, use Equation (8*c*); and the general equation for f, f' (see Equation (5)) is:

$$y = \left(\frac{x^2}{L^2} - \frac{x^3}{L^3}\right) f + \left(\frac{x}{L} - \frac{2\,x^2}{L^2} + \frac{x^3}{L^3}\right) f' \ldots\ldots\ldots\ldots (76)$$

Formulas for influence ordinates for a beam, *A B*, of unit length and various conditions of fixation, are given in Table 2.[34] In connection with Item No. 1,

when y or y' are at one of the third points,

$$f = \frac{9}{2}(2y' - y) \qquad \text{(77a)}$$

and,

$$f' = \frac{9}{2}(2y - y') \ldots\ldots (77b)$$

when h and y are at the center or the quarter-points, respectively,

$$f = 12h - \frac{32y}{3} \ldots\ldots (78a)$$

and,

$$f' = \frac{32y}{3} - 4h \ldots\ldots (78b)$$

Items Nos. 6 to 9, Table 2, are the influence lines of simple beams, combined with that in Item No. 1. When $m = \frac{f}{f'} \leqq 0$, the influence line crosses Axis AB at Point x where $\frac{x}{L} = \frac{f}{(f - f')} = \frac{\theta_B}{(\theta_B - \theta_A)} = \frac{-m}{(1 - m)}$. Any straight line, $A'B'$ (Fig. 33), crosses Beam AB at the intersection of the influence line.

Symmetrical Ordinates.—According to Equation (5), the sum of two ordinates at distances, x and $x' = L - x$, from Point A, is:

$$y_x + y_{x'} = 2y_m = \frac{x x' (f + f')}{L^2} = \frac{8 h x x'}{L^2} \ldots\ldots (79)$$

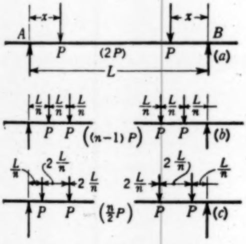

FIG. 34.—SYMMETRICAL CONCENTRATED LOADS

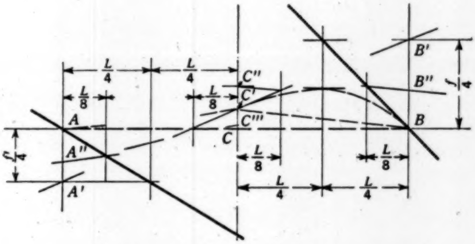

FIG. 35.—INFLUENCE LINE BY PROGRESSIVE CENTER TANGENTS

The stress then produced by two symmetrical loads, P (see Fig. 34a), is $\frac{8 P h x x'}{L^2}$. The relation between two symmetrical ordinates is expressed by:

$$\frac{y_x}{y_{x'}} = \frac{(x f + x' f')}{(x' f + x f')} = \frac{(m x + x')}{(m x' + x)} \ldots\ldots (80)$$

Therefore, when End A is fixed, $f' = 0$ and $\frac{y_x}{y_{x'}} = \frac{x}{x'}$; when End B is fixed, $f = 0$ and $\frac{y_x}{y_{x'}} = \frac{x'}{x}$; when End A is simply supported, $f' = \frac{f}{2}$ and $\frac{y_x}{y_{x'}} = \frac{L + x}{L + x'}$; and, when End B is simply supported, $f = \frac{f'}{2}$ and $\frac{y_x}{y_{x'}} = \frac{L + x'}{L + x}$.

The foregoing coefficients show that when one end of Beam $A\,B$ is fixed, symmetrically located ordinates vary in proportion to their distances from the fixed end; and, when one end is free, they vary in proportion to their distances from the free end, plus L. Consequently, a straight line joining two symmetrical points of the influence line crosses the axis at the fixed support and at a distance, L, beyond the free support, respectively.

When $(n - 1)$ equal loads, P, are acting at equal distances, $\frac{L}{n}$ (see Fig. 34(b)), the sum of the ordinates, according to Equation (79), is:

$$(n-1)\,y_m = 4\,h\left[(n-1) + 2\,(n-2) + 3\,(n-3) + \cdots + \frac{1}{2}\,(n-1)\left(n - \frac{1}{2}\,(n-1)\right)\right]\frac{1}{n^2}$$

For $(n - 1)\,P$ loads, the following apply:

Values of $(n-1)\,P$	Corresponding values of n	Values of $\frac{y_m}{h}$
P	2	1
$2\,P$	3	$\frac{8}{9}$
$3\,P$	4	$\frac{5}{6}$
$4\,P$	5	$\frac{4}{5}$
$5\,P$	6	$\frac{7}{9}$
..	..	..
..	..	..
..	..	..
$n\,P$	..	$\frac{2}{3}$

in which,

$$h = y_c = \frac{(f + f')}{8} \qquad (81)$$

When $\frac{n}{2}$ loads P are acting at a distance $\frac{2\,L}{n}$ from each other, starting at $\frac{L}{n}$ from Points A and B (Fig. 34(c))—so that $x_1 = \frac{L}{n}$; $x_2 = \frac{3\,L}{n}$; $x_3 = \frac{5\,L}{n} \cdots$; and, $x_1' = (n-1)\,\frac{L}{n}$; $x_2' = (n-3)\,L\,n$, Equation (79) yields,

$$y_m = \frac{2\,(n^2 + 2)\,h}{3\,n^2} \qquad (82)$$

For $\frac{P\,n}{2}$ loads, the following apply,

Values of $\frac{P\,n}{2}$	Corresponding values of n	Values of $\frac{y_m}{h}$
P	2	1
$2\,P$	4	$\frac{3}{4}$
$3\,P$	6	$\frac{19}{27}$
$4\,P$	8	$\frac{11}{16}$
$5\,P$	10	$\frac{17}{25}$
..	..	..
..	..	..
..	..	..
$n\,P$	2×number of loads	$\frac{2}{3}$

in which, as before, $h = y_c$, is given by Equation (81).

Slope and Intercepts at A and B of Tangents.—Differentiating Equation (76), or reading directly from Fig. 2(c) considered as the area of the reduced bending moments, the slope of a tangent to the influence line at x from Point A, and at $x' = L - x$ from Point B is given by:

$$\theta_x = \frac{dy}{dx} = \left(\frac{2\,x}{L^2} - \frac{3\,x^2}{L^3}\right) f + \left(\frac{1}{L} - \frac{4\,x}{L^2} + \frac{3\,x^2}{L^3}\right) f'$$

$$= \left[x\,f\,(2\,x' - x) - x'\,f'\,(2\,x - x')\right] \frac{1}{L^3} \quad \ldots\ldots\ldots\ldots (83)$$

Therefore, at the center and at the third-points, respectively:

$$\theta_c = \frac{(f - f')}{4\,L} \quad \ldots\ldots\ldots\ldots (84a)$$

$$\theta_{\frac{L}{3}} = \frac{f}{3\,L} \quad \ldots\ldots\ldots\ldots (84b)$$

and,

$$\theta_{0.67\,L} = -\frac{f'}{3\,L} \quad \ldots\ldots\ldots\ldots (84c)$$

Equations (84) show that the slope of the tangent at the center of the influence line is one-fourth the difference of the slopes of the tangents at Points B and A; at the third-points, it is one-third of the reversed slope at Points B and A, respectively.

The intercepts, f, at Point A and f' at Point B of a tangent at x, equivalent to statical moment of reduced moment area, are:

$$f_x = \left[x^2\,(x - x')\,f + 2\,x^2\,x'\,f'\right] \frac{1}{L^3} \quad \ldots\ldots\ldots\ldots (85a)$$

and,

$$f_x' = \left[2\,x\,(x')^2 f + (x')^2\,(x' - x)\,f'\right] \frac{1}{L^3} \quad \ldots\ldots\ldots\ldots (85b)$$

Therefore, for tangents at the center and at the third-points, respectively,

$$f_c = \frac{f'}{4} \qquad \text{(86a)}$$

$$f_c' = \frac{f}{4} \qquad \text{(86b)}$$

$$f_{0.33L} = \frac{(4f' - f)}{27} \qquad \text{(87a)}$$

$$f_{0.33L}' = \frac{(8f + 4f')}{27} \qquad \text{(87b)}$$

$$f_{0.67L} = \frac{(8f' + 4f)}{27} \qquad \text{(88a)}$$

and,

$$f_{0.67L}' = \frac{(4f - f')}{27} \qquad \text{(88b)}$$

According to Equations (86) the tangent at the center of continuous influence curves crosses ends at one-fourth the distance to the opposite intercept of the end tangent. This leads to a most simple method of designing influence lines the end tangents of which are known (see Fig. 35).

Radius, r, of Influence Line.—Differentiating Equation (83) the curvature at Point x equals,

$$\frac{1}{r} = \frac{d^2 y}{dx^2} = 2\left[(x' - 2x) f + (x - 2x') f'\right] \frac{1}{L^3} \qquad \text{(89)}$$

This makes the radius, r, at several values of x, equal to:

Values of x	Corresponding values of r
0	$-\frac{L^2}{4f' - 2f}$
$\frac{L}{3}$	$-\frac{L^2}{2f'}$
$\frac{L}{2}$	$-\frac{L^2}{f + f'}$
$\frac{2L}{3}$	$-\frac{L^2}{2f}$
L	$-\frac{L^2}{4f - 2f'}$

The radius at the center of the influence curves is equal to L^2 divided by the sum of the end intercepts, $f + f'$, of the end tangents; and the radius at the third-points is equal to $\frac{L^2}{2}$ divided by the far intercept.

Inflection Points.—According to Equation (89) the curvature, $\frac{1}{r}$, is zero at a distance, $x = e$, from Point A. Therefore, the point of inflection is expressed by,

$$e = \frac{L\,(2\,f' - f)}{3\,(f' - f)} = \frac{L\,(2 - m)}{3\,(1 - m)} \quad\ldots\ldots\ldots\ldots\ldots\ldots(90)$$

When Beam $A\,B$ is fixed at Point B, $m = 0$ and $e = \frac{2\,L}{3}$; when it is fixed at Point A: $e = \frac{L}{3}$. Graphically, e is at the intersection with $A\,B$ of the extended straight line connecting the third-points of the end tangents (see Fig. 32). Knowing ordinates y and y' at the third-points,

$$e = \frac{L\,(5\,y - 4\,y')}{9\,(y - y')} \quad\ldots\ldots\ldots\ldots\ldots\ldots(91a)$$

and, knowing $h = y_c$, and $m = \frac{f}{(8\,h - f)}$:

$$e = \frac{L\,(16\,h - 3\,f)}{3\,(8\,h - 2\,f)} \quad\ldots\ldots\ldots\ldots\ldots\ldots(91b)$$

It is of interest to remember that in classical statics, $e = \frac{L\,M_A}{(M_A - M_B)}$; $m = \frac{f}{f'} = \frac{(M_A + 2\,M_B)}{(2\,M_A + M_B)}$; and,

$$M_B = M_A\,\frac{(2\,m - 1)}{(2 - m)} \quad\ldots\ldots\ldots\ldots\ldots\ldots(92)$$

in which M_A and M_B are the bending moments at Points A and B, respectively, due to external loads.

Intercepts f and f'.—Frequently, when using tables containing ordinates of influence lines,[35] f and f' must be calculated from such ordinates. Two symmetrical ordinates (y at x and y' at $x' = L - x$) are expressed in terms of f and f' (see Equation (5)) as follows:

$$f = L^2\,\frac{(y'\,x' - y\,x)}{x\,x'\,(x' - x)} \quad\ldots\ldots\ldots\ldots\ldots\ldots(93a)$$

and,

$$f' = L^2\,\frac{(y\,x' - y'\,x)}{x\,x'\,(x' - x)} \quad\ldots\ldots\ldots\ldots\ldots\ldots(93b)$$

In other words, knowing the ordinates at the third-points, $f = \frac{9\,(2\,y' - y)}{2}$; $f' = \frac{9\,(2\,y - y')}{2}$; $m = \frac{(2\,y' - y)}{(2\,y - y')}$; etc.

If the ordinates, $h = y_c$ and y, at any distance, x, from Point A are known; and, if $x' = L - x$ from Point B:

$$f = \frac{(y\,L^3 - 8\,h\,x\,(x')^2)}{x\,x'\,(x - x')} \quad\ldots\ldots\ldots\ldots\ldots\ldots(94a)$$

---

[35] "Kontinuierliche Träger," by Gustav Griot, Zurich, Switzerland, 1924.

and,

$$f' = \frac{(8\,h\,x^2\,x' - y\,L^3)}{x\,x'\,(x - x')} \qquad \text{(94b)}$$

If one intercept and the ordinate, h, at the center are known: $f = 8\,h - f'$; and, $f' = 8\,h - f$. For a simple graphical determination of f and f' from two symmetrical ordinates, see Fig. 33.

Mean Ordinates, y_m.—Stresses from distributed loads, W, are $W\,y_m$. The area determined by the influence line and the neutral axis of Beam $A\,B$ between Points A (with $y = 0$) and x, according to Equation (76) is,

$$y_m\,x = \int_0^x y\,dx = x^2\left[x\,(4\,L - 3\,x)\,f + (6\,L^2 - 8\,x\,L + 3\,x^2)\,f'\right]\frac{1}{12\,L^3} \qquad \text{(95)}$$

For loads, W, uniformly distributed from zero to $\frac{L}{2}$:

$$y_m = \frac{(5\,f + 11\,f')}{192} \qquad \text{(96a)}$$

for loads uniformly distributed all over Span L:

$$y_m = \frac{(f + f')}{12} = \frac{2\,h}{3} \qquad \text{(96b)}$$

for a triangular load over the entire length, with zero at Point A and maximum at Point B:

$$y_m = \frac{(12\,f + 8\,f')}{120} \qquad \text{(96c)}$$

For a triangular load over the half span, $\frac{L}{2}$, from zero at Point A to a maximum at the center:

$$y_m = \frac{(9\,f + 16\,f')}{120} \qquad \text{(96d)}$$

and, for a symmetrical triangular load with its maximum intensity at the center:

$$y_m = \frac{5\,(f + f')}{48} \qquad \text{(96e)}$$

As an example, let Beam $A\,B$ be fixed at both ends, and loaded by a triangular load, W, with its maximum intensity at the center. Then, $f' = L$ for M_A; $f = 0$; and, therefore, $y_m = \frac{5\,L}{48}$ and $M_A = W\,y_m = \frac{5\,L\,W}{48}$.

Flat Arches.—When values of $\frac{f}{L} = \frac{f'}{L}$ are relatively small the influence line becomes similar to a common parabola and a circular arch, the equation of which is,

$$y = \frac{4\,x\,x'\,h}{L^2} = \frac{x\,x'\,f}{L^2} \qquad (97)$$

Likewise, all other relations become simple; that is, intercepts at Points A and B of tangents expressed by Equations (85) become: $f_x = \frac{x^2}{L^2}\,f$; and, $f_x' = \frac{(x')^2}{L^2}\,f$ and, according to Equation (89), $r = \frac{L^2}{8\,h}$, or $h = \frac{L^2}{8\,r}$. A convenient formula for determining the approximate length, l, of the flat arch is:

$$l = L\sqrt{1 + \frac{16\,h^2}{3\,L^2}} \qquad (98)$$

Graphical Design of General Influence Lines.—Of the many graphical methods of designing influence lines suggested by the foregoing equations, the following seem to be most efficient; they may be useful, also, for any other application in engineering or architecture where two tangents at given points A and B, are to be joined by a continuous curve.

Influence Lines by Tangents in Centers (Fig. 35).—Draw vertical lines at the three-quarter points (Fig. 35) and obtain $A\,A'' = \frac{f'}{4}$, and $B\,B' = \frac{f}{4}$; then, the straight line, $A'\,B'$, is tangent to the influence line at the center of $A\,B$ (see Equations (86)). Similarly, drawing the vertical lines at $\frac{L}{8}$, the tangents, $A''\,C'''$ at $\frac{L}{4}$ and $C''\,B''$ at $\frac{3\,L}{4}$, are found for Branches $A\,C'$ and $C'\,B$, respectively, with Line $A'\,B'$ forming the end tangent at Point C'. Where these five tangents are not sufficient to determine the inscribed influence line, further divisions into lengths of $\frac{L}{16}$ might be made, with the tangents at Point A, $\frac{L}{4}$, $\frac{L}{2}$, $\frac{3\,L}{4}$, and Point B serving as end tangents for each of the four parts of lengths, $\frac{L}{4}$. This method is recommended where all the influence line must be drawn.

Influence Lines by Symmetrical Ordinates (Fig. 33).—To determine the exact ordinates at any distance from Point A (for example, at Points D and E, Fig. 33), Equations (5) and (80) are used. Points D and E are projected to the end tangents and Points $A\,A' = D\,D' = \frac{f'\,x}{L}$; and, $B\,B' = E\,E' = \frac{f\,x}{L}$. Point D'' is plotted on Line $A'\,B$ and Point E'' on Line $A\,B'$, making $A\,A'' = D\,D''$ and $B\,B'' = E\,E''$. The straight line, $A''\,B''$, then determines, at Points D and E, the two points of the influence line, D''' and E'''.

On the other hand, knowing any two symmetrical ordinates, y and y', the end tangents may be obtained by reversing the process (see Fig. 33). The straight line, $A'\,B'$ (Fig. 33), crosses Line $A\,B$ at the intersection of the influence line.

Influence Lines of Bending Moments, Reactions, and Shear.—As shown in Figs. 2, 29, and 30, one span of the structure at a time is being deformed from within, in accordance with the stress for which the influence line is wanted; all other spans are deformed through rotation at the ends, and form general influence lines as analyzed herein. The one span having a special influence line is analyzed by considering it free at the ends and then deducting the effect of the continuity.

Unit Displacement in Simple Beam $A\ B$.—A unit angular displacement or rotation at Point E, distant a from Point A and $a' = L - a$ from Point B, breaks the beam at Point E (Fig. 36(a)) so that $\frac{A\ A'}{A\ E} = 1$. Therefore, $A\ A' = A\ E = a$; and, $A\ E'\ B$ is the influence line of the bending moments, M_E.[36]

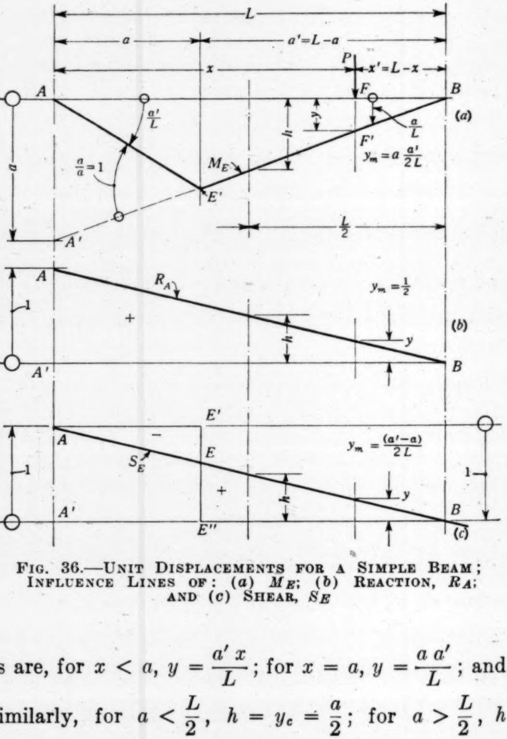

FIG. 36.—UNIT DISPLACEMENTS FOR A SIMPLE BEAM; INFLUENCE LINES OF: (a) M_E; (b) REACTION, R_A; AND (c) SHEAR, S_E

The ordinates are, for $x < a$, $y = \frac{a'\,x}{L}$; for $x = a$, $y = \frac{a\,a'}{L}$; and, for $x > a$, $y = \frac{a\,x'}{L}$. Similarly, for $a < \frac{L}{2}$, $h = y_c = \frac{a}{2}$; for $a > \frac{L}{2}$, $h = \frac{a'}{2}$; and $y_m = \frac{a\,a'}{2\,L}$.

---

[36] "Table of Moment Coefficients for One-Span Beams; Simple or Fixed," by S. M. Cotten, *Engineering News-Record,* September 27, 1917, p. 613.

When Point A is translated one unit (Fig. 36(b)) so that $A' A = 1$, Line $A B$ is the influence line of reaction, R_A, at Point A, so that $R_A = P y$, in which $y = \frac{x'}{L}$; $h = \frac{1}{2}$; and, $y_m = \frac{1}{2}$.

A normal unit displacement at Point E will break the beam so that $E' E'' = 1$. The same effect is obtained by a unit settlement, $A' A$ (Fig. 36(c)). Line $A B$ is the influence line for shear, with the reference axis at $A E'$ from Points A to E and at $E'' B$ from Points E to B. The shear is $S_E = P y$, in which the ordinates are, for $x < a$, $y = -\frac{x}{L}$; and, for $x > a$, $y = \frac{x'}{L}$. Likewise, for $a < \frac{L}{2}$, $h = \frac{1}{2}$; and, for $a > \frac{L}{2}$, $h = -\frac{1}{2}$; and $y_m = \frac{(a' - a)}{2 L}$.

It is to be noted that even in the case of the simple beam the influence lines may be applied to advantage, in comparison with purely algebraic methods, especially in solving for bending moments for great variety of loads.

Influence Lines in Restrained Beams.—When Beam $A B$ is part of a continuous structure (Figs. 1 and 29), the rotation at the ends caused by interior displacements (see Fig. 36), will be resisted by adjoining members, making the influence line, $A B$, the sum of one of a simple beam and a general influence line from restraint at the ends. The corresponding equations of ordinates are indicated in Table 2(c), 2(d), 2(e), and 2(f).

HYDRAULIC TESTS ON THE SPILLWAY OF THE MADDEN DAM

By RICHARD R. RANDOLPH, JR.,[1] ESQ.

WITH DISCUSSION BY MESSRS. ETTORE SCIMEMI, J. C. STEVENS, F. W. EDWARDS, MORROUGH P. O'BRIEN, AND RICHARD R. RANDOLPH, JR.

SYNOPSIS

Several interesting and unique hydraulic tests have been made in connection with the Madden Dam project located on the Chagres River, in the Isthmus of Panama. A number of features of the design of the spillway section, but principally a plan for dissipating the energy of the overflow at the toe of the dam, were developed from model studies. These studies are described in Part I.[2] In order to check the resulting predictions, apparatus as nearly similar as possible to that used on the models, was installed in the prototype spillway at apportionate positions, as described in Part II.

Field tests other than those on the spillway have also been made.[3] The discharge and loss in head through the needle-valve outlet conduits and the sluice-ways were measured. The efficacy of the air vents for these conduits was determined by measuring the quantity of air flowing through them at various heads and gate-openings.

PART I.—MODEL TESTS

THE PROJECT

Madden Dam is a part of the Panama Canal project, being built primarily to create a reservoir for storing water to use for lock operation and for controlling floods. Power development is small and more or less incidental. The dam is on the same river as that which forms Gatun Lake and is situated about 10 miles up stream from the point where the river flows into the canal.

NOTE.—Published in May, 1937, *Proceedings*.

[3] *The Military Engineer*, Vol. XXVIII, No. 162, November-December, 1936, p. 438.

The principal features of the Madden Dam project consist of the main concrete dam across the Chagres River, the power plant, an earth and gravel-fill dam continuing from the left abutment of the main dam; and several earth and gravel-fill dams across saddles around the rim of the reservoir. The main dam is of the massive concrete straight-gravity type, consisting of an overflow spillway section across the river, with abutment sections on either side (see Figs. 12 and 13). It is about 974 ft long at the top and about 220 ft high at the maximum section from the lowest point of the foundation to the top of the roadway. The spillway is divided into four 100-ft openings by three 12-ft concrete piers. Structural steel drum-gates, 18 ft high, are installed on the concrete crests in these openings.

The flood water passing over the spillway crest has a drop of about 173 ft to the toe at the maximum expected discharge of 260 000 cu ft per sec. The energy of this overflow will be more than 5 000 000 hp, and the velocity at the toe will be about 100 ft per sec. With this energy exerted at the base of the dam it was considered advisable to devise means of dissipation so that the velocity would be checked enough to eliminate erosion of the foundation rock.

THE MODEL

During the summer and fall of 1931, a model of Madden Dam was built and tested at the Hydraulic Laboratory of the Colorado Agricultural College, at Fort Collins, Colo.[4] The model of the spillway was built on a scale of 1:72, or 1 in. (linear dimension) on the model equal to 6 ft on the prototype. The spillway section, with drum-gates installed in the crest, was reproduced accurately to scale. The power house was represented with the needle-valves discharging through the down-stream wall. The contours of the river bed below the dam were reproduced from surveys to represent the original rock and overlying earth and gravel deposits. (Described in terms of equivalent prototype dimensions, this model had four 100-ft gate-openings, a spillway crest at Elevation 232.0, and an apron width of 440 ft between side walls. The radius of the bucket is 60 ft. For a flow of 260 000 cu ft per sec, the tail-water depth is approximately 80 ft.)

MODEL TESTS

Dentated Sill Apron.—In the original proposed design of the spillway a concrete apron, extending about 120 ft down stream from the toe of the dam with a dentated sill developed by Professor Theodor Rehbock[5] at the end, was proposed. This apron was level and at a low elevation in order to follow the average rock level.

Tests on a model of this set-up showed that the sheet of water flowing down the spillway cut through the tail-water, which was of considerable depth, at all stages of flow, with very little surface disturbance or loss in velocity, and struck the dentated sill with terrific force. Fig. 1 shows a cross-section along this apron (through the dentate) with the maximum expected discharge. Velocity measurements were taken at various points with a Pitot tube, and lines of equal velocity, converted to prototype scale, have been drawn representing contours. The high-velocity stream is depressed by the back roll of water above the sill and elevated by the roller below the sill. This latter action, of course, relieves the river bed of erosion velocities. The upward deflected jet continues along the surface, however, at comparatively high velocities and erodes the river banks.

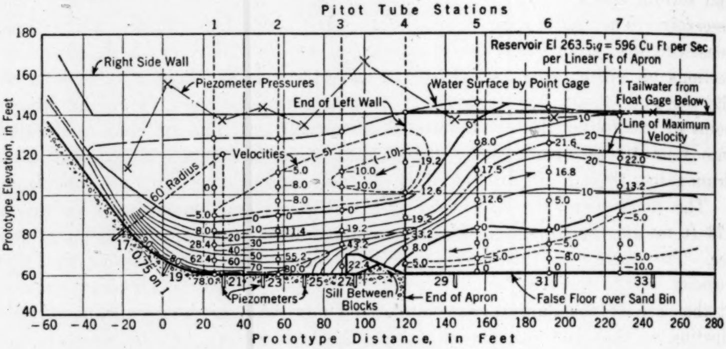

FIG. 1.—VELOCITY CONTOURS ALONG A SECTION THROUGH THE DENTALS; ORIGINAL MODEL DESIGN

The next step in the experiments was to substitute a sill with a solid vertical face for the dentated form. Various heights of this solid sill were tried, and it was found that a height of 6 ft was just as effective in preventing erosion below the apron as the dentated sill 10 ft high. However, the surface flow conditions were unstable, the boil above the solid sill being much more irregular and fluctuating. The flow allowed through the dentates seems to stabilize this boiling, and there is little or no pulsation or surging in the tail-water, making the performance of the dentated sill more satisfactory.

It would seem that a sill under these conditions should be made only high enough to cover the range of the high velocities of the overflow jet along the bottom, and, consequently, its height would vary inversely with that of the dam, because the higher the dam the thinner the overflow sheet will be at the toe. For Madden Dam a satisfactory sill was one-thirtieth of the total height of the dam. The height of the sill varies directly with the depth of water discharging over the crest. In the present case the sill was one-fifth of the expected maximum depth. Another factor, of less importance, is the depth of water that is to be flowing over the sill. The height of the sill is modified directly by the depth of the tail-water because the greater this depth, the thicker the overflowing jet will become in passing through it, and a higher sill is necessitated to cover the range of the thickened jet. A sill, or a series of blocks with no tail-water over them, is practically useless as the jet is merely sprayed into the air almost as high as the original water surface, and falls to the river bed again, gaining nearly all its original velocity. There must be tail-water to float it away, so to speak, after the jet has been deflected from the river bed. Even then, the high velocity is merely transferred to the surface and may erode the banks, and is undesirable.

If any type of block sill is used on this apron, entire dependence is placed on it for stopping the velocity, and a small break starting anywhere would endanger the entire structure. Logs coming over the spillway would be carried down by the high-velocity stream to strike directly against the sill. The proposed dentated sill was 10 ft high and 30 ft wide, involving a large quantity of concrete and form work in its construction. The anchorage would have been difficult and expensive. Furthermore, a royalty would have had to be paid for using this type of sill. With these inherent disadvantages to the use of a block sill, investigation of other devices for dissipating the energy of the overflow was started.

HYDRAULIC-JUMP APRON

Level Apron.—The feasibility of using the phenomenon of the hydraulic jump for energy dissipation was studied first. The dentated sill was removed from the apron. As stated before, this apron was low in the tail-water, being at Elevation 60, and the depths over it at all stages of discharge were apparently too great to allow the hydraulic jump to form, and high velocities persisted along the bottom for a considerable distance down stream. This can be seen in Fig. 2 which shows the distribution of velocities when the tail-water is at its natural depth.

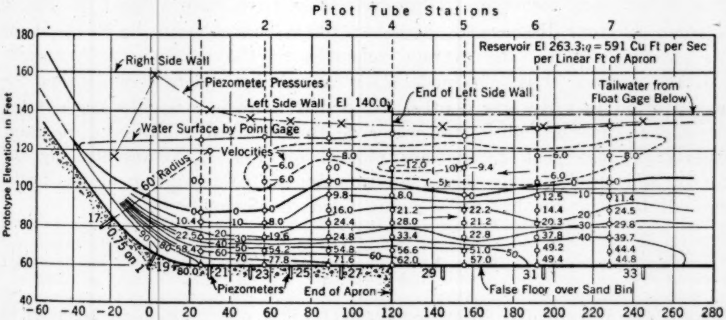

FIG. 2.—VELOCITY CONTOURS FOR FLOW OVER LEVEL APRON, WITH DEEP OR NATURAL TAIL-WATER

It was found that if the tail-water was lowered, the flow over the crest of the dam being kept constant, a certain point was reached at which the surface of the water became very turbulent and rose more or less abruptly from the toe of the dam, thence flowing off in a quiescent state. In other words, an apparently good hydraulic jump formation was taking place.

The tail-water was adjusted to force the beginning of this jump as far as possible back on the toe of the dam without "drowning" it. This adjustment was made for several flows, and the required tail-water noted. A plot of these elevations against the discharge is shown in Fig. 3 as circle points. A check made with a Pitot tube showed that such adjustments of the tail-water were producing the maximum retardation of the velocities along the bottom. A Pitot tube was placed, and remained fixed, at a position within the jump and just off the floor of the apron. The tail-water was then varied and the resultant velocities, as indicated by the Pitot tube, were recorded. These velocities have been plotted in Fig. 4 for three different discharges. Although the velocities from the Pitot tube in this position are not the average velocities of the sections, it is thought that the curves thus obtained, show a relative energy dissipation for the variation in tail-water depths. Note that there is a decided peak in the curves that gives a definite tail-water depth to obtain a minimum resultant velocity. These peak points are plotted on Fig. 3, represented by the crosses, and check closely the first adjustments. Computation of the depths required to form the hydraulic jump, from the formula,

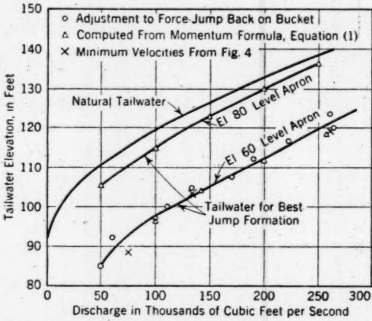

FIG. 3.—TAIL-WATER DEPTHS REQUIRED TO CAUSE THE BEST HYDRAULIC JUMP PERFORMANCE ON LEVEL APRONS AT DIFFERENT ELEVATIONS

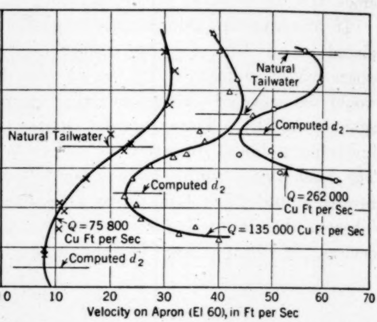

FIG. 4.—VELOCITIES AT VARIOUS DEPTHS OF TAIL-WATER FOR THE SAME FLOW ON A LEVEL APRON

$$d_2 = \sqrt{\frac{d^2_1}{4} + \frac{2V^2_1 d_1}{g}} - \frac{d_1}{2} \quad \dots\dots\dots\dots\dots\dots (1)$$

shows close agreement. These computed points are plotted as triangles in Fig. 3; V_1, or the average velocity before the jump, was obtained from Pitot measurements, and,

$$d_1 = \frac{q}{V_1} \quad \dots\dots\dots\dots\dots\dots\dots\dots (2)$$

was computed, in which $q = C d_c^{\frac{3}{2}}$. (In the notation of this paper an effort has been made to conform with "Symbols for Hydraulics,"[6] compiled by a

Committee of the American Standards Association, with Society representation, and approved by the Association in 1929).

It is seen, then, that the natural tail-water at the dam site affords too great a depth over this apron to allow the jump to form. In fact, at natural tail-water depths, the velocities are about as great as can exist along the bottom, as may be seen in Fig. 4. This is contrary to a somewhat general acceptance that a deep tail-water is an assurance for the dissipation of the overflow velocity. With the natural tail-water lowered to allow the hydraulic jump formation, the rate of velocity retardation is much faster and the final velocity, after the jump has been fully completed, is decidedly less than occurs at the same distance down stream under high tail-water. This may be seen by comparing Figs. 2 and 5. Unfortunately, the section does not extend far enough down stream, in Fig. 5, to show this final point of complete recovery of the jump where the velocity has been reduced to a minimum and is practically constant across the section.

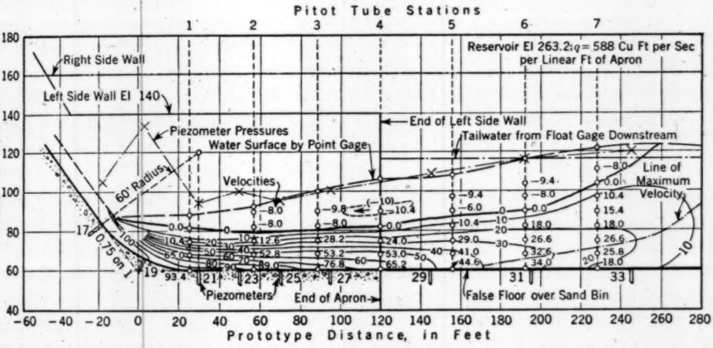

FIG. 5.—VELOCITY CONTOURS FOR FLOW OVER A LEVEL APRON, WITH TAIL-WATER LOWERED TO PERMIT THE FORMATION OF AN HYDRAULIC JUMP

The surface rise in the jump for a flow of this magnitude is very gradual, and the jump action extends for a considerable distance down stream, although the point of beginning is forced back on the toe of the dam. A back flow or roller occurs along the rise. The higher velocities hug closely to the floor until gradually retarded. The flow lines shown in Fig. 5 are typical although for smaller discharges the surface rise is more abrupt and, consequently, the length of the jump is shorter.

The depths required for jump formation, obtained by lowering the tail-water, are considerably less than the actual existent depths over an apron placed at this low level of Elevation 60. Since the natural tail-water at the dam site is fixed, it was necessary to raise the apron to a higher elevation in order to lessen the depths over it so that the jump would not be "drowned out." This alteration was made to the model, the apron being raised 20 ft to Elevation 80 and the foregoing tests were repeated. The jump formed well up on this apron at all flows although indications were that it could be raised 2 or 3 ft higher, which would cause a closer coincidence of the natural tail-water depths to those required to produce the best hydraulic jump. This is illustrated in Fig. 3.

Sloped Apron.—Although a close coincidence may be obtained there would be only one flow, theoretically, where the natural tail-water depth over the level apron would give exactly the depth required for the jump. It was thought that, if the apron was inclined, the jump could move up or down the slope until the depth required was encountered, regardless of the variations in the tail-water. Furthermore, a considerable saving in concrete would result in this case because the sloped apron would more nearly follow the original rock contour.

From the aforementioned experiments of the hydraulic jump on the level apron, it was found that the depths which caused the minimum floor velocities agreed closely with the theoretical depths for the jump formation as computed by the momentum formula. For the sloped apron the computation becomes involved, due to the necessity of considering the gravity component of the water in the jump and nothing satisfactory could be developed from attempts to adapt the formula to this condition. A formula that included this weight component would show that a greater depth is required for the jump, which simply means that it would form farther down the slope where this greater depth is encountered. Even with this knowledge there is no method of predicting a satisfactory tail-water elevation, one that would start the jump well up on the apron at any flow. The difficulty lies in the fact that the datum plane is indeterminate, above which the required vertical depths are to be assumed.

The theoretical position of the jump can be computed but it would not be known whether this position would start the jump well back against the face of the dam and yet not so far back as to "drown it out." Unless the jump starts well up on the apron, full use is not made of the apron length. The calculated position might start the jump some distance down the slope away from the face of the dam and, therefore, for equal protection this length must be added to the pavement down stream.

Apparently, the solution was a case of experimental "cut and try" and a series of tests was made on aprons of various elevations and slopes. Fig. 6 shows tests on aprons of two different slopes. The apron first tested (Apron *A*) had a slope of 1 on 6.6, beginning at Elevation 84. The tail-water below this apron was adjusted so that the jump formed well up on the apron, starting back against the face of the dam. This condition was the first desired prerequisite. It is seen, however, that the required jump depths are less than the actual depths resulting from natural tail-water, indicating that the apron should be raised. This was done until it was found that an apron beginning at about Elevation 97 gave the best average results. The tail-water over this apron was adjusted until the jump was forced back against the face of the dam, as was the first procedure in the tests on each apron. A check was then made of this adjustment by measuring the velocities under various depths of tail-water.

A Pitot tube was placed, and remained fixed, at a point just off the floor and near the end of the apron. The tail-water was raised and lowered until a depth was found which caused the least velocity to be registered.

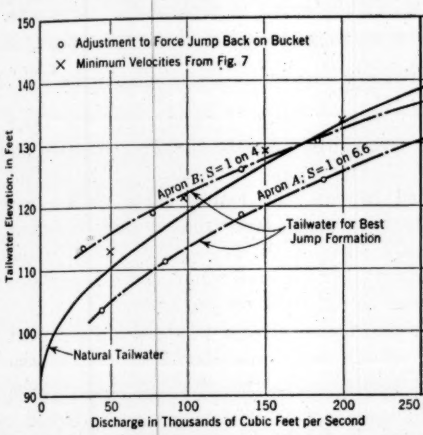

FIG. 6.—TAIL-WATER DEPTHS REQUIRED TO CAUSE THE BEST HYDRAULIC JUMP FORMATION ON SLOPED APRONS AT DIFFERENT ELEVATIONS

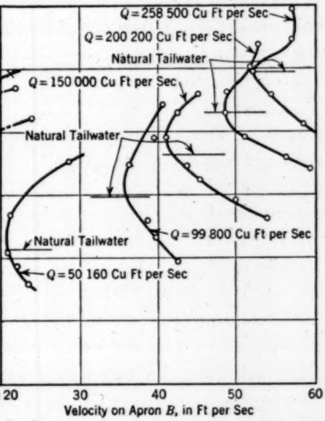

FIG. 7.—VELOCITIES AT VARIOUS DEPTHS OF TAIL-WATER FOR THE SAME FLOW ON A SLOPED APRON

The resulting velocity curves, obtained from the Pitot tube readings, are shown in Fig. 7. The peak points from these curves, indicating the tail-water required for minimum velocities, check closely the tail-water adjustments first made. The latter have been plotted, in Fig. 6, against the discharge to show the range of depths required for the best hydraulic jump formation.

Different slopes were tried, but apparently a slope of 1 on 4 was about as steep as could be used and still retain a good jump formation. On steeper slopes the overflowing jet cut under the tail-water with little surface disturbance or consequent loss of energy. From a study of the curves shown in Fig. 6, indications are that if Apron *A* is raised, a closer average coincidence of the jump depths with the natural tail-water would be obtained than in the case with the raised Apron *B*. This leads to the thought that the shape of the jump curve may be varied by changing the slope of the apron. This curve could then be made to conform closely with any given natural tail-water curve by adopting a proper slope to the apron.

The steepest apron that could be used would result in the greatest economy in this case and since it was found that the depths of the jump over Apron *B*, beginning at Elevation 97.3, averaged closely with the actual tail-water depths, this apron was adopted as satisfactory for the final design of the model. From later studies of the results of these tests, the final construction plans were changed to lengthen the spillway apron by 30 ft and to lower the elevation of beginning of the slope 3 ft.

Both these alterations were seen to be beneficial. The jump curve for Apron *B* shown in Fig. 6 lies above the natural tail-water rating curve at the lower discharges, indicating that the natural depths are not quite sufficient to force the jump well up on the apron at these flows. It may be supposed that, since the tail-water depth is fixed by the rating curve, if the apron is lowered the depth over it is increased and more nearly approaches that required for the jump.

Lowering the apron will improve the jump formation at the lower stages of flow, which occur more frequently. At the higher discharges the required depth of jump will fall slightly below the natural tail-water, but a factor of safety is so obtained in case the rating curve (which was extrapolated for higher flows) is less, or in case the natural tail-water is lowered at the dam site, by the erosion of the gravel beds down stream. Incidentally, the model tests showed that the tail-water could be lowered as much as 20 ft without the jump being swept off the apron.

Extending the apron 30 ft farther down stream would furnish greater protection to the river bed and, as the slope was also flattened, the concrete saved at the upper end was used to make the extension down stream. The apron as built at Madden Dam had a slope of 1 on 4.3, beginning at a point tangent to the bucket (radius, 60 ft) at Elevation 94.3 and extending from this point 158.15 ft down stream with a sill 5.7 ft high, having a sloping face at the end.

Deflector Sill.—At all but the smallest flows the length of the hydraulic jump, or the point down stream where full recovery takes place, is beyond the end of the proposed apron. Theoretically the apron or protective pavement should extend down stream to a point where the bottom velocities have been reduced by the jump to an extent which will not erode the foundation rock. It was found from the tests that a small turn-up sill at the end of the apron would lift the velocities off the river bed below, but would not destroy the functioning of the jump. The thought was that if the sill was too high, impact would result and the stream would be deflected upward, thus "blocking out" the static pressure of the tail-water necessary for the jump. The tail-water might even be swept out between the toe of the dam and the sill. The sill should act only as a deflector, to lift the sheet of water just high enough to clear the bottom, allowing it to continue down stream where the velocities are dissipated in the normal action of the jump.

Expected Jump Performance.—The action of this sill and the functioning of the hydraulic jump on a sloped apron are shown in Fig. 8, which is a composite of some of the results obtained from the model tests on the final design of the sloped apron, under natural tail-water conditions. Water-surface curves, taken by point-gage measurements, are drawn for five different rates of flow, covering the entire range of discharge. Velocities through each cross-section were measured with a Pitot tube. Velocity contours for the lowest flow only (but which are typical) have been drawn in Fig. 8. Energy gradients, representing the maximum velocity heads above the water surface at various stations, are shown for each discharge. The loss in energy through the jump is illustrated graphically, being greater and quicker for the smaller flows. Velocities in the overflowing sheets just before they strike the tail-water were taken with a Pitot tube and were found to agree closely with Equation (2) when d_1 was measured with a point gage. These velocities, especially at the higher flows, amounted to almost the theoretical values since the surfaces of the model were painted and sand-papered to a very smooth finish. On the prototype structure greater loss in friction may be expected. Provision was made at Madden Dam to measure this loss by installing Pitot tubes on the spillway toe. A factor of safety is obtained, however, by keeping the friction losses on the model low.

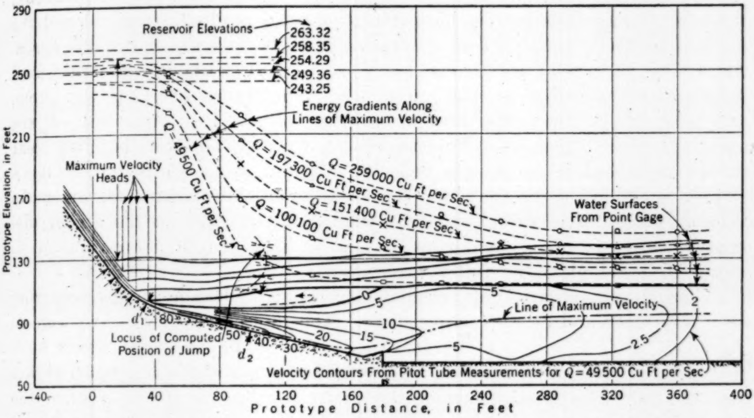

FIG. 8.—HYDRAULIC RELATIONS OF THE FLOW OVER A MODEL OF THE MADDEN SPILLWAY, REPRESENTING NATURAL CONDITIONS FOR THE ENTIRE RANGE OF DISCHARGE

The velocity, V_1, and the depth, d_1, before the jump being measured in each case, the depth required for the hydraulic jump was computed from Equation (1). These depths, or d_2, have been plotted, in Fig. 8, parallel to the slope of the apron and at the points where they are crossed by the tail-water elevations, projected up stream, a line is drawn as the locus of the theoretical position of the jump. It is perhaps significant that these computed positions lie fairly close together near the center of the apron.

As on a level apron, the highest velocities lie along the floor, becoming gradually less toward the top with a reverse flow or back roll on the surface (see Fig. 5). At the beginning of the jump, pressures on the apron, as recorded from piezometers, lie slightly below the water surface, measured with a point gage. This is probably due to the air content of the water. Pressure recorded on the up-stream face of the sill is little greater than the static pressure which indicates only slight impact. Pressure recorded in the curve of the bucket at the toe of the dam is higher than the static depth of water, which may be attributed to the centrifugal force of the stream.

Retardation of the velocity of the overflowing sheet is not instantaneous; the highest velocities persist along the floor until gradually reduced and the jump is not fully recovered until some distance beyond the end of the apron. At a flow of 49 500 cu ft per sec (see Fig 8), although the measured velocity of the water at the toe of the dam before entering the jump, was 89.3 ft per sec, the highest velocity obtained at the end of the apron was 16.8 ft per sec. This remaining velocity, however, is lifted clear of the river bed below by the deflector sill and about 40 ft farther down stream, at which point the jump action is practically completed, the mean velocity of the cross-section was less than 7 ft per sec. At the higher discharges the action is analogous but a greater length down stream is required to complete the full recovery.

There is a similarity of action between the hydraulic jumps occurring on a level floor and on an inclined floor. The rate of velocity retardation on Apron *B*, Fig. 6, seems to be as fast as that along the level apron until the end of the slope is reached, after which the retardation is much slower and the velocities persist farther down stream than is the case when the jump occurs on a level apron. Apparently, the stream is taken down to depths too great to allow the jump to form completely. The steeper the slope of the apron the less perfect is the jump formation. The slope of 1 on 4, adopted here for concrete economy, is about the steepest that can be used and still obtain a satisfactory jump formation.

The jump performance, as discussed in connection with Fig. 8, is typical for the total range of discharge over the spillway. At any flow the beginning of the jump is forced back against the face of the dam and although the distance down stream required for full recovery increases with the discharge and extends beyond the end of the apron, the bottom velocities are lifted free from the foundation rock by the deflector sill so that no erosion results. It was found to be feasible, therefore, to shorten the length of the theoretical spillway apron considerably by placing a sill of the proper dimensions at the end. This apron need only cover the start of the hydraulic jump where the first impact and consequent turmoil occur.

Fig. 9 shows the characteristic relations of the hydraulic jump when it is made to form on a sloped apron at the toe of an over-flow dam. The curves have been obtained from results of these model studies, but it is believed they can be applied, for design approximations, to any installation roughly similar to Madden Dam. The functions represented by the curves are directly proportional to the depth over the crest, and the height of the fall, and the values may be used for any dam where the ratio of these two factors is known.

A datum line is assumed, usually at low flow, or no flow, tail-water elevation. A sufficient length of the apron must be above this elevation in order that the beginning of the jump (which moves up stream at each increase in discharge) may occur on a flat slope. A good jump formation will obtain with the point of beginning on the curved surface of the bucket, but not if it is forced back on the steep slope of the down-stream face of the dam. The jump should begin as far back as possible, however, in order to utilize the full length of the apron. For the maximum expected flow it should begin at the point of curvature of the spillway bucket from the face of the dam.

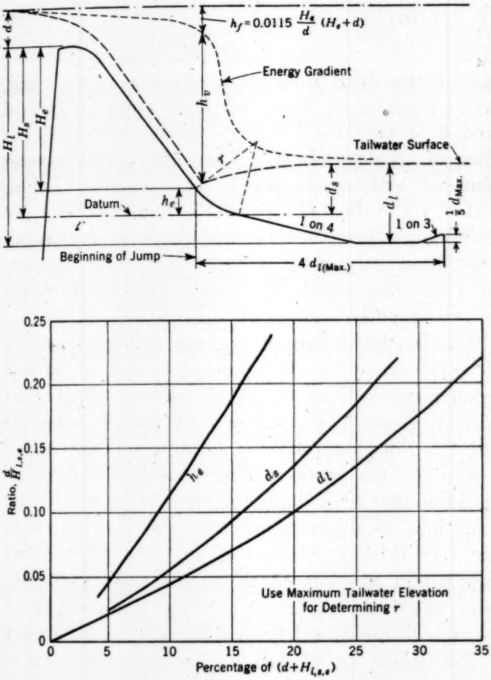

FIG. 9.—HYDRAULIC RELATIONS REQUIRED TO HOLD JUMP FORMATIONS ON THE SLOPED APRON AT TOE OF OVERFLOW DAMS

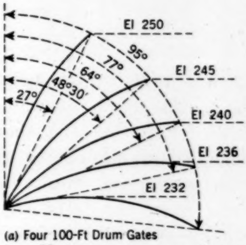

(a) Four 100-Ft Drum Gates

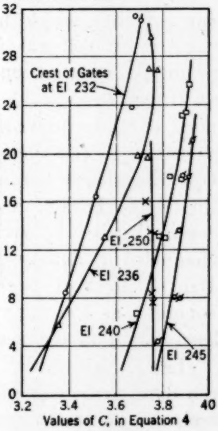

FIG. 10.—COEFFICIENTS OF DISCHARGE OVER CREST, DRUM-GATES AT VARIOUS POSITIONS

The maximum expected tail-water is then used to determine the maximum, d_s, and the maximum, h_e, which locate the point of curvature for the bucket with the radius, r, as shown in Fig. 9. The slope of the apron should not exceed 1 on 4 and should be carried down at least to a depth represented by the function, d_l.

Friction Loss at Toe.—Measurements of the velocity through the overflow jet at the toe of the dam were made with a Pitot tube. They were taken at the same station at the toe, but for various depths of water over the crest. The difference between the indicated mean velocity head from the Pitot tube and the total theoretical velocity head (which is the vertical distance between water surfaces) was taken as the head loss due to friction. The values thus obtained were found to be averaged closely by a curve of the form:

$$h_f = 0.0115 \frac{H}{d_c} (H + d_c) \text{ ....(3)}$$

in which H = the height of the dam, from apex of crest to toe; and, d_c = the depth of water over the crest, from reservoir level to apex of crest. Equation (3) should hold true for friction loss at the toe of any model dam similar to that of Madden Dam. This model was covered with galvanized iron, enameled and sand-papered very smooth. Indications from the tests are that the value, C = 0.0115, increases with the roughness of the surface and would be 0.0135 for models covered with galvanized iron which had not been painted or sand-papered. For concrete dams C = 0.02 was found to average closely the values obtained from the prototype tests, discussed subsequently.

Other Devices.—Variations in the design of the apron were tried but none of them proved successful enough to be incorporated or to warrant a change in the sloped apron layout. Some of the alterations tested were: (*a*) The sloped apron built in steps; (*b*) a channel or pocket below the lip of the bucket cut into the sloped apron; (*c*) a high spillway bucket designed with a vertical drop to the apron paving[7]; and (*d*) transverse channels or dentates cut into the high bucket (later used at Tygart Dam).[8] Most of these alterations were attempted with the idea of saving concrete, as the apron was very thick at the toe of the dam after it had been raised to the necessary height to cause the hydraulic jump formation.

Later, this heavy apron was included in computing the stability of the dam, greatly increasing the factor of safety against earthquake stresses and also against sliding. The simplicity of design, the ruggedness of performance, and the adaptability to conditions at Madden Dam gave preference to the use of the plain sloped apron, with a small deflector sill, to obtain the hydraulic jump; so that investigations of other devices for dissipating the energy of the overflow were discontinued.

OTHER FACTORS OF SPILLWAY DESIGN

Right Bank Excavation.—In addition to the development of the spillway apron, model tests were made to determine other features of the spillway design. The proper treatment of the excavation along the right bank proved difficult of a theoretical analysis. Immediately below the dam site, the river bends abruptly to the left and the original contours of the right bank protruded across the flow from the last spillway gate. The original design contemplated leaving this hillside in place and paving the steep 1 on 1 slope for protection against the spillway flow. The model tests showed that the hillside was too steep for the water to "ride" and, consequently, the flow slipped down into a concentrated jet at the foot of the slope and caused disastrous erosion down stream from the pavement. Alterations were tried in which this slope was made flatter, but little success was attained in attempting to make the water flow in a uniform sheet along a slope of almost any inclination, however slight. A warped surface probably could have been developed that would carry its share of the discharge but still no provision would be made for checking the velocity of the water. A sill placed along the top was not very satisfactory as the tail-water over it became less and less up the slope and the flow was sprayed into the air, only to fall back on the unprotected bank below the apron.

---

[7] *Engineering News-Record,* March 14, 1935, p. 376.

[8] *The Military Engineer,* September-October, 1936, p. 331.

It was finally decided that the safest and most positive results would be attained by cutting into the bank and extending the apron across the full width of the spillway. It was found possible to level off gradually and raise the down-stream end of the sloped apron toward this right bank (see Figs. 12 and 13). However, the apron was kept down under the tail-water so that the depth of water over it was sufficient to form the hydraulic jump at any flow.

Tail-Race Walls.—Another problem that arose from the effects of this bend in the river below the dam was the checking of the eddy or reverse flow which naturally formed along the left bank. This eddy is accentuated by the water surface in the hydraulic jump on the spillway apron which is at a lower elevation than the tail-water below the power house. This condition creates a difference in pressure and a cross-flow. The effect is detrimental to the functioning of the jump, causing an unbalanced condition resulting in concentrations of velocity. This reverse flow also tends to deposit sand and gravel in the draft-tube openings and to set up surgings in the tail-race which might hinder the speed regulation of the turbines.

To remedy the condition a division wall was placed down stream from the power house to separate the spillway and turbine tail-race. Theoretically, this wall should be high enough to prevent overflow into the spillway at any discharge and should extend down stream until the water-surface rise in hydraulic jumps levels out. It was found by experimentation that if the height of the wall followed the actual surface rise in the jump, the over-pour on to the top of the jump caused no harm. Accordingly, the wall was built at this point 12 ft below the elevation of the maximum expected tail-water, with a resultant saving in concrete. On the other side of the river, the hydraulic jump is contained by paving along the bank.

Erosion Below Spillway Apron.—Prediction of the nature of the erosion likely to occur below the spillway apron was possible from the model studies. As previously stated, the original gravel deposits in the river bed were represented on the model by building up the contours in sand (see Fig. 1). No attempt was made to graduate this sand to the scale of the model as the objective was to reduce the velocities to a point where no erosion of the foundation rock itself would occur. Thus, erosion tests on the model were qualitative rather than quantitative. It was found that for the smaller flows, up to a quantity representing 50 000 cu ft per sec, the sand contours were scarcely disturbed, but for larger flows the over-burden was washed from the right bank and river bottom below the apron and deposited as a bar across the main river channel. As successive floods free from sediment are passed over the spillway, this bar may be expected to move farther down stream and expose the bed-rock. The maximum expected velocity to which this rock may be subjected is about 25 ft per sec moving along the surface without direct impact. From field tests in which specimens of the foundation rock were subjected to high velocity jets, no erosion is expected at this velocity.

Drum-Gate Operation.—The proper operation of the spillway drum-gates was quickly seen from the model performance. The operation is necessarily fixed by the method adopted for dissipating the energy of the overflow. One of the first prerequisites of a good hydraulic jump formation is to have the water enter the jump in a uniform jet of equal velocity across its entire width. This is readily accomplished at Madden Dam by opening the four spillway drum-gates simultaneously. The design of these gates allows for spilling over the top at any partial opening. If one, two, or three gates are opened, the jump on the apron is broken up by the inpour of the adjacent tail-water. The water below a closed gate will be at a higher elevation than the surface rise of the water in the jump and a cross-flow will result. Although the jump is not completely "drowned out" it was found that concentrations of flow were set up which greatly aggravated the erosion below the apron. Except for the small flows, or for very short periods of time, it would be dangerous to open the gates singly.

Discharge of Drum-Gates.—In the crest of the model, the drum-gates were reproduced to scale. With the gates at several different positions of closure and the pond at various elevations, coefficients of discharge curves were determined by plotting values of C in the formula:

$$Q = C L H^{1.5} \dotfill (4)$$

against the head on the gate crest (see Fig. 10). In the tests the head was measured, in the customary manner, from the highest point on the gate to the water surface up stream where the velocity of approach was negligible.

From these curves the maximum discharge of the spillway was determined, and was found to be in excess of the design assumptions.

The quantity of water that would discharge over the top of the gates in the fully raised position was found. This information was desired as it may prove advantageous to throttle the discharge by raising the gates after the peak of a flood has passed, in order to protect shipping in the canal. Passage is interrupted when the flow exceeds 50 000 cu ft per sec at the point where the river and the canal join down stream. This was one of the factors considered in determining the height of the drum-gates.

Nappes and Pressures on the Crest.—At different gate-openings, with various heads of water flowing over the crest of the gates, the outlines of the surface curves were taken by means of a point gage. The pressures along the crest were obtained by piezometers. Fig. 11 with Table 1 shows a typical set of curves taken for a condition representing the drum-gates fully opened. It will be noted that a vacuum was recorded on the down-stream face of the crest for all the flows tested. Preliminary analysis of the proposed crest by the flow-net method showed this vacuum to exist, and its effect was recognized in the design of the crest. A check of this analysis was made by reproducing the assumed conditions on the model. A very close agreement was found in the pressures, both negative and positive, along the crest. However, the water-surface curve obtained on the model lay considerably below the water surface assumed for the computation, from the apex of the crest down stream.

3.........	150 000	22.33	6.........	253 500	31.01

Spillway Retaining Walls.—In order to check the height and stability of end retaining walls of the spillway, nappes and pressures against them were measured at various positions of the gates. The maximum possible case was taken with the forebay at its highest elevation and the gates opening. It was found that as originally designed, the wall needed to be raised slightly and the outline changed in order to follow more closely the shape taken by the overflowing nappe.

At one position of the partly opened gate, this nappe rose nearly to the top of the wall for practically its entire length. Nevertheless, the velocity of the water was such that a negligible pressure was recorded against the wall, except at the very bottom where the jet has finally spread enough to cause impact. This impact amounted roughly to a pressure equal to the depth of water flowing over the crest of the gate.

Other Features.—Other features of the design (not previously discussed herein), that were developed from the model tests included: The proper location of sluice-ways through the spillway section; the shape of the deflecting lip over the sluice-way exits; and the location of the control float intake, at the drum-gate. The sluice-ways, which were rectangular (5 ft 8 in. by 10 ft 0 in. high) discharged into the hydraulic jump on the spillway apron at Elevation 89.67, about the level of low tail-water (see Fig. 13). No serious interference with the jump formation was noted in the tests when the sluice-ways were located between the spillway gates; that is, below the spillway piers. The original plans were changed to move them to this location from the first position which was midway between the piers. Over the exit, where the sluice-way comes through the down-stream face of the spillway section, a deflector lip, the proper dimensions of which were determined by experimentation, was placed to relieve back pressure that may be caused by spillway flow. A check was made to be sure that no vacuum developed in the sluice-ways during the flow over the spillway exits.

Considerable data were obtained on hydraulic jump performance, both on level and sloping aprons, which included velocity contours, water surfaces, and pressures through the jump at various flows. Comparative data on the performance of sills of various heights and shapes were also secured. Performance data were obtained on the action of the other devices previously mentioned for dissipating the energy of the overflow at the toe of ogee dams. Motion and still pictures were taken of nearly every set-up that was tested on the model.

CONCLUSIONS SUPPORTED BY MODEL TESTS

Conclusions pertaining to model tests of Madden Dam may be stated on the basis of the foregoing data, as follows:

(1) The hydraulic jump is very effective in dissipating the energy of the overflow at the toe of ogee dams, the resultant velocities at the end of the jump being little greater than those normally present in the river channel during a given flow, if no dam were present.

(2) The jump can be formed and controlled best by placing a sloped apron down stream, tangent to the bucket at the toe. It will move up or down the slope with variations in tail-water due to different discharge.

(3) The elevation of the apron must be placed relative to the tail-water so that the depths over it will start the jump precisely at the toe of the dam, for all flows, in order that the total length of the apron may be utilized.

(4) The slope of the apron should not be steeper than 1 on 4. A change in the slope alters the shape of the required jump-depth curve. By adopting a proper slope to the apron a close coincidence may be obtained with the natural tail-water depths throughout the entire range of discharges.

(5) The length of the jump, or the distance down stream required for full recovery, varies as its magnitude, increasing with the discharge.

(6) The highest velocities through the jump occur near the floor until they are gradually retarded

(7) The length of the spillway apron then should cover the range of velocity retardation until a point is reached where the velocities are low enough not to cause the river bed to scour down stream.

(8) This apron length may be shortened by placing a sill, with a gradually sloping face, at the end to deflect the floor velocities just free from the river bed below, until they are retarded in the natural action of the jump.

(9) The jump should be protected or enclosed by vertical side walls to a height, at least, which follows the rise in the water surface through the jump, in order to prevent "washing out" by the cross-flow of the adjacent quiet tail-water. It is more desirable to have the side walls high enough to exclude the adjacent tail-water entirely. The walls should extend down stream to the point of full recovery where the water surface reaches the same elevation as that of the adjacent tail-water.

(10) The water entering the jump should be of equal depth and velocity across the entire width; or, in other words, the discharge over the dam crest should be uniform. This is accomplished at Madden Dam, without the use of training walls for each gate, by simultaneously lowering the four drum-gates to the same opening.

(11) The hydraulic jump method is much more advantageous than any other device for dissipating the energy of the overflow below dams. The design is simpler and more rugged when the energy is dissipated by the impact of water on water. The spillway is free from obstructions that may be damaged by logs and other debris coming over the dam. Sills, piers, etc., to break the force of the water are expensive and difficult to reinforce and anchor and are always liable to damage. A break at any point creates a high velocity concentration, which starts erosion that may undermine the entire structure. Difficulties of repair are likely to prove costly as these sills, etc., are usually under a considerable depth of tail-water; if they are not, they are practically useless in dissipating the energy.

Conclusions (1) to (11) have been reached from the tests on the design of Madden Dam. The apron is placed, by experimentation, so that

FIG. 13.—SECTIONS AND ELEVATIONS, MADDEN DAM

a balanced effective hydraulic jump occurs well up on the apron at any given flow over the spillway. This is accomplished more easily at Madden Dam than elsewhere, perhaps, as the foundation rock was of sufficient depth below the natural tail-water so that an apron of the proper elevation and slope could be constructed. It is thought, however, that from the results of these tests, principles may be established that will allow the adaptation, at other projects, of this type of apron for obtaining the hydraulic jump. The tendency in later designs of overflow dams has been to use a sloped apron for obtaining the hydraulic jump as a means of dissipating the energy at the toe. Similar aprons were later used at the Norris Dam,[9] and at the Hamilton Dam, in Texas. Preliminary designs for the Marshall Ford Dam, in Texas, and the Friant and Kennett Dams, in California, contemplate the use of this type of apron.

The effectiveness of the hydraulic jump and the possibilities of a sloped apron as a means for controlling it were fully demonstrated by the model studies of Madden Dam.

PART II.—PROTOTYPE TESTS

INTRODUCTION

In order to check the model predictions and also to obtain hydraulic data on a full-sized structure, test apparatus was installed at Madden Dam similar to that used on the model. Piezometers were placed along the spillway crest of one gate in the sides of the spillway piers, and down the training wall. Provision was made to measure the water surface over the crest. Piezometers and Pitot tubes were placed at the toe of the spillway, to measure the head lost in friction, and along the length of the apron to measure the velocity lost through the jump. A gaging station is situated just down stream from the dam for obtaining the quantity of water flowing.

The concrete apron built at the toe of the spillway is constructed on a slope of 1 on 4.3, taking off tangent to the curved bucket at the toe and terminating in a small sloped-face deflector sill. The dimensions are given in Figs. 12 and 13 which show a general layout of the dam. As stated in Part I this apron was adopted after extensive model tests had been made to determine the best method for dissipating the energy of the overflow.

The largest flow that has been passed over the spillway to date (1937) has been about 32 000 cu ft per sec. Complete model data for a direct comparison are not available at this relatively low discharge, but the results obtained are interesting and are indicative of the performance to be expected for greater flows.

NAPPES AND PRESSURES OVER THE CREST

The water-surface profiles of the flow over the spillway crest were obtained by dropping a heavy steel plumb-bob, attached to a steel tape, from a platform which was suspended beneath the archway of the first drum-gate. At approximate 4-ft intervals along the center line of the gate, holes were cut in the floor of the platform and a known bench-mark was established near each hole, from which measurements of the distance to the water surface were taken.

---

[9] *Civil Engineering*, April, 1935.

Pressures along the crest were taken from piezometers placed in the concrete and in the steel drum-gate itself, at positions as indicated in Fig. 14. The piezometer openings were connected by pipes to a mercury U-tube in one of the galleries of the dam. When there was no water flowing over the crest, the deflection of the U-tube at a known elevation of the lake, was taken as a datum, and subsequent readings taken during the tests were translated in elevations of the water columns above each piezometer opening.

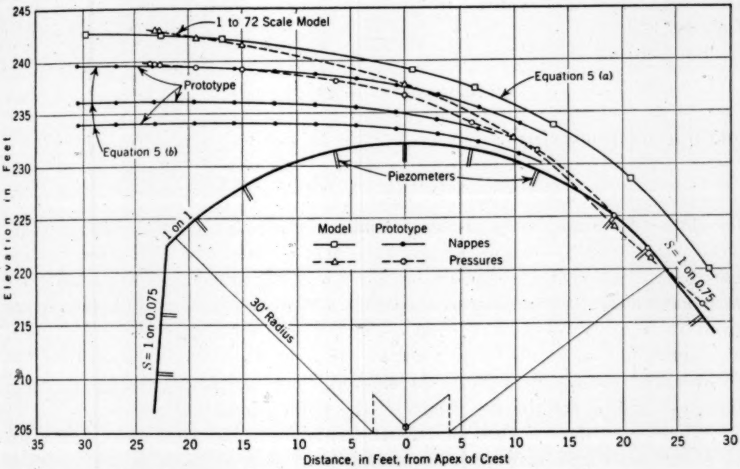

FIG. 14.—NAPPES AND PRESSURES OVER THE SPILLWAY CREST, FOR THE PROTOTYPE AND MODEL

It will be noted that the pressures as recorded by the piezometers on the up-stream face of the dam lie above the measured water surface, indicating impact. The pressures drop off rapidly along the crest due to the centrifugal force, reaching a negative pressure at a point on the downstream side, showing a tendency of the jet to leap the crest. The model tests showed that this tendency increased at higher heads. The vacuum thus produced was taken into account in the stability design of the crest, as its existence was early recognized.

Fig. 14 shows the nappes taken over the prototype crest for three heads. Three other intermediate heads were also taken for this position of the gate fully opened (lowered), and lie consistently between the ones shown. The piezometer pressures are plotted for the higher profile only, in order to avoid confusion in Fig. 14, but the pressures for the lower heads fall in a similar manner below the water-surface nappe in each case. A water-surface curve line of pressures taken on the model, is also shown in Fig. 14. This is the lowest head on which complete data were taken for the model tests. However, there is a remarkable consistency in the curves indicating similarity of performance. Nappes and pressures were also taken with the gate in three different positions of closure.

Many trials were made to obtain an equation for these overflow nappes. For water surfaces over the crest when the drum-gates were fully opened (lowered) the most consistent formulas that could be derived were as follows:

For the model:

$$-y = (0.164\,H - 0.692)\,1.223^{xH^{-0.5}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

and, for the prototype:

$$-y = (0.0733\,H - 0.206)\;1.266^{xH^{-0.5}} \quad \ldots\ldots\ldots\ldots\ldots (5b)$$

in which: $\pm\,x$ and $-\,y$ are co-ordinates of a point on the water surface, with the Y-axis at the up-stream face of the dam and the X-axis as the horizontal line of the reservoir level. The model formula (Equation (5*a*)) was derived from five measured nappes, at heads corresponding to a range from 11 ft to 31 ft over the crest. The prototype formula (Equation (5*b*)), was derived from points on five curves taken up to a maximum head of 7.78 ft over the crest. Each formula showed close agreement with its respective test points, within the range of the points actually taken.

When applied to a head of 7.78 ft (which was the highest head attained over the prototype spillway), Equation (5*a*) showed close agreement with the actual measured water surface on the prototype On the other hand, Equation (5*b*) gave a profile much higher than the actual measured water surface over the model for a head corresponding to 11.3 ft over the crest (which was the lowest head measured on the model). In other words, the model formula could be extrapolated to check the prototype measurements, but the prototype formula, when extrapolated, would not check the model nappes. Equation (5*a*) seems to be more accurate for design approximations, until further tests are taken to check Equation (5*b*).

A row of piezometers was placed along the face of one of the end spillway piers. In general, the pressures recorded on these piezometers fell slightly below the profile of the water surface There was a noticeable disturbance at the end piers of the spillway. The slight drop below static pressure which was recorded along this end pier may be due to the tendency of the flow into the gate to leave the side of the pier as it comes in from the dead end of the spillway. This disturbance could be eliminated, perhaps, by extending the end piers a distance up stream, although in most instances this is not practical. At the intermediate piers, when adjacent gates are opened, there is no disturbance, the flow being symmetrical and uniform on both sides of the pier.

Piezometers were located along the drum-gate just beneath the downstream tip of the top skin-plate. These piezometers, however, did not indicate vacuum for any of the flows attained to date. With the drum-gate fully opened (at which position it conforms with the crest curve), the vacuum (see Fig. 14) noticed at the higher heads occurs at a point down stream from the tip of the gate. At any of the partly raised positions of the gate, there is no indication of a vacuum on the under side, the overflowing sheet of water being quite sufficiently aerated at the ends, through the space behind the square end piers. Piezometers were installed in the left retaining wall of the spillway, but the flows have not yet been high enough to obtain readings from them.

SPILLWAY DISCHARGE

Simultaneously, with the observations being taken at Madden Dam, stream-gage measurements were made at the permanent station about ½ mile down stream. The readings were made with a current meter at 1-ft depth, the mean velocity being obtained by using a correction factor of 0.9. This factor (0.9) was established for the station after a long period of observations in which complete traverses were made. Due to the high velocity through the gaging section of the river it was not possible to make complete traverses during the larger flows, and the 0.9 factor used may be in considerable error for the higher discharges. It is apparent that to measure the discharge in a degree of accuracy comparable with the model tests special apparatus must be used to hold the current meter in the high velocity water so that a complete traverse of the section can be made.

The results as obtained may prove interesting, however. A curve of coefficients of discharge was computed, using the simultaneous discharges taken from a rating curve of the gaging station established from readings taken during these tests. The equation of the coefficient curve for drum-gates fully opened, was obtained from the test points and showed that the coefficient of discharge was a function of the

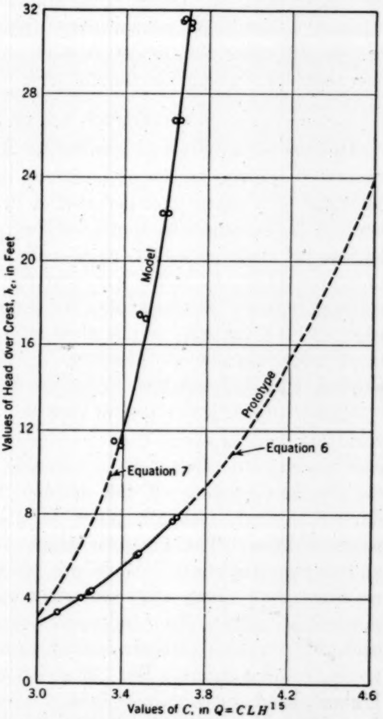

FIG. 15.—COEFFICIENTS OF DISCHARGE

head as well as of the crest shape:

$$C = 2.44 \ h_c^{0.20} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Fig. 15 shows a plotting of this coefficient curve, extrapolated by Equation (6) for heads higher than those tested, for comparison with the model coefficient curve, similarly extrapolated downward by the formula:

$$C = 2.69 \ h_c^{0.094} \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

to cover the range of the lower prototype test heads. At the maximum prototype test head of 7.78 ft over the crest, the indicated discharge is about 13% greater than that predicted from the model tests. Some of this flow may be due to the possible error in the stream gaging. There is an apparent definite discrepancy, however, as the two curves have marked different characteristics.

This discrepancy is interesting as it is a generally accepted procedure to use directly, coefficients of discharge obtained from model tests. In some instances a great saving in spillway length can be effected if the true coefficient of the crest is known. The data are yet too meager to attempt a thorough comparative analysis, but it would seem that some factors affecting the model flow, such as capillarity action and viscosity, have not been given full cognizance.

Velocities Along Spillway Apron

During construction a number of fixed Pitot tube nozzles were installed along the spillway apron at positions indicated in Fig. 16. The Pitot tubes consisted of a plate steel pedestal, 4 in. wide by 12 in. long, the plate being bent to a stream-line shape, welded, and filled in with concrete. The bottom of the pedestals were embedded and anchored in the concrete and protruded 14 in. for some to 20 in. for others above the floor of the spillway apron. A piece of 1-in. pipe projected 4 in. from the up-stream edge of the pedestal at heights above the floor varying from 3 in. for those pedestals above tail-water, to 12 in. and 18 in. for those pedestals covered with tail-water.

These projecting pipes or nozzles were connected by 1-in, pipes to a manifold and pressure gage in the basement of the power station. Below each nozzle, but offset 2 ft to one side, were piezometers, opening flush with the concrete surface of the apron. These piezometer openings were conducted through separate pipes to a manifold and pressure gage in the power station. The pressure gages were accurately calibrated previous to and during the tests. With any given flow over the crest, a number of readings were taken simultaneously on both the Pitot nozzle gage and the piezometer gage. The indicated water pressures were then plotted over each Pitot nozzle and piezometer as the kinetic and static energy, respectively, at that point. Fig. 16 shows the plotting of such readings for the highest head yet obtained over the crest. The Pitot nozzles are situated just off the surface of the apron and will register the highest velocity of the water through the hydraulic jump. This was found to be true from tests on the model (see Fig. 8). The indicated velocity, of course, is not the average velocity of the cross-section, but will show the relative change, which was the original objective of the Pitot tubes as installed. The loss in energy is great and occurs mainly just at the beginning of the jump. The flow off the end of the apron is of low velocity, not sufficient to register on the test apparatus. The effectiveness of the hydraulic jump in dissipating the energy of the overflow is vividly illustrated by the sudden drop obtained in the energy gradient curve as shown in Fig. 16.

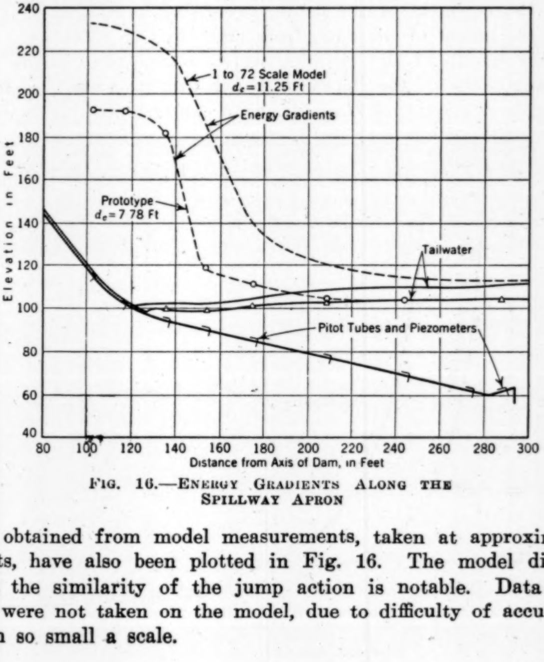

FIG. 16.—ENERGY GRADIENTS ALONG THE SPILLWAY APRON

Curves obtained from model measurements, taken at approximately the same points, have also been plotted in Fig. 16. The model discharge is higher but the similarity of the jump action is notable. Data for lower discharges were not taken on the model, due to difficulty of accurate measurement on so small a scale.

FRICTION LOSS AT THE TOE

From the readings of the Pitot tubes on the apron, which were not covered by the tail-water during the tests, values of the velocity were obtained for five different heads over the crest, with the drum-gates fully opened. These velocities were used to compute the depth of the stream, the rate, Q, having been obtained from stream gaging below the dam. The difference between the velocity head as indicated by the Pitot tube readings and the theoretic velocity head (which is the difference between water surfaces) was taken as the loss in head due to friction on the overflowing sheet of water. These rather crude Pitot tubes will not, of course, measure the true mean velocity of the stream, but a discussion of the friction loss as so indicated by them may prove interesting. It was found that the average of the five readings obtained at different heads over the crest could be expressed by an equation of the following form:

$$h_f = \frac{f_n \, H \, (H + d_c)}{d^q_c} \quad \text{.....................(8)}$$

in which h_f = the friction head loss at a given station on the toe of the dam; f_n = the friction coefficient depending on the roughness of the surface; q = the exponent of the depth, expressing a relation to the friction loss; H = the height of the dam, from crest apex to station on toe (factor involving the length of the channel, which is practically constant for all overflow dams); d_c = the depth of water over the crest, from reservoir elevation to crest apex; and $H + d_c$ = an expression of the velocity.

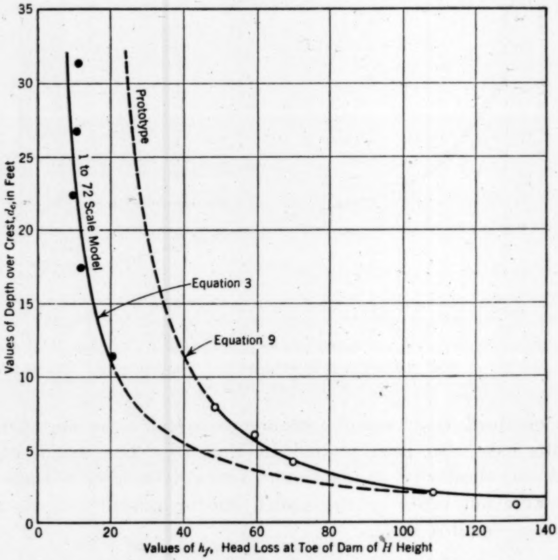

FIG. 17.—CURVES EXPRESSING FRICTION LOSS AT TOE OF OVERFLOW DAMS, AS OBTAINED FROM OBSERVATIONS ON MODEL AND PROTOTYPE

By averaging all test points, $f_n = 0.00934$ and $q = 0.623$ were obtained so that Equation (8) becomes:

$$h_f = \frac{0.00934 \, H \, (H + d_c)}{d^{0.623}} \quad \text{.....................(9)}$$

A curve of Equation (9) with the test points shown, has been plotted in Fig. 17. Extrapolation is made for comparison with a curve similarly obtained from the model tests (Equation (3)).

The prototype curve can be made to fit the model-test points very closely by changing the coefficient, $f_n = 0.00934$ to $f_n = 0.00374$, or 0.4 of the prototype coefficient. The friction loss, then, occurring at the toe of an overflow dam of any size, whether model or prototype, may be expressed by Equation (8) when f_n is a coefficient of friction depending on the roughness of the surface, varying from $f_n = 0.00374$ for the painted galvanized-iron surface of the model, to $f_n = 0.00934$ for the concrete surface of the prototype dam. The formula is expressed in prototype values and the resulting friction loss, h_f, must be divided by the scale of the model (in this case, 72) to obtain the actual value in terms of the model dimensions.

In attempting to check the theory that this difference in energy loss might be due to the roughness of the surface, numerous attempts were made to apply the Chezy formula to the test points. Results varied, depending on assumptions, as to the mean velocity and the mean hydraulic radius. A constant, n, could not be obtained by substitution in Kutter's or Manning's formula. Consistent values were not obtained until the mean velocity, V_m, was assumed to be the average of the velocity at the crest apex (see Fig. 11 and Fig. 14) and at the toe, and taking the mean hydraulic radius, R_m, at the depth where this mean velocity occurs. A formula was obtained in the exponential form which satisfied both the model and prototype test points within 8% ±, as follows:

$$V_m = \frac{1.233}{n} R_m^{0.45} S^{0.57} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

in which $S = \frac{h_f}{L}$; h_f = the measured friction loss at the toe, from Fig. 17; L = the length of the spillway from the crest apex to the toe (the velocity at the crest apex being $\frac{3\,q}{2\,d_c}$; and, the velocity at the toe being taken from the Pitot tube measurements); $V_m \doteq$ the average of the velocity at the crest and at the toe; R_m = the depth at the point of mean velocity $= \frac{q}{V_m}$; q = the discharge per linear foot of crest; and, n = the friction coefficient corresponding to Kutter's n (taken as 0.009 for the model and 0.016 for the prototype). The values assumed for n seem logical. The model was enameled and sand-papered to a very smooth finish. Form marks left at the horizontal construction joints made the down-stream face of the prototype dam unusually rough. It is indicated, then, that Equation (10) could be used for computing resulting velocities at the toe of dams, by substituting the proper value of n for the surface and solving in the same manner as that used to derive the equation.

When and if further tests are made on the prototype at heads comparable to the model data, the coefficient of the Pitot tubes as used could be obtained from tests on a model, resulting in more accurate data for determination of the friction loss. The comparisons that have been attempted show the possibilities.

Drum-Gate Operation

The correct procedure for operating the drum-gates was derived from the model tests, as previously discussed. It was found that in order to obtain the proper functioning of the hydraulic jump, all spillway drum-gates should be opened to the same amount. To verify this model prediction, an attempt was made to measure the resulting erosion below the spillway apron, with various combinations of drum-gate openings.

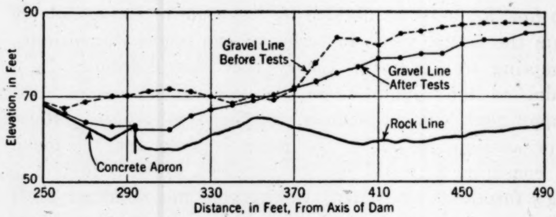

Fig. 18.—Typical Erosion Below Apron

A schedule of tests was run in which, first only one gate was opened fully and allowed to spill for 3 hr, then all four gates were opened partly so that the same quantity of water was spilled as was passed through the

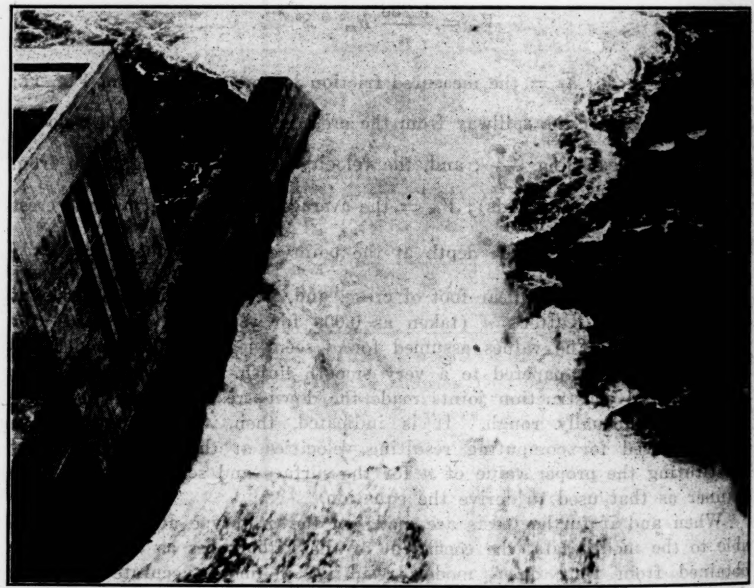

Fig. 19.—View of Spillway Bridge, Showing Interference with Hydraulic Jump on Apron, Caused by the Tail-Water Below Closed Gates; Flow, 7 500 Cubic Feet per Second

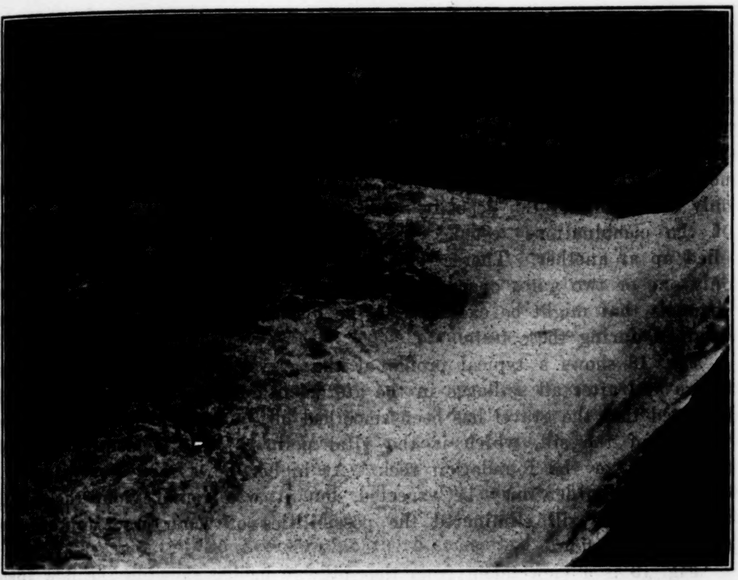

FIG. 20.—VIEW FROM SPILLWAY BRIDGE, SHOWING HYDRAULIC JUMP ON APRON; FLOW, 7 600 CUBIC FEET PER SECOND

FIG. 21.—VIEW OF HYDRAULIC JUMP ON SLOPED SPILLWAY; FLOW, 31 800 CUBIC FEET PER SECOND

one gate. The four gates were then allowed to spill for 3 hr. This same procedure was repeated with two gates fully opened and then with the four gates partly opened to pass the same quantity of flow; and, similarly, with three gates. After each of these settings, soundings of the river bottom were taken in the tail-race below the apron for the purpose of comparison. The change in the profile of the river gravel was so slight, however, that no definitely conclusive comparison could be reached. There seemed to be only a shifting of the deposits, with little movement down stream, at any of the combinations tested. The gravel was moved at one place and piled up at another. There were indications, however, that the flow, with only one or two gates opened, tended to form concentrations and to erode channels that might be excessive if the discharges were greater than those attained during these tests.

Fig. 18 shows a typical profile of the gravel deposits below the apron before and after all spillages in the aforementioned series of tests. It will be noted that the gravel has been smoothed off, but no erosion occurs below the lip of the sill, which is the vital point. Quite a depth of gravel remained over the foundation rock. At higher flows more severe erosion of the over-burden may be expected, but it was found from the model tests that the sill eliminated the possibilities of scour undermining the apron, at any flow.

Fig. 19 is a view taken from the spillway bridge showing the flow from one gate only. Note that the adjacent tail-water crowds the beginning of the jump, causing the flow to concentrate toward the retaining wall. This concentration produced excessive gravel erosion below the apron.

A more positive indication of the effects of one gate operation was obtained from readings taken on the Pitot tubes along the apron, which were situated below Gate No. 1. If this gate were opened alone there was a marked increase in the velocity along the apron as compared with the velocity existing if all four gates are opened partly to pass the same flow. A visual comparison is readily made by referring to Fig. 20 which shows the same flow being passed over all drum-gates, lowered to the same opening.

Obviously, the best method is to operate the gates simultaneously which can be easily done because the drum-gates allow spillages over the top in any position, without detriment. The controls are designed to hold the gate in any position. Except for short periods, or at low heads, the indications are that it would be dangerous to allow spillages from the gates opened individually.

CONCLUSIONS: HYDRAULIC JUMP PERFORMANCES

At the flows over Madden Dam spillway to date, the performance of the hydraulic jump has been consistent with the predictions made from the model tests. The depths furnished by the natural tail-water have caused the jump to begin just at the toe of the dam at any flow. Fig. 21 shows the hydraulic jump at the toe of the dam for the maximum flow attained to date, of 31 800 cu ft per sec. Fig. 20 shows the jump at a lower flow.

The loss in energy in the jump has been almost instantaneous and the resultant erosion of the gravel deposits beyond the concrete apron, almost negligible (see Figs. 16 and 18).

It will be noted from Fig. 17, that the measured velocity at the toe was less on the prototype. This may be attributed to the difference in the roughness of the surface of the model and the concrete dam, as discussed previously.

For other comparative measurements it was found that the nappe curves taken over the spillway crest on the model could be used to predict the prototype nappes within a reasonable degree of accuracy. The comparative pressures on the crest seemed consistent. An apparent increase was obtained in the discharge over the crest of the prototype dam from that predicted from the model. All the model predictions were on the safe side, however.

The foregoing prototype test data were obtained at comparatively low flows over the spillway and there are no corresponding model data available for a direct comparison. Accurate and complete data were not taken on the model for very low heads over the crest for two reasons: (1) The model was built on a rather small scale (1:72) and very low quantities of discharge were difficult to measure; (2) the principal objective of the model experiments was to determine the best method to handle the larger and maximum flows safely, so that few data were obtained on flows less than a prototype equivalent of 50 000 cu ft per sec. For greater flows however, complete and accurate records were obtained at various increments of flow up to the maximum expected discharge of 260 000 cu ft per sec.

The comparisons which have been attempted herein were made from extrapolations, but it will not be until these tests are completed for higher discharges that a comprehensive study can be made. From what has been indicated, many valuable and interesting data could be developed by further testing, which, in comparison with the model data, would establish a more reliable criterion for model similitude.

ACKNOWLEDGMENTS

Acknowledgment is due to James W. Ball, Jun. Am. Soc. C. E., for his assistance in conducting the model tests, and to Mr. W. F. Bingham[10] for his aid in preparing the report on the model tests. Messrs. P. S. O'Shaughnessy[11] and J. C. French assisted in the prototype test program, which was conducted under the administrative direction of Mr. W. L. Hersh. The model tests were conducted under the direction of E. W. Lane, M. Am. Soc. C. E.[10]

The Madden Dam project was completed in 1935 under the administrative direction of Col. Julian L. Schley, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., then Governor of The Panama Canal, assisted by Col. Clarence S. Ridley, Corps of Engineers, U. S. Army, then Engineer of Maintenance; and Lt. Col. William E. R. Covell, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., then Assistant Engineer of Maintenance.

Edward S. Randolph, M. Am. Soc. C. E., was first Designing Engineer and, later, Construction Engineer, on the project. The designs and specifications were prepared by the forces of the U. S. Bureau of Reclamation, in Denver, Colo., in collaboration with the Panama Canal organization. Raymond F. Walter, M. Am. Soc. C. E., Chief Engineer, and John L. Savage, M. Am. Soc. C. E., Chief Designing Engineer, of the U. S. Bureau of Reclamation, served as Consulting Engineers for the design and construction.

DISCUSSION

Ettore Scimemi,[12] Esq. (by letter).—Those who are studying the possibility of applying experimental results obtained from model tests to the prototype, will find this paper of the greatest interest. Experiments of the type demonstrated by the author are now very often made in laboratories, whereas those obtained directly from the original structure are very rare or are lacking entirely. Knowing how very difficult it is to make exact measurements, the writer feels that Mr. Randolph deserves unlimited praise. Especially interesting is the fact that there is good correspondence between the discharges and the distribution of the pressure along the crest of the dam.

For the shape of the spillway of the Madden Dam the author has adopted a circular profile; and yet this profile is neither the most economical nor the most suitable one for a spillway dam. One type that is now quite popular is that recommended by William P. Creager, M. Am. Soc. C. E., about 1917.[13] About 1930 the writer analyzed this profile,[14] but only with regard to the shape of the hydraulic sheet (see Fig. 22); he noted then that the Creager profile is always above the lower nappe of the sheet.

Mr. Creager gives the co-ordinates of this profile in a table which is now included in almost every handbook on the subject.[13] The zero, or the origin, of reference should be referred to the vertex, or the summit, of the dam, as shown in Table 2 and Fig. 23. It is not necessary to describe a complete curve for the up-stream part of this vertex. The lower nappe adapts itself to an arc of a circle equivalent to 0.40 H, in radius, and a rise equal to 0.12 H; the measurements in Fig. 23, of course, are computed for a head equal to unity, as in the Creager method. As to the down-stream part, however, Fig. 23 shows three profiles: The lower one, which

is dotted, is of the lower nappe of the sheet, and its equation is approximately,

$$Y = 0.5\ X^{1.85} \qquad \text{(11)}$$

the upper one, a solid curve, is that given by Mr. Creager, and the third, identified by dots and dashes, is the curve of the equation,

$$Y = 0.47\ X^{1.8} \qquad \text{(12)}$$

Fig. 23 shows that the curve defined by Equation (12) corresponds almost exactly to the Creager profile, and Table 2 shows the computed numerical differences between the two curves (differences which are absolutely negligible).

Recently, the writer examined the Creager profile as designed for an Italian dam, 70 m (229.7 ft) high, and on which the spillway allows for a head of 4.40 m (14.4 ft). The dimensions of this dam, therefore, do not differ very much from those of the Madden Dam, studied by the author. The spillway is surmounted by plain sluice-gates. A model was constructed on a scale of 1:25, and the problem was to determine the discharge capacity and the distribution of the pressures along the crest. The determination of the distribution of pressure is very simple, with piezometer orifices, when the overflow is free. Fig. 24(*c*) indeed shows the pressures that have been recorded from the crest. These pressures prove to be positive until the head on the crest reaches unity or until it exceeds 1.10. For these reasons the Creager profile may be called rational as regards the pressure, as long as the overflow is free; but this is not the case if the sluice-gates are opened; that is, as long as the sluice-gates are wide open (not less than 0.50 for a head, $H = 1$), the pressures occur as if the overflow were free (Fig. 24(*b*)); but, if the sluice-gates are open less than 0.50, one immediately observes negative pressures on the crest which reach their highest value when the opening is 0.25, and then reverse.

The profiles of these negative pressures are shown in Fig. 24(*b*), in which, however, one can observe that this zone of vacuum, on the whole, is rather limited, and the absolute value of the vacuum is, generally, a matter of no importance. For instance, if the head on the dam is 10 m (32.8 ft) the vacuum is only 0.50 m (1.64 ft). In the greater number of cases one may assume that these negative pressures will not damage the structure, especially if it is a solid gravity dam. However, if it is a hollow type of dam, it is possible that the vibrations due to the vacuum will cause damage and then it is necessary to reduce the head on the dam. Mr. L. Escande[15] has suggested reducing the water head to 0.70 as a remedy, and the writer has been able to verify this value as is illustrated by Fig. 24(*a*), in which the head on the crest has been kept at not greater than 0.70; that is, 0.70, with the profile of the dam as described. In that case, all the pressures on the crest are positive; but it may also be seen in Fig. 24(*a*), that they come close to zero, so that the advantage with regard to the phenomena obtained by the experiments, on Fig. 24(*a*), is indeed not very remarkable.

---

J. C. STEVENS,[16] M. AM. SOC. C. E. (by letter).—One of the projects early adopted by the Special Committee of the Society on Hydraulic Research,[17] is to gather data on the conformity of prototype behavior to model tests. Mr. Randolph has added important data to the Committee's store.

In so many cases the works vary from the design developed by model tests, to such a degree that a direct comparison is impossible. Fortunately, in this case, the prototype was constructed to conform to the design shown by model studies to be the best, and direct comparisons are possible. The construction management is to be complimented for installing the facilities by which such direct comparisons could be made.

It should be recognized that there is no virtue in the sloping deck, as such, to aid in the dissipation of energy. Better results would have been secured had the deck been horizontal at the proper elevation. The sloping deck was used only to save concrete.

Little is known about hydraulic-jump characteristics on sloping beds. A stream flowing down the face of a dam acquires a high kinetic energy at the bottom, which must be destroyed (converted to heat). The hydraulic jump is the most potent factor known in absorbing such energy, and the proportion of total energy that can be destroyed will depend on the ratio of kinetic to potential energy ("kineticity") possessed by the water just prior to the jump and upon the opposing forces that cause the jump. If the jump occurs on a sloping deck the force of gravity on the water prism acts in the direction of flow and, therefore, tends to increase rather than to retard velocity.

In many cases, baffles of various types are placed on the apron to constitute an opposing force and thus aid the formation of the jump and insure its forming on the deck or apron. In this case, the deflector at the end of the apron serves as a retarding force and, to some extent, counteracts the force of gravity on the sloping deck. For high dams and low discharges per unit width, the force of gravity on a sloping apron may be relatively unimportant, but for greater discharges per unit width this force cannot be ignored.

The writer seriously questions the author's Conclusion (2) that the jump can be "controlled best by placing a sloping apron down stream, * * *." This conclusion cannot be supported in theory because little is known of the jump on such slopes. It cannot be supported in practice because the prototype discharge concentrations are too low to serve as a check on the model studies. For the Bonneville Dam with high discharge concentrations model studies showed the sloping deck to be the worst possible form that could be devised.

Fig. 25(*a*) shows the scour resulting from Experiment No. 46, with a deck sloping 1 on 4 from an elevation corresponding to —25. The discharge concentration on the deck, beyond the piers, was 852 cu ft per sec per ft of width. The model river material was scoured to the flume bed—

---

[16] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

[17] Year Book, Am. Soc. C. E., 1937, p. 8.

a depth corresponding to 50 ft on the prototype. If deeper material had been available it might easily have scoured to twice that depth. Of the 172 experiments made for scour prevention for this dam, Experiment No. 46, with the 1 on 4 sloping deck, showed the maximum scour. Fig. 25(*b*)

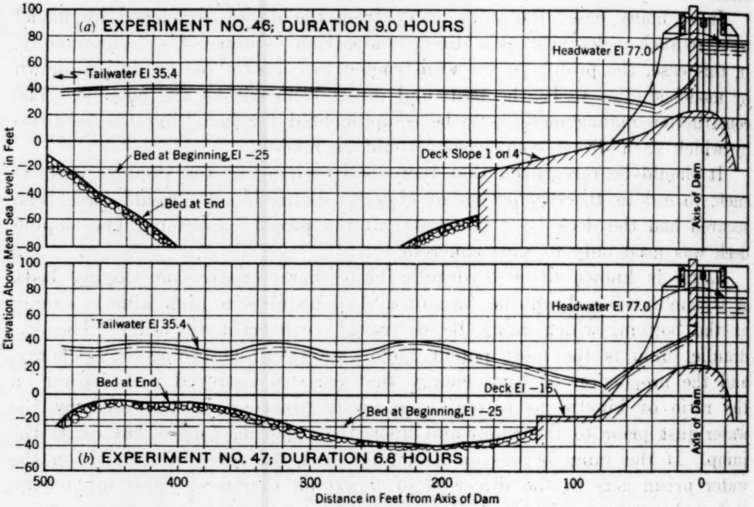

FIG. 25.—COMPARATIVE STUDY OF SCOUR, BONNEVILLE DAM, WITH A DISCHARGE OF 400 000 CUBIC FEET PER SECOND THROUGH EIGHT GATES

shows the results of Experiment No. 47 for the same discharge concentration, but with a horizontal deck corresponding to Elevation —16.0. The maximum scour corresponded to a depth of 15 ft. Although the length of run for Experiment No. 46 corresponded to 9 hr while that for Experiment No. 47 corresponded to 6.8 hr, the flume bed of Experiment No. 46 had been exposed completely and most of the scour had occurred in the first 7 hr. On the Bonneville deck it was necessary to place baffles[18] to insure the jump forming on the deck or apron and to aid in dissipating the energy.

Fig. 3 shows that if a horizontal apron could have been built at Elevation 83 a good correspondence between height of jump and the normal tail-water level could have been secured for practically the entire range of discharge. By proper manipulation of the crest gates as good correspondence might also have been had with a lower apron. This point is well illustrated in Fig. 26 which shows the correspondence between the height of the jump and the tail-water level for the Bonneville Dam. Fig. 26(*a*) shows that with twelve gates open equal distances, the deck should have been placed at Elevation —7.0 for good correspondence, for dis-

---

[18] See *Engineering News-Record,* January 14, 1937, p. 61, for description of the baffles used.

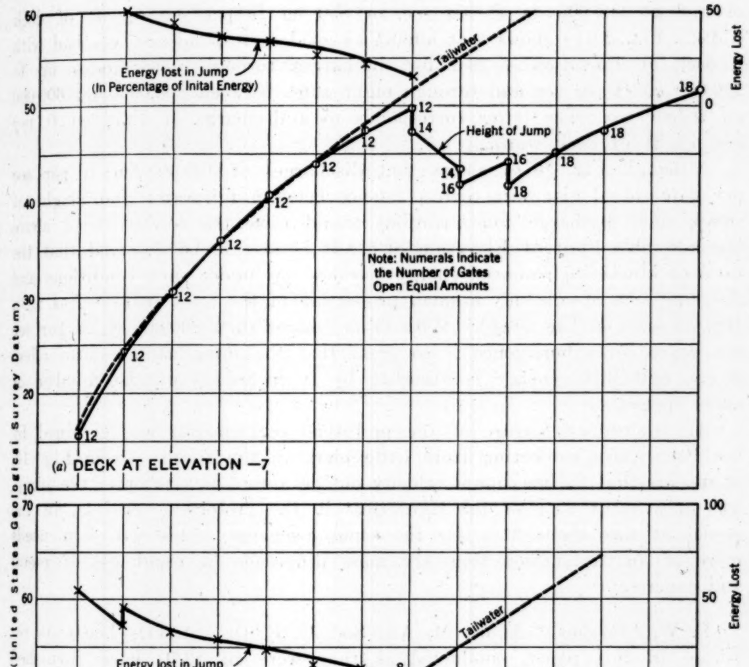

FIG. 26.—CORRESPONDENCE OF TAIL-WATER LEVELS WITH COMPUTED HEIGHT OF HYDRAULIC JUMP

charges to 600 000 cu ft per sec, or 850 cu ft per sec per ft of deck width. Fig. 26(*b*) shows that almost as good correspondence was had with a deck at Elevation — 16.0 for discharges through seven gates up to 200 000 cu ft per sec and through eight gates between 200 000 and 600 000 cu ft per sec. The latter corresponds to a discharge of 1 275 cu ft per sec per ft of deck width.

Although Fig. 26(*b*) shows that discharges of 100 000 cu ft per sec per gate would give fair correspondence between tail-water and height of jump, such discharge concentrations would raise the forebay level above the allowable limit of Elevation 82.5. It is also to be observed that the ratio of kinetic to potential energy becomes low under such conditions and the jump can absorb only a small proportion of the total energy—less than 10% as seen in Fig. 26(*b*). With flows greater than 800 000 cu ft per sec the degree of submergence is so great that the jump cannot form effectively, and little energy is absorbed by it regardless of the number of gates opened.

An interesting feature of the prototype performance was obtained by the Pitot tubes projecting from little piers on the apron. From Fig. 16, it appears that the maximum velocity on the apron, just prior to the jump, was only about 69% of the theoretical in the prototype, whereas, in the model, it was about 91% for the same discharge. This variation needs more of an explanation than the mere difference in roughness of metal and concrete.

F. W. EDWARDS,[19] ASSOC. M. AM. SOC. C. E. (by letter).—The tests reported in this paper, conducted as they were in 1931, have furnished a pattern for numerous later experiments on similar structures.[20] In addition, the paper describes the preparations made for comparative tests on the prototype. Unfortunately, as repeatedly emphasized by the author, the spillway discharges to date have been insufficient in magnitude to make direct comparisons with the model. Extrapolations in studies of this nature are very unsatisfactory. However, the paper should serve to stimulate interest in obtaining data, and thus insure complete measurements on the prototype when the opportunity is presented.

Model Tests.—It is interesting to review the conclusions reached from the model tests of Madden Dam in the light of the results obtained from the model tests of the Conchas Dam in New Mexico,[21] conducted at the U. S. Waterways Experiment Station in 1936.

Conclusions (1), (5), (6), (7), and (10), in Part I of the paper, were entirely substantiated by the Conchas Dam tests. Conclusions (8) and (9), when qualified slightly, were also substantiated by the Conchas Dam tests.

The tests at Conchas Dam indicated that the apron could be shortened by use of a sill (see Conclusion (8)) but, in addition, they indicated the advantages of an end sill when the apron of the stilling-basin extended down stream beyond the point of full recovery for the hydraulic jump. Several types of end sills, including the sloped-face type, were tested, and a stepped sill was selected as the best of those investigated. The essential factor, therefore, is the sill rather than the specific type of sill.

No doubt, the plan suggested in Conclusion (9) produces the very best conditions, but the tests for Conchas Dam indicated that where the stilling-basin is confined within a relatively narrow canyon, the side walls could be sloped off on the down-stream end without seriously interfering with the jump action. As far as stream-bed velocities and erosion down stream were concerned, the essential feature was an adequate apron having an end sill.

Conclusions (2), (3), and (4) were not factors in the design of Conchas Dam, where a horizontal apron was feasible.

The final conclusion, (11), listed by the author in Part I, incorporates more than its first sentence would imply. Although the writer agrees thoroughly with the first part of the paragraph, the remainder appears to delve too much into matter of opinion instead of presenting a definite conclusion based upon the model tests.

There are two schools of thought regarding baffles. One believes that baffles are absolutely essential in combination with the hydraulic jump to help dissipate, sufficiently, the excess energy in the over-fall from a high dam. The other school believes, like the author, that baffles are actually dangerous. It appears that a compromise might be effective in some cases. This was the attitude taken at Conchas Dam where one row of baffles, placed far enough down stream to avoid excessive impact, was used. The stilling-basin selected from the model tests performed satisfactorily when equipped with an end sill alone, but the one row of baffle-blocks was added principally to improve the performance of the basin when the conduits were discharging alone. The baffles definitely improved the action of the jump for high spillway discharges as well, and were considered an additional factor of safety in the design. By placing the baffles relatively far down stream, full advantage was taken of the impact of water on water before giving additional aid with the baffles.

Prototype Tests.—The agreement between corresponding nappes and pressures over the crest of the spillway for the model and its prototype appears to be highly satisfactory. The indicated energy gradients also appear to be in satisfactory agreement. However, the implication regarding coefficients of discharge for the spillway (see Fig. 15) should not be overlooked. Judging from the results of others, whose methods of measuring discharge were superior to those described for Madden Dam, one is inclined to accept the model results at least for the maximum heads. No doubt, viscosity and surface tension do affect coefficients of discharge for very small heads in models, but it seems unlikely that the effect would be great for heads of 0.45 ft (32 ft in Nature), the maximum head on the model of Madden Dam.

It would be extremely interesting and worth while to the Engineering Profession if measurements could be made upon the spillway similar to those made by Albion Davis, M. Am. Soc. C. E., and the late Floyd A. Nagler, M. Am. Soc. C. E., on the Keokuk Dam,[22] and to those made by Louis G. Puls, Assoc. M. Am. Soc. C. E., on the Wilson Dam.[23] These measurements would be especially valuable because of the comparison that could be made with the relatively small model.

In discussing friction loss at the toe of the dam, the author states that, "the difference between the velocity head as indicated by the Pitot tube readings and the theoretic velocity head (which is the difference between water surfaces) was taken as the loss in head due to friction on the overflowing sheet of water." The statement in parenthesis indicates that the correct value for the loss of head was used; but it is incorrect to state that the theoretical velocity head equals the difference in water surfaces, or that the head loss is the difference between the measured and the theoretical velocity heads. To obtain the true loss in head, it is necessary to take the difference between the theoretical energy line (theoretical depth plus theoretical velocity head) and the actual energy line (actual depth plus actual velocity head). The fact that the theoretical depth is different from the actual depth makes the author's statement incorrect.

Although the abscissas in Fig. 17 are entitled, "Values of h_f, Head Loss at Toe of Dam of H Height," it appears that the numerical values shown are for the Madden Dam, of specific height.

MORROUGH P. O'BRIEN,[24] ASSOC. M. AM. SOC. C. E.—The use of the hydraulic jump at the base of a spillway for dissipating energy has been frequently discussed in the technical journals, but several features have not been sufficiently emphasized. The sloping apron of the Madden Dam spillway illustrates one of these points.

In the analysis of the jump, the hydraulic elements are obtained from the summation of pressure force and rate of transportation of momentum. This analysis gives the depth below the jump, but fails to give an adequate explanation of the fact that energy is dissipated in a flow system assumed to be frictionless. The explanation lies in the moments applied which are of such a nature as to produce rotation. At the down-stream section, the same total energy per unit weight is present in mechanical form (potential plus kinetic), but a portion of the kinetic energy is accounted for by the rotation of small masses of fluid and is unavailable. Stated more simply, the adverse slope of the water surface and large bottom velocities combine to bring about a rotation which is the first step in the final conversion of a part of the mechanical energy into heat. The practical significance of this fact is that "drowning" of a jump reduces this moment by eliminating the sloping water surface and results in less effective operation. The sloping apron at Madden Dam prevents drowning and thus increases the energy dissipation over a range of discharges. Only in the event that the back-water curve from the next control down stream produces submergence at each discharge exactly equal to the "jump depth" can a horizontal apron be as effective as a sloping apron which produces a true jump but prevents drowning.

Information on the jump produced at the bottom of a steeply sloping channel is meager. Fig. 27 shows data obtained in a small laboratory channel by Lieut. B. D. Rindlaub, Corps of Engineers, U. S. Army.[25] The dimensionless variables entering the problem are, $\frac{d_2}{d_1}$; $\frac{l}{d_1}$; and, $\lambda = \frac{Q^2}{g\,d^3}$. The curves show constant values of $\frac{l}{d_1}$ at three slopes. The dashed line, $\frac{d_2}{d_1}$, is a function of λ for horizontal channels.

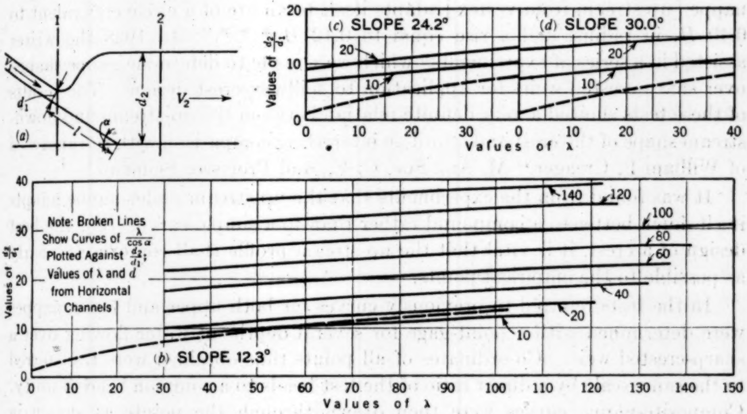

FIG. 27.—RELATIONSHIP OF $\frac{d_2}{d_1}$ TO λ FOR CONSTANT VALUES OF $\frac{l}{d_1}$ AT VARIOUS BOTTOM SLOPES

RICHARD R. RANDOLPH, JR.,[26] ESQ. (by letter).—Professor Scimemi states that the profile of the spillway crest at Madden Dam "is neither the most economical nor the most suitable one for a spillway dam." The adopted crest profile resulted from structural rather than hydraulic considerations. In order to accommodate the drum-gates (which are the largest built to date, 1938) in a well in the crest, it was necessary to broaden the profile beyond one that is theoretically better hydraulically. A drop in the coefficient of discharge resulted, but it was found that the capacity was still ample to handle the maximum expected flow. For most of the time the discharge will be regulated by lowering the drum-gates, and for this condition, with the water passing over the tops of the gates, a consistently high coefficient is obtained (see Fig. 10). A better arrangement in which the theoretical profile was maintained, was later developed by the U. S. Bureau of Reclamation for a similar drum-gate installation at Norris Dam.

[26] With U. S. Bureau of Reclamation, Denver, Colo.

It would not seem advisable to neglect the shape of the dam crest up stream from the apex, as the down-stream profile is entirely dependent on the preceding curvature. It is presumed that Professor Scimemi has reference only to the illustration as presented in his discussion when he stated that "it is not necessary to describe a complete curve for the up-stream part of this vertex. The lower nappe [up stream from vertex] adapts itself to an arc of a circle equivalent to 0.40 H, in radius, and a rise equal to 0.12 H * * *." In 1928 the writer assisted in a series of experiments[27] which were made to determine nappe shapes over sharp-crested weirs for application to spillway-crest design. The results of these tests showed a very definite relation between the up-stream and down-stream shape of the crest and afford an interesting comparison with the analyses of William P. Creager,[13] M. Am. Soc. C. E., and Professor Scimemi.

It was found from the experiments that the up-stream under-nappe adapts itself much better to a compound rather than to a simple curve. For the best design of a crest, it is vital that the up-stream profile shall conform as nearly as possible to the empirical points.

In the tests referred to previously curves for both upper and lower nappes were determined with a point-gage for several depths of water flowing over a sharp-crested weir. Co-ordinates of all points thus obtained were transferred to the same scale by a direct ratio of the test heads to a common head of unity. Composite-nappe curves were then drawn through the points as shown in Fig. 28. The co-ordinates illustrated were scaled to averaging lines as drawn. The points were obtained by stepping the measurements of the nappes to one common unit head. To design the crest, H was taken as the maximum and the curve was proportioned in terms of this head, as shown. The coefficient of friction, C, in Equation (4) will be 3.97 at the designed head.

The part of the lower nappe curve that is up stream from the apex fits very closely to a compound curve with a radius of 0.5 H tangent at the apex, continuing from 0.18 H out, with a tangent radius of 0.2 H to the weir face, which is 0.287 H out from the vertex (see Fig. 28). Down stream from the apex, the lower nappe curve was found to have the approximate formula,

$$-Y = \frac{0.53}{H^{0.8}} X^{1.8} \qquad (13)$$

or, if $H = 1.0$; $Y = 0.53\,X^{1.8}$.

Equation (13) closely resembles Professor Scimemi's Equation (11) and there is little divergence between the plotted curves. The factor, H, must be introduced in formulas, however, before they can be used for design at any head, as is done in Equation (13). It would not seem necessary to use Equation (12), whose curve would lie above the free nappe curve, for the design of the down-stream part of the dam crest if the crest is designed for the maximum expected head, as in Equation (13).

The coefficient of discharge of the sharp-crested weir used in the experiments was found to be 3.3 for all the heads tested. The distance from the apex of the lower nappe curve to forebay level was scaled from the nappe curves obtained from point-gage readings at four different depths over the weir. If this distance is taken as the head on the crest, a coefficient of discharge of 4.0 resulted in each case. This substantiates the accuracy of the testing and justifies the method of transposing test points to a common head in order to obtain the composite nappe curves.

FIG. 28.—CALIBRATION OF FREE NAPPE OVER VERTICAL SHARP-CRESTED WEIR. DIMENSIONS OF EMPIRICAL CREST S C AND STABILITY DIAGRAM, MAY 31, 1928

If a spillway crest is made to conform to the profile of the under-nappe of the overflowing sheet, a coefficient of discharge of 4.0 should obtain, and no pressures should exist along the crest. A model of such a crest was made and tested. Actually, a coefficient of 3.97 was obtained indicating only a little drag on the structure. Piezometers along the crest of the model showed no deflection when the exact head of water was overflowing for which the crest profile was designed. When the head was lowered to 66% of the designed head a pressure resulted along the crest and when the head was raised to 133% of the designed head negative deflections were produced in the piezometer columns. Computations were made of the resultant of pressures acting on the crest, assuming two-thirds uplift, and it was found that the stability of the crest was actually threatened when the overflow head was 133% of the designed head.

It has been advocated that crests be designed for heads less than the maximum which will be obtained over them in order to increase the discharge. The danger of this is indicated, and it would be necessary to investigate, thoroughly, the stability conditions as well as possible cavitation effects before such a design is adopted.

The coefficient of discharge was obtained for various depths of flow over the model crest, up to a maximum of 150% of the designed head. The coefficient increases rapidly with the head and although there was no indication of the nappe tending to leap the down-stream face of the crest, a vacuum immediately exists when the overflow exceeds the designed head. The curve for coefficient of discharge was found to be closely approximated by the equation,

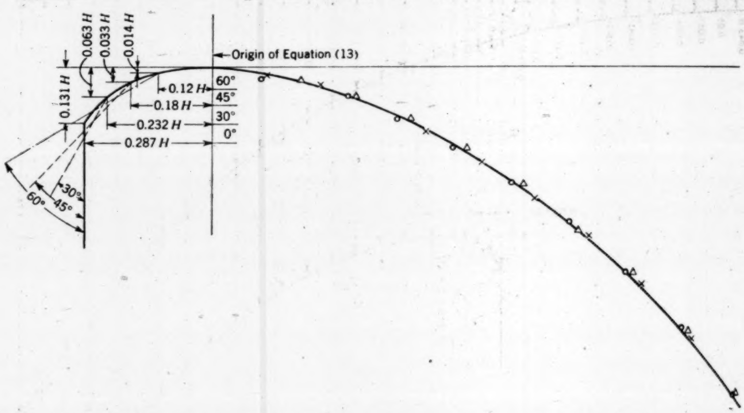

FIG. 29.—CALIBRATION OF NAPPES OVER SHARP-CRESTED WEIR WITH SLOPED FACE. DIMENSIONS OF PIER S C AND EMPIRICAL CREST S C WITH SLOPED FACE, MAY 4, 1928

$$C = 3.97 \left(\frac{h}{H} \right)^{0.17} \qquad \text{(14)}$$

in which, h = any depth over the crest; and H = the designed head of the crest. On the theory that contraction is the same on the sides as on the bottom of an orifice, an empirical pier was laid out using the same curvature for the pier nose as was obtained for the crest. Tests showed that the coefficient of discharge decreased only a little when such a pier was used, the resulting equation being:

$$C = 3.95 \left(\frac{h}{H} \right)^{0.17} \qquad \text{(15)}$$

To ascertain the effects of a sloped-face weir, a series of tests was made with the sharp-crested weir inclined at various degrees with the vertical. The overflow head was kept at the same depth, as nearly as possible, for each of the three inclinations tested.

By transferring the co-ordinates of the measured nappe points to a common head of unity, a composite curve is obtained as given in Fig. 29. It is seen that the sloped faces cut the nappe curve, as obtained for a vertical face, at various points, but the slopes are not tangent to the crest curve. Intersection points of slopes other than those tested may be interpolated.

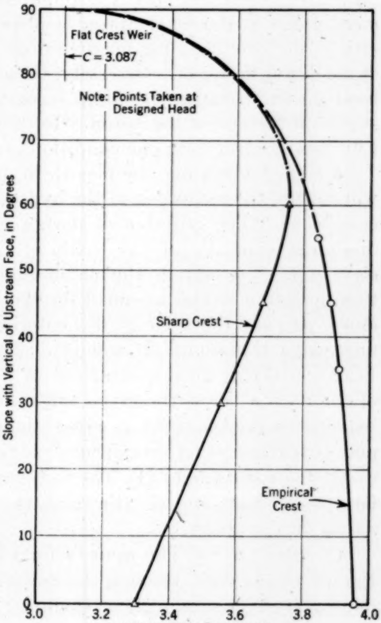

FIG. 30.—EFFECT OF SLOPE TO UPSTREAM FACE OF DAM

The effect of sloping the face was to cause an immediate, although not rapid, decrease in the coefficient of discharge (see Fig. 30). This is probably due to friction of the flow on the long sloping face, as the slopes were carried down to the bottom of the approach channel which was a distance 4 H below the crest. The discharge of the sharp-crested weir increased for inclinations as steep as about 62° with the vertical, probably due to the lessened contraction of the jet. Both curves (Fig. 30) are assumed to drop off to a coefficient of 3.087 for a flat-crested weir although this assumption was not tested.

Discussions.—Mr. Stevens questions Conclusion (2) that the jump can be "controlled best by placing a sloped apron down stream * * *," and states further "that there is no virtue in the sloping deck, as such, to aid in the dissipation of energy." Conclusion (2) stated that the jump could be better "controlled" on the sloping apron; and did not state that the jump was more effective. The writer had previously stated that "the steeper the slope of the apron the less perfect is the jump formation" (see heading, "Hydraulic-Jump Apron: Expected Jump Performance"), but that good dissipation could be obtained on a slope if it were not made too steep, 1 on 4 being approximately the maximum. Control of the hydraulic jump was intended to mean that an effective jump must be made to form well up on the concrete apron for any and all discharges and for various depths of tail-water. To this end it was thought that a sloped apron was better adapted than a level apron. For a level apron the tail-water must furnish a depth over the apron that exactly corresponds to the required jump depth in each and every case and over the entire range of flow. Such a coincidence is very rarely found. The tail-water elevations predicted for the higher flows (and the tail-water for the designed maximum flow is invariably a prediction) are in themselves liable to considerable error. The tail-water curve may also be changed after the dam is built due to old coffer-dams being left in, or due to erosion of the stream bed and lack of sediment deposition by the clear water overflowing the dam, so that in such a case the criterion for design of the level apron is in itself subject to considerable variation.

In the great majority of cases it will be found that the plotted curve of the tail-water depth will cross the required jump-depth curve at an angle. This means that if the level apron is placed at a depth below the tail-water to satisfy the condition for maximum discharge, the jump will be drowned out at the lower flows; or, conversely, there will not be enough tail-water over the level apron to cause the jump formation, and the high velocity sheet may sweep off the end of the apron. In other words, the level apron, theoretically, will usually meet only one condition of flow.

A sloped apron may be placed, in proper reference to the tail-water, which will control the formation of the hydraulic jump for any variation of tail-water conditions. The criterion of design for the apron is usually the maximum discharge capacity of the spillway, resulting in the maximum tail-water elevation. To compute the maximum required jump-depth, D_2, for this condition, a datum is first assumed for the apron level. Referring to Fig. 31, the depth, D_1, and the velocity, V_1, entering the jump are computed at the datum line, using Equations (2) and (3). The jump-depth, D_2, is then found from Equation (1); it must correspond to the depth first assumed for the distance of the datum below the given tail-water elevation. The factors are made to balance by trial and error. Investigation of flows lower than the maximum may reveal one of two conditions existing, if the apron is assumed level at this computed datum line: (1) The tail-water may be too deep and the jump will be drowned out; and (2) the tail-water will be too shallow and the jump will sweep off the apron.

Condition (1).—The remedy for Condition (1) is to raise the apron near the toe of the dam, keeping the down-stream end at the computed maximum depth, D_2. This will allow shallower depths over the sloped apron, which will satisfy the required jump-depths for the lower flows. Tests at Madden Dam indicate that the apron may be raised as much as 0.2 D_2 (maximum) without materially affecting the jump performance at maximum discharge $\left(\text{see Fig. 9; } 1 - \frac{d_s}{d_1}\right)$. The slope of the apron would be 0.0667 if the length is taken as 3 D_2, a conservative value (see Fig. 31). If the apron slope is made steeper than this value, the length of the apron must be increased, as the beginning of the jump at maximum discharge will move down the apron and the distance must be added down stream to afford equal protection.

Condition (2).—The remedy for Condition (2) is to slope the apron. If at some critical lower discharge it is found that the natural tail-water depth is too shallow for jump formation, the apron may be sloped down into the tail-water until the required jump-depth is encountered. The slope may be made as steep as 1 on 4 (maximum). The upper end of the apron must be raised 0.2 D_2 to keep from drowning the jump at maximum discharge (see Fig. 31).

Somewhere along its length, such a sloped apron will furnish the required jump-depth for all stages of flow.

Condition (3).—A third condition may be found to exist in the relation of the jump-depths and the tail-water. The foundation rock may lie so deep under the tail-water that the jump on an apron at this elevation will be drowned out for all stages of discharge. Again, the remedy is to raise and slope the apron. At the toe of the dam the apron is raised 0.2 D_2 (maximum), and sloped down stream to bed-rock. The slope should not be steeper than 1 on 4

and the length of the apron should be at least $3D_2$ (maximum). The apron is joined to the down-stream face of the dam by a radius tangent at a distance, $0.7\,D_2\left(\text{see Fig. 9; } 0.2\,D_2 + \frac{h_e}{d_i}\right)$ above the datum line (see Fig. 31). The beginning of the jump for maximum discharge will then be at the point of curvature of the bucket radius and the jump will not be drowned out. At less discharges the jump will form lower down the slope, thus affording protection throughout the total range of flow.

This condition was encountered at Madden Dam. The sloped apron was adopted mainly for economy of concrete. However, there were other inherent advantages. On a sloped apron the jump is stabilized, forming in a straight line across the channel. The slope allows for an adjustment of the jump for tail-water variations, if the actual tail-water does not conform to the predicted curve used for the model tests.

As Mr. Stevens stated, a good correspondence was obtained with a level apron located at Elevation 83 (see Fig. 3), assuming, of course, that the tail-water curve is absolutely correct. He further states that "by proper manipulation of the crest gates as good correspondence might also have been had with a lower apron." As applied to the present case, the writer does not agree. With all crest-gates fully opened at the maximum forebay level, an apron at Elevation 83 was required for the jump. On a lower apron the jump would have been drowned out and little dissipation of energy would have been accomplished.

On a plain level apron, the jump is comparatively unstable, moving up and down the apron with slight tail-water variations. It is practically necessary to place baffles or large sills on a level apron, in order to stabilize the jump and assure its formation on the apron. Such baffles and sills do allow the use of a shorter apron but will not function properly unless there is a depth of tail-water over them equal, at least, to the required jump-depth. Their principal capacity is to break up flow concentrations and to diffuse the stream leaving the apron. The dentated sill or the diffuser sill is well adapted to this purpose.

A sloping apron will stabilize the jump, causing it to form in a uniform line across the channel, and if the slope is properly placed in respect to the tail-water, a good "control" of the hydraulic jump is effected and velocity retardation will be quite satisfactory.

Due to the variations of conditions, both structural and operating, encountered for different projects, it becomes practically impossible to formulate set rules for spillway design. The pure hydraulic-jump apron functions best when the flow can be discharged uniformly along the apron, as at Madden Dam. At Bonneville Dam, due to submergence of the spillway crest, gate operation becomes a factor in the design of the stilling-basin. It is for this reason that hydraulic model studies become a practical necessity. Their cost is usually more than compensated for by the economies effected. Proper design is assured and many problems can be solved satisfactorily that are difficult of theoretical analysis.

Mr. Stevens condemns the sloping apron, from comparison of the erosion tests made in the model studies of Bonneville Dam as illustrated in Fig. 25. He offers no proof that the velocity retardation is more effective on the level apron. Even if the velocity at the end of each apron was the same, and if this velocity is directed downward on the river bed, as is the case with the illustrated sloping apron, it is natural that more erosion would occur. The apron would need to be extended down stream to cover a greater part of the jump action so that the velocities off the end are insufficient to cause damage to the river bed. The apron could have been shortened by placing a deflector sill at the end.

It would seem, however, that the sloping apron, as illustrated in Fig. 25, is improperly located to obtain the most effective jump formation. Apparently, the beginning of the jump is forced too far back against the face of the dam, which indicates that lowering the apron would be beneficial. Such a sloped apron at Bonneville may have effected quite an economy in apron concrete. Mr. Stevens does not state the results of tests on the sloped apron using the adopted baffles or a deflector sill similar to one used at Madden Dam.

Mr. Stevens notes from Fig. 16 that the velocity at the toe of the dam is only 69% of the theoretical velocity whereas on the model "it was about 91% for the same discharge"; and questions whether this variation is due to the difference in roughness of metal and concrete. His values of 69% and 91% apparently refer to the velocity-head ratios and not to the velocity ratios, which are about 83% and 95 per cent. This indicates a smaller variance in the velocity ratios than was stated by Mr. Stevens; and it would be even less if the discharges were the same. Values given for the model correspond to a 11.25-ft depth over the crest and those for the prototype are for a 7.78-ft depth. The equivalent model discharge is considerably greater. The percentage of the theoretical velocity head manifested at the toe increases with the discharge so that for a depth of 11.25 ft over the prototype the ratio, 83%, increases and, if the discharges were the same, there would actually be less difference between the comparative prototype ratio and the model ratio of 95 per cent.

Mr. Stevens would probably attribute the difference in this ratio to the air content of the water. For shallow depths of overflow there is no question but that the entrained air will affect the velocity of the sheet; but at greater depths the overflowing sheet may reach the toe of the dam in a solid mass with little or no entrained air present. Fig. 21 shows the condition of the overflow sheet just prior to the jump. The depth over the crest is only 8.0 ft, and yet there is indication of only a slight aeration in the sheet between the piers. For greater depths the only retarding factor for practical consideration would be friction.

Application of the existing friction-loss formulas to flow down steep chutes seems to be impractical; but to state that the velocity of the overflowing sheet has an upper limit of about 80 ft per sec seems equally impractical.

The friction loss will depend on the depth of overflow as well as the length of the chute and the velocity of the water. As a matter of practical usefulness, it would seem desirable to obtain an empirical relation of the governing factors in as simple an expression as possible, as is done in Equation (3). It was with this thought in mind, aside from the idea of checking prototype against model results, that the writer conceived of, and designed, the Pitot tube pedestals placed on the apron at Madden Dam.[28] It is to be hoped that readings on the tubes may be obtained for greater depths over the crest than were available during these tests. The writer has urged the placing of these tubes on the aprons of other dams designed by the U. S. Bureau of Reclamation, and it is also to be hoped that other investigators may take similar steps to obtain needed data on this debatable subject.

Importance of Hydraulic Jump.—It is gratifying to note that Mr. Edwards gives due credit in stating that "the tests * * *, conducted as they were in 1931, have furnished a pattern for numerous later experiments on similar structures." The original report[2] was widely circulated among Government departments and libraries. It may be said that the Madden studies created a "hydraulic-jump consciousness" in relation to its use for stilling-basins at the toe of overflow dams. Certain phases of the laboratory technique have also been widely used, making speedy construction and testing of models possible.

The program for prototype testing pioneered in its comprehensiveness, and it is indeed regrettable that it reached a state of indifferent stagnation before all possible data were obtained.

---

[28] *Engineering News-Record,* February 10, 1938, p. 237.

The stilling-basin design for Conchas Dam again demonstrates the value of the use of the hydraulic jump. It becomes a practical necessity, however, to use comparatively heavy sills on a level apron in order to stabilize the formation of the jump.

A sloped apron allows much greater latitude in design assumptions and will stabilize the jump without the use of large blocks or sills, which are susceptible to damage. As part of his design for the stilling-basin at Bonneville Dam, Mr. Stevens includes a caisson to be used for "examination and repair" of the baffles.[18]

Professor O'Brien substantiates the writer's contention that the jump can be "controlled best by placing a sloped apron down stream." One of his closing statements may well be used to summarize this discussion: "Only in the event that the [true] back-water curve from the next control down stream produces submergence at each discharge exactly equal to the 'jump-depth' can a horizontal apron be as effective as a sloping apron which produces a true jump but prevents drowning."

EFFECT OF DOWEL-BAR MISALIGNMENT ACROSS CONCRETE PAVEMENT JOINTS

By Arthur R. Smith,[1] M. Am. Soc. C. E., and Sanford W. Benham,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. L. W. Teller, David J. Peery, L. J. Mensch, W. O. Fremont, George A. Smith, L. E. Grinter, and Arthur R. Smith and Sanford W. Benham.

Synopsis

The subject of joints in concrete pavements, to provide for expansion and contraction, and the means of transferring load across joints, is of particular interest to those engaged in highway construction. Common dowel bars, passing through the joint and embedded in the two adjacent slabs, have long been used for this purpose. The importance of installing the bars correctly, that is, perpendicular to the cross-section of the pavement, will be recognized since dowels, incorrectly installed, will not slip freely in the concrete. This paper describes an investigation to determine the accuracy with which road-building contractors were installing dowel bars, and another investigation which was conducted to determine, by experiment, the degree of precision necessary to assure satisfactory functioning of joints.

Introduction

In accordance with the specifications of the State Highway Commission of Indiana, 1-in. expansion joints are installed in concrete pavement at 80-ft intervals, with a transverse contraction joint in the center of each 80-ft section. As a means of transferring load across joints, dowel bars of intermediate grade steel (0.75 in. in diameter by 24 in. long) at 12-in. centers, are placed in the pavement across all contraction joints and across some types of expansion joints. To prevent bond, the bars are coated with an asphalt paint and are also oiled. Fig. 1 illustrates an assembly of

twenty dowel bars wired to two spacer bars, as installed across expansion and contraction joints in 20-ft pavement.

The importance of placing the bars correctly, that is, perpendicular to the cross-section of the pavement, will be readily appreciated when it is realized that if they are imperfect in this respect, binding between them and the concrete will occur when the joint opens or closes. As a consequence, either the bars will become distorted or the concrete will be damaged in the vicinity of the bars.

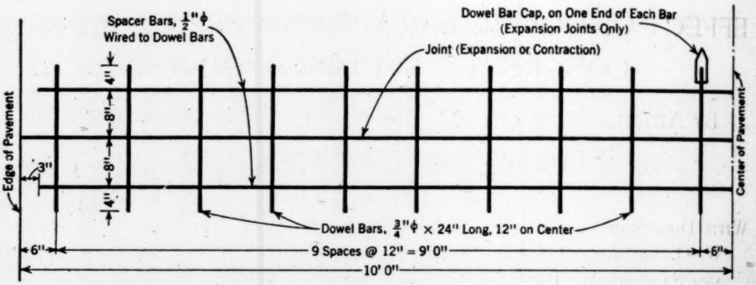

Fig. 1.—Typical Dowel-Bar Assembly in 20-Foot Pavement.

A faulty installation of dowel bars across a contraction joint constitutes a serious hazard. When contraction of the pavement opens the joint cracking or spalling of the concrete may occur. If the concrete is strong enough to resist such damage, however, the joint, instead of being a plane of weakness, may offer more resistance to movement than the tensile strength of the unimpaired cross-section of the pavement. In this case the contraction joint will not fulfill its function and cracks will occur in the pavement at random as if no provision had been made to locate them. In like manner, a faulty installation of dowel bars across an expansion joint will cause damage to the concrete, the bars, or to both, when expansion of the pavement reverses the process and closes the joint. In this case, also, if the concrete and dowel bars offer sufficient resistance to such damage, the joint will not fulfill its function and there will be no provision for expansion. Therefore, to avoid damage to the pavement in the vicinity of expansion and contraction joints the dowel bars must be placed in their proper positions and held in those positions by some method that will prevent their movement during the placing and finishing of the concrete.

During the summer of 1935, the Bureau of Materials and Tests of the State Highway Commission of Indiana, conducted a number of field tests (Special Investigation *A*-7) to determine the accuracy with which dowel bars were being installed by various contractors. When a dowel bar is in perfect position, that is, perpendicular to the cross-section of the pavement, the projected length of its axis on the cross-section is zero. The projected length is equal to the hypotenuse of a right triangle, the altitude of which is the vertical error of the bar, that is, the difference in elevation between the two ends of the bar with respect to the surface of the pavement. The base of the triangle is the horizontal error of the bar, that is, the difference between the distances from the edge of the pavement to the two ends of the bar. Thus, dowel-bar error which, in this paper, is defined as the projected length on the cross-section of the pavement per 22 in. of dowel-bar length, is equal to the square root of the sums of the squares of the horizontal and vertical errors. Although the bars are 24 in. long, the field tests were conducted more easily by choosing points 1 in. inward from each end of the bar to represent the ends of the bar. In conducting the tests, data were obtained, by means of the apparatus described herein under "Methods of Test", from which it was possible to compute the error of each dowel bar in each installation checked. Several different methods of installing the bars were being utilized, namely:

(1) Sheet metal chairs, of the pin type, driven into the sub-grade, with the upper end bent around the dowel bar or spacer bar (see Fig. 2).

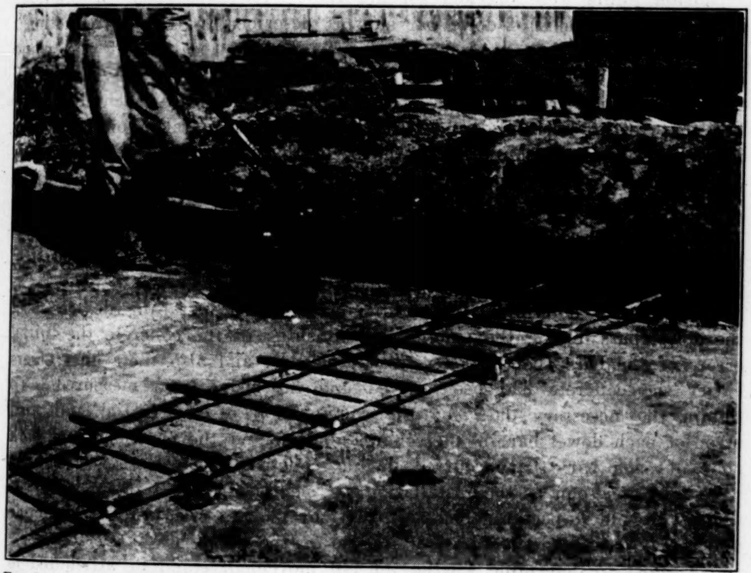

Fig. 2.—Sheet Metal Chairs of the Pin Type Driven into the Sub-Grade (Test No. 6).

(2) Welded assemblies, consisting of heavy, wire, **U**-shaped chairs welded to the spacer bars. The upper ends of the chairs are bent around the dowel bars and the horizontal part of the **U** rests on the sub-grade (see Fig. 3).

(3) Specially designed holders, which span the sub-grade and are supported by the forms. The dowels are thereby held during the placing of the concrete and are left "floating" in the concrete after the removal of the holder. One type of holder is shown in Fig. 4. No satisfactory

photograph is available of one that is supported entirely from the forms (independent of the sub-grade).

(4) Combinations of Methods (1) and (3).

Two claims of superiority for Method (3) have been advanced: First, the holder is supported by the forms, which determine the position of the cross-section of the pavement, thereby eliminating the objections to methods in which the positions of the dowels are governed by the contour of the sub-grade, which is never perfect; and, second, the installation of dowel bars is accomplished more quickly and easily with a holder than with chairs. The first claim, of course, is based on the assumption that the holder is made accurately, is sufficiently strong to resist distortion in handling, and that it is placed on the forms in the proper position.

METHODS OF TEST

Installations of dowel bars across nine contraction joints and across five expansion joints were checked for accuracy. These fourteen installations included the methods of dowel-bar support described in the "Introduction".

The contour of a concrete pavement and the location of the plane representing its cross-section are determined by the tops of the forms, since these lines are the paths of travel of the finishing machine screed. For that reason horizontal and vertical readings were taken on both ends of each bar from a reference line the position of which was definitely fixed with respect to the tops of the forms. This reference line, described briefly, consisted of a steel tape graduated to 0.01 ft, riveted to the lower flange of a 4-in. aluminum I-beam, spanning the sub-grade and resting on the tops of the forms, the points of support being three sharp pointed steel pegs.

In order to determine the rigidity with which installing devices held the dowel bars during the placing and finishing of the concrete the initial errors of the bars (before concrete was placed), and also their final errors (after the concrete had been placed and finished), were measured. To obtain the necessary data for the computation of the initial and final error of each dowel bar in a given installation and the movements of both ends of each bar, that occurred during construction operations, readings were taken as soon as the installation was completed and pronounced satisfactory by the inspector. The operations of placing and finishing concrete and the extent to which workmen stepped on the bars, were observed closely in an effort to determine whether or not movement could be attributed to carelessness. As soon as the finishing machine had passed over the joint for the last time, sufficient concrete was removed from the newly finished surface of the pavement to expose both ends of each dowel bar and permit final readings.

DISCUSSION OF RESULTS

The results of Special Investigation *A*-7 revealed that, in some of the installations checked, the bars were in extremely faulty positions. Twelve of the fourteen installations tested were in 20-ft pavement and two were in 10-ft pavement (widening projects). Consequently, the errors of 260

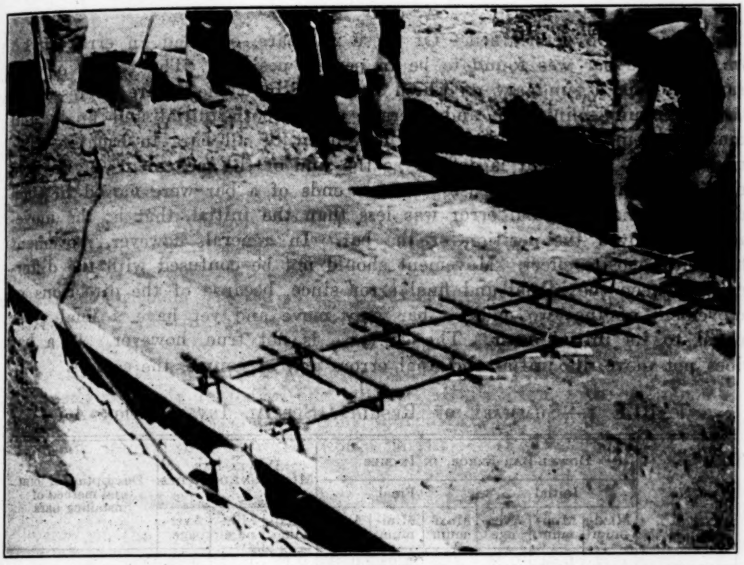

Fig. 3.—U-Shaped Chairs Resting on the Sub-Grade and Welded to the Spacer Bars (Test No. 12).

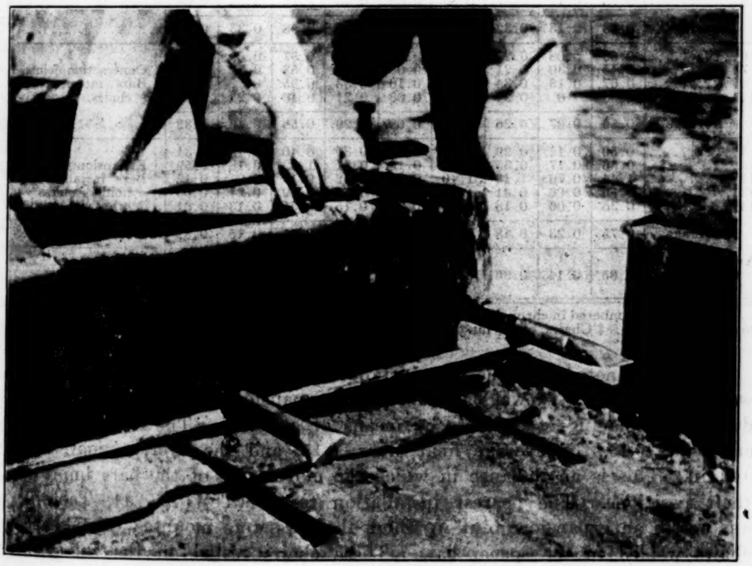

Fig. 4.—View Showing the Use of a Holder (Test No. 14).

dowel bars were determined. Of these 260 bars, one had an error of 1.5 in., and one bar was found to be in perfect position. The results of this investigation, a summary of which is shown in Table 1, are expressed as the maximum, minimum, and average error (both initial and final) and maximum, minimum, and average movement of all bars in each installation tested. Movement is defined as the sum of the movements of the two ends of a bar. In some cases the two ends of a bar were moved in such directions that the final error was less than the initial, that is, the movement improved the position of the bar. In general, however, movement had the opposite effect. Movement should not be confused with the difference between the initial and final error since, because of the directions of movement of the two ends, a bar may move and yet have a final error equal to its initial error. The converse is not true, however. If a bar does not move, its initial and final errors are, of course, the same.

* Tests were numbered in chronological order. † U-shaped chairs resting on sub-grade and welded to spacer bars. ‡ Chairs, of the pin type, were used (one to each dowel bar), in addition to the holder.

It will be noted that the best installation tested (Test No. 14, Table 1) was an assembly of dowel bars, across an expansion joint, held in position during the placing of concrete by means of a holder. The average initial error was 0.18, the average final error, 0.15, and the average movement, 0.31 in. This is an instance in which the movements of the bars improved their positions. The poorest installation tested (Test No. 11, Table 1) was across an expansion joint in which the bars were mounted on U-shaped chairs welded to the spacer bars. These chairs rested on the sub-grade. The average error was 1.16 in., initial, and 1.12 in., final. Quite paradoxically this was the best installation so far as movement was concerned

(0.12 in.). The poorest installation so far as movement is concerned was across a contraction joint in which the bars were installed with a poorly designed holder (Test No. 9, Table 1). The average movement was 0.89 in., and the directions of movement were such that the initial error was increased.

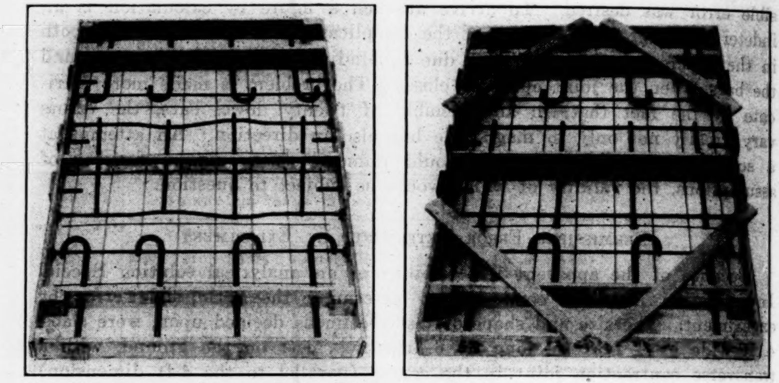
The results of the investigation indicated the need of information concerning the effect on the pavement of given degrees of error in dowel-bar placement. Since it is not feasible to require that every dowel bar in every installation be in perfect position, some figure specifying the permissible error was desired. To arrive at such a figure by calculation is an indeterminate problem because of the complication of stresses induced both in the concrete and in the bars, due to binding between the concrete and the bars, when the joint opens or closes. The problem is made more intricate by the fact that, in an assembly of twenty dowel bars, the errors vary greatly not only in magnitude but also in direction. An attempt at a solution of such a problem would immediately require a number of assumptions, the validity of which would be subject to question.

Permissible Error Determined by Experiment

Because of the apparent impossibility of an analytical solution Special Investigation *A*-8 was conducted to determine the permissible error by experiment. The size and shape of test specimens decided upon, were slabs, 4 ft wide by 4 ft 8 in. long by 6 in. thick, cast on the ground, with a transverse contraction joint in the center (parallel to the 4-ft dimension) through which four dowel bars were placed at 12-in. centers. The slabs were made in groups of five, all five being poured from the same batch of ready-mixed concrete. In one slab the dowel bars were installed in perfect position (with zero error); in the other four slabs, they were purposely set at errors of 0.25 in., 0.5 in., 1 in., and 1.5 in. The second group of slabs, made on a different day, were duplicates of the first group except that 1-in. air cushion expansion joints were provided instead of contraction joints. Groups 3 and 4 were duplicates respectively of Groups 1 and 2 except for thickness, which was reduced to 5 in. In all, the test specimens consisted of twenty experimental slabs, each containing four dowel bars, including two slab thicknesses for each of five errors, for both contraction and expansion joints.

The design of the experimental slabs and the directions of dowel-bar errors will be more readily undertsood by referring to the photograph of an empty form (Fig. 5(*a*)). This form is for the fabrication of a 6-in. slab containing a contraction joint, the dowel bars having an error of 1.5 in. The two outside dowel bars have no error vertically; that is, they are level, but a plan view would show that each one has a projected length on the cross-section of the slab of 1.5 in., and that they converge toward the reader. A plan view would show the two interior bars in perfect position but, due to the difference in elevation between the two ends of each bar, each one has a projected length of 1.5 in. Note the relative positions of these two bars. The end toward the reader, of the bar on the left, is 1.5 in.

higher than the opposite end. The end toward the reader, of the bar on the right, is 1.5 in. lower than the opposite end. As this contraction joint is opened the two interior bars tend to rotate the slab (clockwise from the reader's position), which tendency is resisted by the two outside bars which produce compression (horizontally) in the half of the slab toward the reader and tension in the opposite half. Consequently, opening the joint produces stresses in the concrete and dowel bars which are not only severe but of a complicated distribution. This same arrangement of dowel-bar positions was used in all slabs containing dowel bars in error.



(*a*) CONTRACTION JOINT; DOWEL-BAR ERROR = 1.5 INCHES.

(*b*) EXPANSION JOINT; DOWEL-BAR ERROR = 0.

FIG. 5.—FORM FOR THE FABRICATION OF A 6-INCH SLAB.

The method of forming the contraction joint is also shown in Fig. 5(*a*)). The pre-molded material with which contraction joints are usually filled is simulated by a piece of wood, 0.75 in. thick, having a vertical dimension equal to one-third the slab thickness. A weakened plane was created by installing a piece of No. 24 gage galvanized iron, extending from the wood strip downward to the sub-grade. The dowel bars pass through semicircular openings, 3 in. in diameter, in the sheet metal. Expansion joints were formed by installing a cork filler, 1 in. thick, as shown in Fig. 5(*b*), which also shows the corner bracing used on all forms to prevent distortion during the placing of the concrete. To give the cork sufficient rigidity against bending during the placing of the concrete, it was backed up with a board which was removed after the form was filled. Before the slabs were tested the cork was removed with a chisel. In Fig. 5(*b*) the dowel bars are in perfect position with respect to the cross-section of the slab—that is, zero error. Anchor bars were installed in both ends of the slabs at the time of fabrication, as shown in Fig. 5, for attaching the testing equipment.

In addition to the twenty experimental slabs containing common dowel bars, thirteen slabs were made for the study of another type of load-transfer device. For the purpose of this paper, however, the discussion of

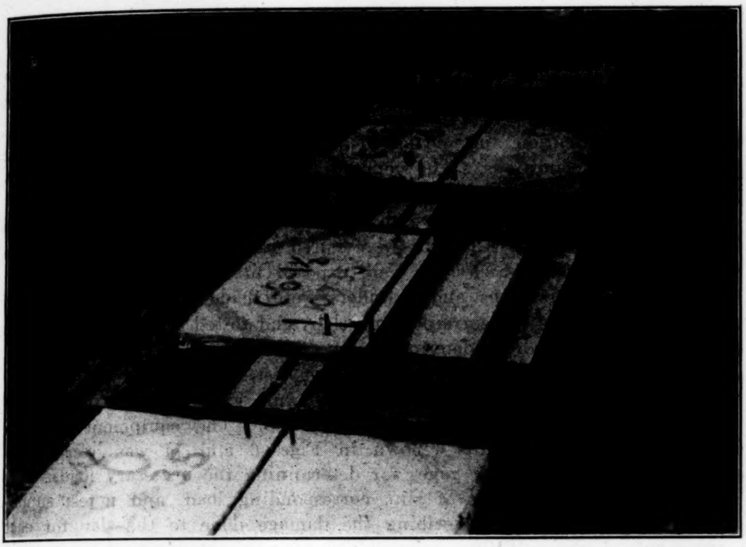


FIG. 6.—EQUIPMENT FOR OPENING A CONTRACTION JOINT.

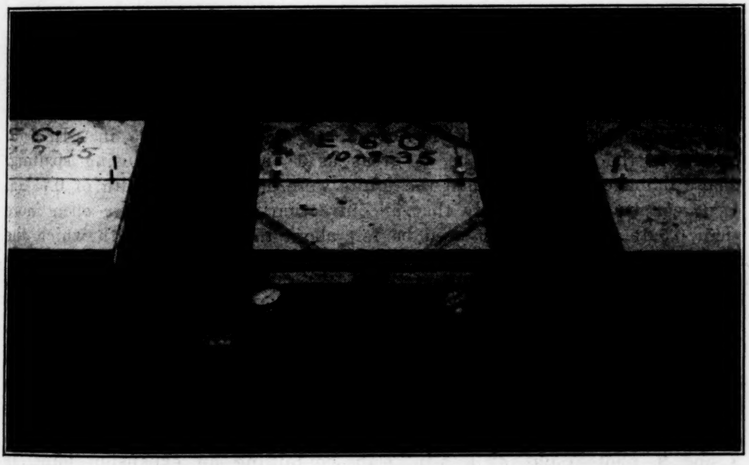

FIG. 7.—EQUIPMENT FOR CLOSING AN EXPANSION JOINT.

results is confined to those obtained with common dowel bars since they are in so much more general use than any proprietary device. The entire investigation required the fabrication and testing of thirty-three experimental slabs.

In the fabrication and curing of the slabs every effort was made to duplicate field conditions. The concrete was of the same cement content and consistency as that used in practice and the slabs were reinforced with standard wire mesh. The sub-grade was tamped and sprinkled before placing the concrete. All slabs were cured under wet burlap during the first ten days, after which they were exposed to the weather. From each batch of concrete, beams and cylinders were made which were cured in the same manner as the corresponding slabs and tested at the same time the slabs were tested, thereby determining the flexural and compressive strength of the concrete in the slabs at the time of test.

At the age of 28 days all contraction joints were opened a distance of 0.75 in. and all expansion joints were closed. The equipment used for opening and closing joints (shown in Figs. 6 and 7) was operated by hydraulic jacks fitted with gages for determining the necessary loads. The test data included records of slip, corresponding load, and notes, supplemented by photographs, describing the damage done to the slab for each increment of slip. Within a few days after all contraction joints were opened and all expansion joints closed, the process was reversed and the contraction joints were closed and the expansion joints opened to their original positions, thus completing one cycle of movement. At the age of one year all slabs were opened and closed nine more times, completing ten cycles of movement, and then pulled entirely apart in order that the cracking and spalling on the faces of the joints could be photographed.

Results and Conclusions

The results of the tests indicate that common dowel bars across contraction joints in 5-in. pavement will cause a very slight spalling of the concrete around the bars if the errors are as great as 0.25 in. In 6-in. pavement the errors may be as great as 1 in. without causing spalling. These damages occurred when the joints were opened to a width of 0.75 in. If it can be assumed safely that a contraction joint will never open more than 0.5 in., little concern need be felt about the accuracy with which the dowel bars are installed. When opened to this width (0.5 in.) the only slab that showed any spalling was the 5-in. slab in which the bars were in error 1.5 in.

The refinement with which dowel bars are placed is more important in expansion joints than in contraction joints. An error of 0.25 in. caused slight spalling and when the joint spaces were closed 0.75 in., to a width of 0.25 in. (which may occur in practice), errors of 1 in. caused the slabs to crack and spall. Typical cracking and spalling are shown in Figs. 8 and 9, photographs of a 5-in. slab, containing an expansion joint, in which the dowel bar error was 1.5 in., after one cycle of movement (Fig. 8) and after ten cycles of movement (Fig. 9).

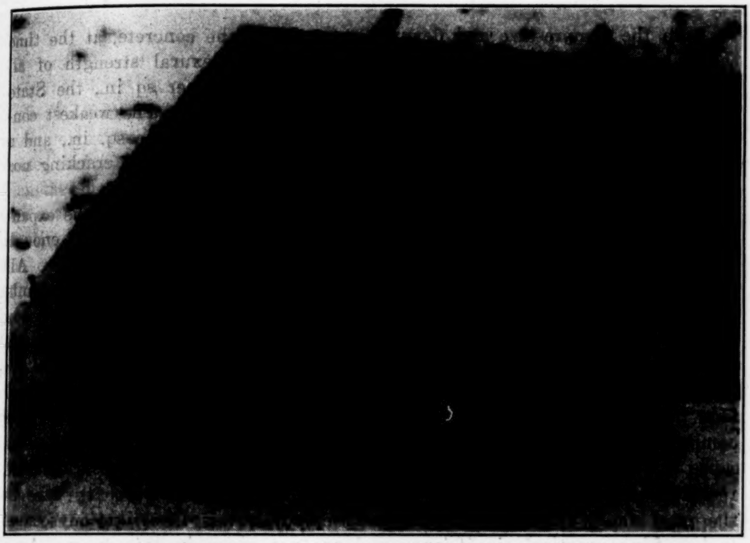

FIG. 8.—DAMAGE DONE TO TEST SLAB BY ONE CYCLE OF MOVEMENT (THICKNESS OF SLAB, 5 INCHES; AND DOWEL-BAR ERROR, 1.5 INCHES.)

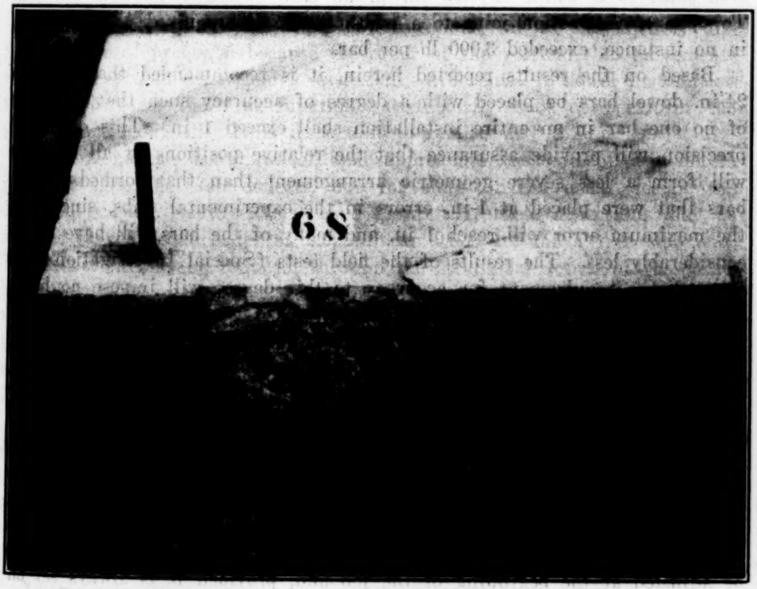

FIG. 9.—SAME SLAB AS SHOWN IN FIG. 8, AFTER TEN CYCLES OF MOVEMENT.

Both the compressive and flexural strengths of the concrete, at the time the slabs were tested, were unusually high. The flexural strength of all test specimens was considerably greater than 550 lb per sq in., the State requirement for opening pavement to traffic in Indiana. The weakest concrete tested had a 28-day modulus of rupture of 670 lb per sq. in., and a compressive strength of 4 010 lb per sq in. Consequently, no cracking nor spalling of the slabs can be attributed to inferior concrete.

The loads required to open or close either the contraction or the expansion joints were less than anticipated and in no case were they great enough to stress the slab dangerously either in direct tension or compression. All damage done to the slabs was plainly due to stresses caused when the joints were being opened or closed, by the wedging and twisting effect of bar misalignment. The loads necessary to open and close the joints were not great enough to produce tensile or compressive stresses approaching the strength of the interior of the slabs—that is, the parts in which no dowel bars nor anchor bars were present. This statement is proved not only by computation, but by observation, since no transverse cracks occurred. Because the slabs were capable of transmitting forces so far in excess of those required to open and close the joints, even when the dowel bars were in the most faulty positions, the loads observed in this investigation seemed to be of no practical significance and are not given in this paper. As a matter of general interest, however, the load necessary to close an expansion joint to a width of 0.25 in. in no case exceeded 4 000 lb per bar. To open a contraction joint to a width of 0.5 in. required a load which, in no instance, exceeded 3 000 lb per bar.

Based on the results reported herein, it is recommended that common 24-in. dowel bars be placed with a degree of accuracy such that the error of no one bar in an entire installation shall exceed 1 in. This degree of precision will provide assurance that the relative positions of all the bars will form a less severe geometric arrangement than that formed by the bars that were placed at 1-in. errors in the experimental slabs, since only the maximum error will reach 1 in. and many of the bars will have errors considerably less. The results of the field tests (Special Investigation *A*-7) show that a requirement for accuracy to this degree will impose no hardship on the contractor. The vertical position of each bar can be checked quickly with a carpenter's level, as shown in Fig. 4, and adjusted if necessary, until the bubble position is approximately the same as when the level is set on the forms. The horizontal position can be made perfect by adjusting each bar so that the distances from each end to one of the forms are equal. Since the total error (projected length on the cross-section of the pavement) of a bar is equal to the square root of the sums of the squares of its vertical and horizontal errors, the vertical and horizontal error could each be as great as 0.707 in. and still comply with this specification. If some type of holder is used to install the bars, it should be adjusted at the beginning of the job and, provided it is always set on the forms in correct position and does not become damaged in handling, all installations should be correct.

DISCUSSION

L. W. TELLER,[3] ASSOC. M. AM. SOC. C. E. (by letter).—A subject that is of importance to every designer and builder of concrete pavements is treated in this commendable paper. The data which the authors furnish from measurements of dowel positions in place, are useful in demonstrating, rather conclusively, what is more or less common belief—that, frequently, good dowel-bar alignment is not obtained in actual construction. The effect of such misalignment upon dowel efficiency is a matter that should receive very careful consideration before an attempt is made to draw broad conclusions or to recommend general tolerances for field construction. Unfortunately, the authors did not include all the data from the experiments that were used to determine the permissible errors that are recommended, and, therefore, no detailed discussion of their test data is possible. Some general discussion of the subject of dowel efficiency is pertinent, however.

A dowel-bar installation really has two functions in a concrete pavement: First, it prevents any gross faulting of the two slab ends and preserves the general continuity of the pavement surface at the transverse joint; and, second, through its shear resistance, it assists the slab end in carrying wheel loads by transferring a part of the load across the joint to the adjacent slab. The installation requirements for the dowels, in order that they may perform these two functions, are of two entirely different orders of precision because the order of the vertical slab movements with which each is concerned is essentially different. A dowel installation that will perform the first function satisfactorily may not perform the second function at all. It is important to realize why this is so.

When a normal heavy wheel load approaches the end of a concrete pavement slab, the slab deflects, but for slabs of the usual design the deflection is quite small. Tests[4] have shown that these deflections may be expected to be of the order of 0.020 in. to 0.030 in. for a free slab end. This deflection may be reduced, through the structural action of the joint, by possibly 0.010 or 0.015 in. Thus, it is apparent that whatever the single dowel is to accomplish must be done during a relative displacement of the two slab ends of only a few thousandths of an inch. The bearing of the dowel on the concrete must be maintained within close limits if the unit is to develop shear resistance and thus transfer load.

In their "Synopsis," the authors state quite correctly that it is important to place the bars accurately. If they are not perpendicular to the cross-section of the pavement, binding between them and the concrete will occur when the joint opens or closes. As a consequence, "either the bars will become distorted or the concrete will be damaged in the vicinity of the bars."

---

[3] Senior Engr. of Tests, Bureau of Public Roads, U. S. Dept. of Agriculture, Washington, D. C.

[4] "Structural Design of Concrete Pavements"; Pt. 4, "A Study of the Structural Action of Several Types of Transverse and Longitudinal Joint Designs," *Public Roads*, Vol. 17, No. 7, September, 1936, p. 166.

The bearing stress imposed on the concrete by the round steel dowel bar is very high, and it is the concrete that fails first. The type of failure known as "funneling," observed under certain conditions in the concrete immediately around a dowel, is the direct result of repeated applications of this high bearing stress.

Since the effectiveness of a dowel can be lost entirely if a relatively small amount of "play" is developed between it and its socket, it is apparent that, in the tests reported by the authors, the absence of structural cracking or visible spalling does not necessarily mean that the dowels retained their effectiveness so far as their function of transferring load is concerned.

When a wheel load rests on a slab end at a distance from a corner the critical stress in the concrete is a tensile stress in the bottom of the slab directly under the wheel load. The direction of this critical deformation is parallel to the edge of the slab. The load-transfer feature of a joint installation is intended to relieve this stress and the degree to which it accomplishes this relief is a measure of the efficiency of the joint action.[5] The only apparent way in which one can determine joint efficiency (or change in joint efficiency) is by means of stress determinations that will show, directly, the degree to which the joint is fulfilling its function of relieving the critical edge stress. The authors do not report tests of this kind and without them the effect of dowel alignment on dowel efficiency remains unknown.

The authors do not present the data on the forces required to produce slab displacements for various degrees of misalignment, but state that in no case did they exceed 4 000 lb per bar. From this they reason that the loads "seemed to be of no practical significance." As far as compressive stress is concerned this may be true, but if poor dowel alignment can cause tensile stresses of the order of 50 lb per sq in. in the concrete, then the stress has practical significance. In certain parts of the slab, loads and temperature warping produce tensile stresses at a common point. If joint resistance adds to this, it subtracts directly from the stress resistance available to carry wheel loads. A properly installed plain round dowel should not develop more than about 100 lb of total resistance to longitudinal movement, which is equivalent to about 1 lb per sq in. of concrete stress.

It is not the writer's purpose to criticize the authors nor the tests that they made, but rather the generality of the conclusions which they draw. Until such time as tests are made that measure directly the effect of misalignment of dowels on the structural efficiency of the joints in which they are installed designers should bend every effort toward the development of means for installing them as perfectly as possible and not encourage careless installation in the field by recommendations such as are made in this paper.

DAVID J. PEERY,[6] JUN. AM. SOC. C. E. (by letter).—An investigation of the alignment of pavement dowels supplies information for studying the efficiency of the dowel bars in transferring loads across joints. A homogeneous slab of uniform thickness, supported on an elastic sub-grade, will be much more highly stressed by a load applied at a free edge of the slab than by the same load applied at the interior of the slab. A balanced slab design, in which the maximum stresses at the edges are equal to the maximum stresses in the interior, is approached by thickening the edges or by providing dowel bars to transfer part of the load to the edge of adjacent slabs.

---

[5] *Public Roads*, Vol. 17, No. 7, September, 1936, p. 152.

[6] Instructor, Carnegie Inst. of Technology, Pittsburgh, Pa.

If dowels are strong and stiff enough to cause equal deflections of the two slabs at the points of connection, they will transmit about one-half the total load applied at the edge of one slab. This condition, however, does not reduce the critical stress in the loaded slab by one-half, but it does result in a considerable reduction if the dowels are spaced closely. With information available as to the vertical misalignment of dowels in pavements representing common construction practice, it is possible to investigate the effectiveness of dowels in deflecting the points of connection equally.

For effective dowel action the difference in deflections between the edges of the two slabs at the points of connection must be very small in relation to the deflection of the free edge of one slab under a wheel load. The maximum deflection of a free edge of a homogeneous slab under a concentrated load at the edge may be determined by an equation,[7] proposed by H. M. Westergaard, M. Am. Soc. C. E.:

$$z_0 = 0.434 \frac{P}{k\, l^2} \qquad (1)$$

in which, z_0 = maximum slab deflection; P = wheel load; k = sub-grade modulus; and, l = radius of relative stiffness. For a wheel load of 10 000 lb at the edge of a 7-in. slab, with $k = 200$ lb in.$^{-3}$, and $l = 25.73$ in., the maximum deflection is 0.0327 in. This value will be used only to represent the general magnitude of the deflections. The relative deflections between any two dowels would be much smaller.

An investigation of a series of adjacent dowels with similar vertical misalignments will show what relative vertical displacements occur when a joint opens or closes. Assuming a vertical error of 1 in. in installing 22-in. dowels, and an expansion joint movement of 0.75 in., a relative vertical displacement will occur equal to $\frac{1}{22} \times 0.75 = 0.0341$ in. Since this is even larger than the deflection caused by the load, the dowels do not aid in reducing stresses by load transfer. The nature of this distortion is shown in Fig. 10. If a load is placed on either side of the joint, the deflection of the slabs tends to return the left slab to its unstressed position, and most of the load is carried by the slab on the right.

It is evident that dowels which are this much out of line are objectionable because they fail to transfer load. They also cause stresses in the slab by a wedging action, and they resist movement at the joint. If adjacent dowels are inclined in opposite directions, any movement of the joint will cause local over-stresses and elastic failures. Although these may or may not cause complete failure after several cycles of reversal, they will produce enough yielding and play in joints so that effective load transfer is lost.

---

[7] "Spacing of Dowels," Highway Research Board, 8th *Proceedings*, p. 156.

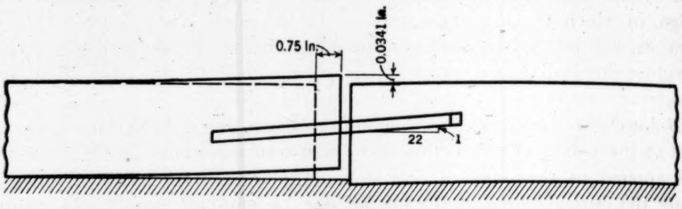

FIG. 10

Any type of pavement joint which transfers load should be designed and installed with great care. As slab deflections under loads are usually less than $\frac{1}{32}$ in., any load-transfer device must be constructed so as to permit very little relative vertical movement between the connected edges of the slab.

L. J. MENSCH,[8] M. AM. SOC. C. E. (by letter).—The art of making joints in concrete construction in general and in pavements in particular is still in the stage of discovery and invention, and is a lucrative field for the patent lawyer and the mountebank. Although many millions of dollars are expended annually on joints, the development of the art has covered a long period of time, and "the trade" has been subject to the losses, faults, and checks to which haphazard knowledge, without adequate tests and proper analysis based on them, is peculiarly liable.

The specifications of State highway departments for joints have lagged seriously behind the best accepted rules of structural engineering and concrete practice and have acted as a deterrent to more scientific development by independent manufacturers of joints. The successful designer of joints must have an unusually thorough training, and long and wide experience, if he is to comprehend and provide successfully for all the variation of stress in dowels and concrete due to many influences, such as warping of the slabs from wet sub-grade or from temperature variation, misalignment of dowels, and movements of the slabs as a whole, vibrations of slabs, cavities at the joints caused by the pumping action of traffic on the water-soaked sub-grade, heavy wheel loads on one side of the joint, etc.

The most satisfactory pavement would be one without joints; this, however, does not seem possible of attainment as the aforementioned influences cause considerable irregular cracking in every direction. The Bates Road tests in Illinois, and the Pittsburg, Calif., tests of fifteen years ago, have taught American engineers that longitudinal joints greatly prevent irregular longitudinal cracks.[9] Nothing so clear was learned by these tests, about transverse joints. In the years following, most pavements were constructed with tongue-and-groove longitudinal joints, thickened edges, and transverse joints rather far apart. After five years these pavements showed many irregular transverse cracks, and after ten years, blow-ups occurred as often as one every three miles, once each year. Early in 1934, the U. S. Bureau of Public Roads required, on all Federal Aid roads, the use of expansion joints not more than 100 ft apart to guard against blow-ups, and the use of contraction joints for crack control. The Bureau also required effective means of load transfer at both expansion and contraction joints, the minimum allowable being the use of $\frac{3}{4}$-in. dowels, 24 in. long, 12 to 15 in. on centers. Even at that time doubt was expressed as to whether $\frac{3}{4}$-in. dowels were sufficiently strong for the purpose.

[8] Civ. Engr. and Constructor, Chicago, Ill.

[9] "Highway Research in Illinois," by Clifford Older, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1180; and Report of Highway Research at Pittsburg, Calif., 1921–22, Dept. of Public Works, California.

The Highway Department of Indiana like those of many other States which did not specify transverse joints in its pavements, was suddenly compelled to use them, and evidently the authors were astounded when they saw the recklessness and disregard of engineering principles with which dowels were installed in the slabs. They made the tests described in this paper and did a very meritorious job. They not only proved: (1) That dowels were not installed parallel to the longitudinal axis of the road when unusual care was exercised and when special installation devices were used; (2) that the dowels were not parallel when they were welded to two $\frac{5}{8}$-in. cross-bars, showing errors as great as 1 in. on account of the bending of the cross-bars in shipping and handling; but (3) they also proved (what is even to-day scarcely realized by many highway engineers) that the concrete operations and the action of the mechanical strike-off machine (mis-named finishing machine) cause a still greater error in the location of the dowels. Any engineer who watches the modern method of placing concrete in pavements must be surprised that contractors are permitted to dump an entire yard of concrete crudely by the nearly uncontrollable opening of the traveling bucket of the mixer, often producing a wave-like motion of the heavy mass which throws joints and anchoring devices many inches out of line. Furthermore, the top of the dumped concrete is often many inches above the top of the pavement and offers a great resistance to the advancing strike-off machine, which again throws the joint out of line, rarely less than 0.5 in. and often as much as 1.5 in. on top. From his many observations of paving operations the writer is convinced that the errors produced by concreting and by the strike-off machine are much larger than those found by the authors.

Some highly speculative studies on the load transfer of dowels have been published. These studies were not based on any tests and evidently did not agree with the findings of the authors; therefore, they assumed that the subject is impossible of analytical solution. Although the task is certainly difficult and unusual, the writer has shown[10] that a rational description of the action of dowels is possible without the use of too much higher calculus and will now offer an improved and simplified analysis.

---

[10] "Joints for Concrete Pavements," Chicago, 1935.

In Fig. 11 let the verticals through Points *A* and *F* represent the original slab faces of an expansion joint with an opening of 1 in., and the verticals through Points *A′* and *B′*, the faces of the slabs after the joint has been compressed; let Line *A B* be the direction of the mis-aligned dowel, and the distance, *B F*, be the error of $\frac{1}{24}$ in. corresponding to an error of 1 in. in 24 in. By closing the joint space, Point *A* moves to *A′* and Point *B* to *B′* and the dowels would be bent into a broken line, *E A′ B′ D*, if the resistance of the concrete proved to be greater than that of the steel of the dowel. Since concrete is the weaker material, the dowel will deform according to a smooth curve, somewhat as shown by *A″ C B″*, having a point of inflection at Point *C*. This bending can be imagined to be caused by a shear, *P*, acting at Point *C* which will produce high compression in the concrete at the under side of the dowel at Point *B″*. The

action of the dowel is very much like that of nails in timber construction. On any reinforced concrete job one can easily observe the shape into which the nails are deformed after they are highly strained, when the lumber is cleaned and assembled for re-use.

The greatest curvature of the nail or dowel is found only a short distance from Point B', and between the latter point and the point of greatest curvature a permanent deformation of the timber is produced. Point D is about twice as far from Point B' as the point of greatest curvature of the nail or dowel; beyond Point D and up to Point G the nail is nearly straight and does not produce a permanent deformation of the timber. Fig. 11(*b*) shows the probable deformation.

The stresses in dowels and in the surrounding concrete in the part, $B'D$, are always high in the tests offered by the authors, being mostly beyond the yield point, and the distribution of the stresses exerted by the dowel on the concrete in the part, $B'D$, can be assumed to be according to a cubic parabola, as shown in Fig. 11(*c*). The writer has previously shown[10] that the part, DG, behaves nearly like a cantilever, projecting beyond Point D at the angle, α, and bent down by an ideal uniform load w, so that the end of the cantilever reaches the level of Point G. By computing many cases, he found that a good assumption is,

$$w = \frac{w_m}{10} \qquad \text{(2)}$$

when w_m is the maximum pressure at Point B'. The dowel can now be considered as a simple beam affected at Point C by the unknown shear, P, loaded in the part, $B'D$, by the upward concrete stresses which are decreased from a maximum value, w_m, at Point B', according to a cubic parabola, to zero at Point D, and loaded by the ideal uniform downward stresses, $\frac{w_m}{10}$ in the part, DG; and the following equations can be written:

The sum of all vertical forces must be zero, or,

$$P + w L_3 = \tfrac{3}{4} w_m L_2 \qquad \text{(3)}$$

The moments about Point B' must be zero:

$$P L_1 + \tfrac{3}{4} w_m L_2 \times 0.4 L_2 = w L_3 (0.5 L_3 + L_2) \qquad \text{(4)}$$

From Equation (2) and Equation (3),

$$w_m = \frac{P}{0.75 L_2 - 0.1 L_3} \qquad \text{(5)}$$

The value of w_m introduced in Equation (4), gives a quadratic equation in L_3 from which:

$$L_3 = -(L_1 + L_2) + \sqrt{(L_1 + L_2) + 10 L_2 (1.5 L_1 + 0.6 L_2)} \qquad \text{(6)}$$

The authors advise assuming $L_1 = 0.25$ in.; by assigning to L_2 various probable values, such as 1.5 in., 2 in., 2.5 in., etc., Equation (6) leads to a very close approximation:

$$L_3 = 1.9 L_2 \qquad \text{(7)}$$

and Equation (5) reduces to:

$$w_m = \frac{P}{0.75\,L_2 - \dfrac{1.9\,L_2}{10}} = \frac{P}{0.56\,L_2} \quad\ldots\ldots\ldots\ldots\ldots(8)$$

It is clear that the deflection of the dowel under the assumed loading must be equal to $B'\,B'''$, which, in the present case, is one-fourth of $\frac{1}{24}$ in., or $\frac{1}{96}$ in. An expression for this deflection, y, can be obtained as follows: The angle, α, for the cantilever, $D\,G$, equals[10]:

$$\alpha = \frac{w\,L_3^3}{8\,E\,I} \quad\ldots\ldots\ldots\ldots\ldots(9)$$

Introducing into Equation (9) the values from Equations (2), (7), and (8),

$$\alpha = \frac{0.153\,P\,L_2^2}{E\,I} \quad\ldots\ldots\ldots\ldots\ldots(10)$$

and the deflection of the dowel at Point C from the rotation, α, is:

$$y_C = (L_1 + L_2)\,\alpha = \frac{0.153\,(L_1 + L_2)\,P\,(L_2)^2}{E\,I} \quad\ldots\ldots\ldots\ldots(11)$$

The deflection of the dowel at Point C from the moments acting in the part, $B'\,D$, is best found by the moment-area method; thus, the moment at Point D is,

$$M_D = \frac{w\,L_3^2}{2} = \frac{P}{5.6\,L_2} \times 1.9^2 \times \frac{L_2^2}{2} = 0.322\,P\,L_2 \ldots\ldots\ldots(12)$$

and the moment at Point B' is

$$M_B = w\,L_3\,(0.5\,L_3 + L_2) = 0.662\,P\,L_2 \ldots\ldots\ldots\ldots(13)$$

This latter moment, M_B, is diminished by the moment of the upward concrete stresses acting in $B'\,D$, or,

$$M_B' = 0.75\,w_m\,L_2 \times 0.4\,L_2 = 0.537\,P\,L_2 \ldots\ldots\ldots\ldots(14)$$

The deflection of the dowel at Point C from the moment area, $B'\,D\,T$, in Fig. 11(*d*) is the moment area times the distance of its center of gravity from C:

$$y_C' = 0.173\,\frac{P\,L_2^3}{E\,I} + 0.317\,\frac{P\,L_1\,L_2^2}{E\,I} \quad\ldots\ldots\ldots\ldots\ldots(15)$$

and the total deflection is found by adding Equation (11) and Equation (15), or,

$$y = 0.326\,\frac{P\,L_2^3}{E\,I} + 0.47\,\frac{P\,L_1\,L_2^2}{E\,I} \quad\ldots\ldots\ldots\ldots\ldots(16)$$

Instead of Equation (16) it will be more convenient to use the approximate formula:

$$y = 0.38\,\frac{P\,L_2^3}{E\,I} \quad\ldots\ldots\ldots\ldots\ldots(17a)$$

and,

$$P = \frac{E\,I\,y}{0.38\,L_2^3} \quad\ldots\ldots\ldots\ldots\ldots(17b)$$

in which E equals 30 000 000 and I is the moment of inertia of the dowel (0.0155 for $\frac{3}{4}$-in. dowel). By assuming various probable values of L_2 (say, from 1 in. to $2\frac{1}{2}$ in.) and of y, the deflection produced by the movement of the joint faces ($\frac{1}{96}$ in. in the present case), the corresponding values of the ideal shear, P, can be computed from Equation (17*b*) and the corresponding maximum pressures, w_m, in pounds per linear inch, which the dowel exerts on the concrete, can be computed by Equation (8). From Fig. 11(*d*) it may be further noted that the greatest moment exerted on the dowel by the concrete pressures is $0.41\,P\,L_2$ which values divided by the section modulus of a $\frac{3}{4}$-in. bar (0.0414) give the unit steel stresses in the dowels. The values thus computed are given in Table 2.

TABLE 2.—STRESSES IN DOWELS AND CONCRETE

Description	VALUES OF LENGTH, L_2, IN INCHES				
	1	$1\frac{1}{2}$	$1\frac{3}{4}$	2	$2\frac{1}{2}$
Shear, P, in pounds, from Equation (17*a*)	12 600	3 740	2 340	1 560	810
Maximum unit pressure, w_m, in pounds per linear inch, from Equation (8)	22 500	4 350	2 400	1 400	580
Values of $\frac{w_m}{0.75}$, in pounds per square inch, for $\frac{3}{4}$-in. dowels	30 000	5 800	3 200	1 870	773
Moment, $M = 0.41\,P\,L_2$, in inch-pounds	5 160	2 300	1 680	1 280	835
Steel stresses, S_s, in $\frac{3}{4}$-in. dowels, in pounds per square inch	124 000	55 800	41 000	31 000	20 200

Inasmuch as neither P nor L_2 is given, and as it is extremely difficult to measure either the concrete or the steel stresses, it is very difficult to determine which group of values refer to a particular test. The authors state that they observed crushing and splitting in the concrete in the case of a 5-in. slab. They probably also found pulverization of the concrete at Point B' in the 6-in. slabs; hence one may conclude that the stresses in a 6-in. slab were also very high.

In Table 2, the column for $L_2 = 1\frac{3}{4}$ in. shows concrete and steel stresses of 3 200 and 41 000 lb per sq in., respectively. These are by no means unlikely values as it is quite common to observe steps in joints due to the movements of the slabs. Such steps indicate very high stresses in the dowels and concrete. When $L_2 = 2$ in., concrete stresses equal 1 879 lb per sq in., and steel stresses, 31 000 lb per sq in., which are still very high values. The results of this analysis will scarcely be changed when one slab is fixed and the other slab moves the entire 0.5 in.

Assuming that more scientific and more extensive tests may demonstrate that correction factors must be applied to all the foregoing equations, they are unlikely to change values more than 30 per cent. This analysis shows that slab movements of 0.5 in. may cause very high stresses in concrete and anchoring devices, as usually installed, and there is very little strength left for the primary function of the dowels and anchoring devices —the transfer of loads. Searcy B. Slack, M. Am. Soc. C. E., made tests[11] which demonstrated that $\frac{3}{4}$-in. dowels did not transfer any load in actual pavements after they had been in service for a few years.

---

[11] *Engineering News-Record*, July 9, 1931.

Imitating modern connectors for timber construction several joint manufacturers are using sleeves over $\frac{3}{4}$-in. dowels in order to diminish the high concrete stresses at Point B'. Table 2 enables one to judge their merits. For $L_2 = 1$ in. and a sleeve diameter of 1.5 in., the concrete stresses would be $\frac{22\,500}{1.5} = 15\,000$ lb per sq in., and the steel stresses, $0.41\,P \times \frac{1}{0.0414} = 71\,000$ lb per sq in.; whereas, for $L_2 = 1.5$ in., the stresses would be 2 900 and 47 800 lb per sq in., on concrete and steel, respectively. The sleeves and dowels being very short one is not entitled to assume larger values of L_2. The writer has heard that the authors made tests to study the sliding of such devices and found resistances to sliding four times as great as for $\frac{3}{4}$-in. dowels without sleeves.

In the writer's own tests on sliding of misaligned $\frac{3}{4}$-in. dowel bars[10], the resistance to sliding was much greater than that found by the authors on account of the greater stiffness of the high-carbon dowels used. The authors proved by their tests that the slip-shod methods used at present to place and hold dowels and anchoring devices before and after concreting, must be abandoned. Positive means are needed to hold dowels, anchoring devices, and the entire joint assembly in correct alignment until the concrete has set.

The closer the expansion joints are spaced, the less is the movement and the less are the stresses caused by misaligned dowels and anchoring devices; and it is very probable that in the near future expansion joints in pavements will be placed about 30 ft apart instead of 80 ft to 100 ft as at present, and some kind of inexpensive contraction joint will be used between the expansion joints.

W. O. FREMONT,[12] M. AM. SOC. C. E. (by letter).—The type of failures described in this paper depends to a great extent on the direct action of the bar on the concrete in the vicinity of the dowel. This action depends on the bending moment, shear force, and longitudinal force in the dowel. Similar functions of the outer forces are produced in the dowels also by vertical loads as well as by the curling and warping of the slabs due to changes of moisture and temperature. Therefore, the effects of the opening or closing of the joint must be studied in conjunction with the effects of all the other factors. If the concrete fails at a certain amount of opening or closing of the joint, it does not mean that it will not fail at a much smaller opening or closing when the vertical load and curling, with warping, are acting in addition.

Conclusions drawn on the basis of joint opening and closing tests alone, therefore, without at least the vertical forces, seem insufficient, if not useless, for practical purposes. It is difficult to believe that the small specimens, cut from the entire pavement construction, truly represent or simulate the actual service conditions. The rotation of the slabs mentioned under the heading, "Permissible Error Determined by Experiment," will be quite different under actual service conditions. The distribution and magnitude of pressure on the sub-grade from the joint-opening forces, or by the closing forces alone, will also be different in actual large pavement slabs. Therefore, the action of the dowels will also be quite different.

---

[12] Bridge Designer, State Highway Dept., Lansing, Mich.

The authors state that the dowel bars were coated with asphalt paint and oil. No information is given about the thickness of the coats applied and other details. From theoretical considerations it seems that errors in the alignment of the dowels of the magnitude used in the tests are permissible only because of the clearances between the dowels and the concrete formed by the coating applied. It seems that no exact definition is given as to what is understood in Table 1 under "Dowel-Bar Movements."

In the last paragraph of the paper the authors recommend that "common 24-in. dowel bars be placed with a degree of accuracy such that the error of no one bar in an entire installation shall exceed 1 in." This conflicts with the statement a few paragraphs preceding it, that "errors of 1 in. caused the slabs to crack and spall." According to the authors it required a tension force of 3 000 lb per dowel to open a contraction joint to a width of 0.5 in., which means a tensile stress of 50 lb per sq in. in the concrete slab 5 in. thick. Considering the high tensile stresses in the concrete slab from vertical loads, an addition of 50 lb per sq. in. is appreciable inasmuch as this addition might become larger in the actual pavement slabs farther away from the joint, because of the friction between slabs and sub-grade.

George A. Smith,[13] Esq. (by letter).—Those interested in the design and construction of concrete highways should appreciate the information contained in the paper by Messrs. Smith and Benham and should be grateful to learn that relatively large errors in the alignment of dowels in joints in concrete pavements may not contribute materially to failures at contraction and expansion joints. The design and construction of joints in concrete highways have probably been given as much consideration as any other single factor relating to such work and, although the particular tests reported relate to a single phase of the subject, their findings certainly answer a moot question.

A review of this paper cannot fail to leave the impression that the work involved was ably conducted and that the results, although general, were presented in a clear, concise, and accurate manner. The paper offers little, if any, grounds for critical comment, but does prompt the asking of several questions which, should the studies be continued and the investigation extended, may be worthy of some consideration.

The authors indicate that, when the misalignment of dowel bars is not in excess of 1 in., no particularly serious results need be anticipated. This was based on conditions obtaining after ten cycles of opening and closing, or closing and opening, of the joints. It would be of interest to know whether there was any progressive destructive action noted during the tests, either when the error was small or when large errors existed. There is also the question of what would have happened had the number of cycles been such as would compare with the number that would occur during the life of the pavement.

---

[13] With National Park Service, U. S. Dept. of the Interior, Washington, D. C.

From an analysis of conditions that exist when the error in alignment is large, it appears that two types of failure may occur. For a vertical misalignment the failure appears to be in tension, whereas a shear failure, the result of a compressive stress, is indicated when a horizontal error exists. Since the resistance to failure is less in the case of vertical errors, one wonders what the maximum permissible errors in the two directions might be, and if there is actually more likelihood of a failure in the case of a vertical error than for a horizontal error of the same magnitude. From the fact that the tendency to spall was decreased as the thickness of the slab was increased, it would appear that such might be the condition.

It is of interest to note that the effect of errors in alignment is greater at expansion joints than it is at contraction joints. Except for slight differences in the location of the dowels relative to the top and the bottom of a slab and for the fact that only one end of the dowel is free to move in the case of an expansion joint, the conditions are much the same. However, a 3 000-lb pull per bar in the case of a contraction joint, as opposed to a 4 000-lb compression for an expansion joint, would be expected to accentuate the tendency to spall in the case of the contraction joint, as is evidenced by the fact that some spalling is observed occasionally in pull-out tests where bars are axially stressed in tension and the concrete is stressed because of the bond. In the tests reported, an effort was made to reduce the bond. However, the pull required is evidence of the fact that some direct tension was imparted to the concrete when opening a contraction joint, and there is little doubt but that some of the tension was resisted by the concrete immediately adjacent to the joint. One wonders also if confining the movement of the dowel to one part of the slab might not have been in some degree responsible for the greater tendency to spall. Although it is difficult to understand how the condition could produce the effect observed, the increased load required to close an expansion joint, as compared with that for opening a contraction joint, is more readily explainable when reference is made to load-slip data obtained in pull-out tests.

On the basis of their observations, the authors have recommended that 24-in. dowels be placed so that the maximum error will not exceed 1 in. Any deviation from perfect alignment is undesirable, despite the fact that small errors appear to cause no serious results. Consequently, it is the writer's opinion that engineers should require and insist on the making of every reasonable effort to insure all dowels being installed as nearly as possible parallel to the longitudinal elements of the pavement. Particularly should this be the case since, as stated by the authors, there is always some likelihood of there being some movement of the dowels during the placing of the concrete.

L. E. Grinter,[14] M. Am. Soc. C. E. (by letter).—This excellent paper reports the results of tests made to determine a second influence on the action of dowels that may be quite as important as their action in resisting vertical shear caused by wheel loads. Any attempt to design dowels to resist, safely, the shear produced as a wheel load moves across the joint evidently will fail in its major objective if misalignment can produce failure anyway. Strangely enough, the stresses produced by wheel loads and the stresses produced by misalignment are essentially alike, and this statement holds true both for the stresses in the bar and for the stresses that the bar produces in the concrete slab. The result of excessive stresses in either case would be a spalling failure of the concrete as illustrated so clearly in Fig. 9. It must be the purpose of good design to prevent such failure from the action of the various possible load conditions, and it is the purpose of good construction to prevent such possibility from misalignment.

Internal Deformations.—An understanding of the kinds of strains produced by misalignment might aid one in an interpretation of the author's conclusions. It will be evident from Fig. 12 that the influence of a wheel load or of a heaving sub-grade, as indicated in Fig. 12(*a*), is identical with the influence of misalignment, as shown in Fig. 12(*b*). In either case the dowel across the joint acts as a short beam, restrained at its two ends, which undergoes differential settlement. If its end conditions are identical, this beam will deflect in a symmetrical reversed curve and will show a point of contra-flexure midway between the slabs. However, since the end conditions are unlike, one end being bonded and the other end being unbonded (and, therefore, slightly loose in the concrete), it is qualitatively justifiable to assume that the moment at the sliding end is only 50% or less of the moment at the bonded end.

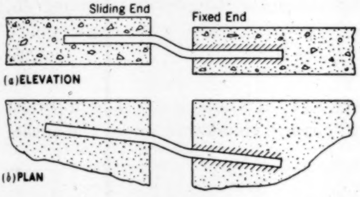

Fig. 12.—Distortion from Settlement and Misalignment

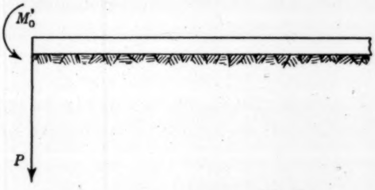

Fig. 13.—Bar on an Elastic Foundation

The general load condition, then, of a misaligned dowel bar is similar in most respects to the problem of any bar or beam of indefinite length, supported on an elastic foundation, as shown in Fig. 13. This problem has been analyzed by Professor S. Timoshenko[15] who found the deflection at the end of the bar to be:

$$y_0 = \frac{P + \beta\, M_0}{2\, \beta^3\, E\, I} \quad \text{.........................(18)}$$

in which,

$$\beta = \sqrt[4]{\frac{K\, b}{4\, E\, I}} \quad \text{.........................(19)}$$

In Equations (18) and (19), E, I, and b are, respectively, the modulus of elasticity, the moment of inertia, and the breadth or diameter of the bar; K is the foundation modulus, in pounds per square inch per inch of settlement. Hence, K is essentially an indeterminate factor in the case of a loaded dowel bar since it should combine the resistance of the slab with that of the sub-grade. For a dowel bar misaligned in the horizontal plane, K apparently becomes the same as the modulus of elasticity of the concrete.

It is possible to avoid a discussion of the factor, K, in one study by investigating the general equation for the deflection of the bar,

$$y = \frac{e^{-\beta\, x}}{2\, \beta^3\, E\, I} \left[P \cos \beta\, x + \beta\, M_0 \left(\cos \beta\, x - \sin \beta\, x\right)\right] \text{......(20a)}$$

which will be simplified temporarily by dropping the term involving M_0,

$$y = \frac{e^{-\beta\, x}}{2\, \beta^3\, E\, I} \left(P \cos \beta\, x\right) \text{...................(20b)}$$

Equation (20*b*) is plotted in Fig. 14 in terms of the angle, $\beta\, x$. The important considerations are that the positive or downward deflection under the applied load exists over a length, a, which is one-third the length to the second point of zero deflection.

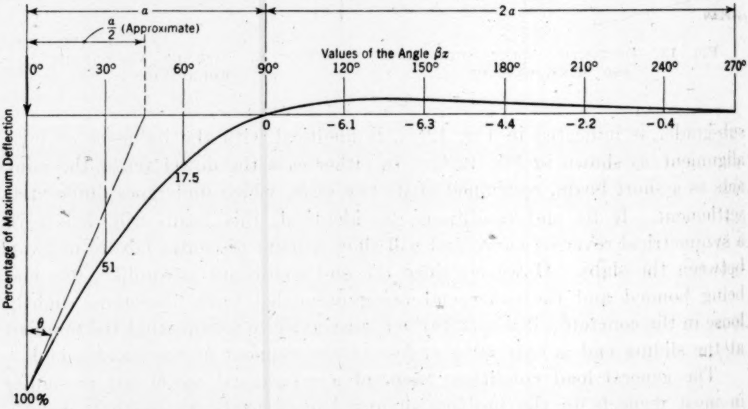

FIG. 14.—DEFLECTION DIAGRAM FOR A BAR ON AN ELASTIC SUPPORTING MEDIUM

From a study of Fig. 14 it seems reasonably evident that any dowel bar must act at some stage of its life in such a manner that only bearing pressure under about one-third its embedded length is available to resist the dowel shear, and that over this length the bearing pressure reduces in nearly a parabolic line from a maximum value to zero. The dowel moment, M_0, will act to increase the severity of the dowel pressure, but, in so far as the general shape of the deflection curve is concerned, the influence of M_0 will not be important.

Example of Misalignment Study.—If the concrete of the slab has an ultimate compressive strength of 3 000 lb per sq in., and if the dowels are $\frac{3}{4}$-in. round bars, 24 in. long, the ultimate shearing capacity per dowel before the concrete begins to spall slightly, probably, is not greater than $V = \frac{3\,000}{3}\left(\frac{12}{3} \times \frac{3}{4}\right) = 3\,000$ lb. This conclusion is based upon the form of the deflection curve of Fig. 14. The authors found that the alignment error in a 6-in. pavement could be 1 in. without causing spalling even when the joint was opened to a width of 0.75 in. An error of 1 in. in 22 in. amounts to 0.03 in. in a length of 0.75 in.

If the misalignment to be considered is in the horizontal plane of the pavement, the elastic compression of the concrete due to the bar pressure can be computed from Equation (18) when the value of K is the modulus of elasticity of the concrete. This modulus is assumed herein at the low value of 1 500 000 to account in a crude manner for deformations at stresses near the ultimate. Hence, by Equation (19) $\beta = \sqrt[4]{\frac{1\,500\,000 \times 0.75}{4 \times 30\,000\,000 \times 0.049 \times 0.75^4}}$ $= 0.88$. In order to obtain an average condition (joint open 0.75 in.), M_0 may be taken at $0.375 \times 3\,000$; and, by Equation (18),

$$y_0 = \frac{3\,000 + 3\,000 \times 0.375 \times 0.88}{2 \times 0.88^3 \times 30\,000\,000 \times 0.049 \times 0.75^4} = 0.0062 \text{ in.}$$

As shown by the exaggerated picture, Fig. 15, the misalignment is accounted for by three distortions:

(*a*) The bending of the bar as a fixed-end beam in the gap between slabs (this contribution is small, amounting to only 0.0002 in.);

(*b*) The movement, y, permitted by the elastic and inelastic deformation of the concrete; and,

(*c*) The movement, $\theta\, x$, that is permitted by the slope taken by the bar across the open joint.

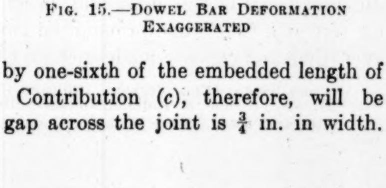

FIG. 15.—DOWEL BAR DEFORMATION EXAGGERATED

Contribution (*b*) evidently is twice the value of 0.0062 computed by Equation (18), or 0.0124 in. Angle θ can be approximated from Fig. 15 as the deflection divided by one-sixth of the embedded length of bar or $0.0062 \div 2 = 0.0031$ radian. Contribution (*c*), therefore, will be $0.0031 \times 0.75 = 0.0023$ in. when the gap across the joint is $\frac{3}{4}$ in. in width.

Hence, the total misalignment deformation would become 0.0124 + 0.0023 + 0.0002 = 0.015 in.

Conclusion.—Since this deflection is only about one-half the movement that the authors consider permissible, it appears that the action of the test slabs could be explained on one of the following bases:

(1) That the bars did not fit tightly into the slabs and, therefore, were able to "give" slightly (such dowels are of questionable value in transferring load across a joint, which is their major function since an unsupported interior edge is a line of great weakness);

(2) There may have been some undetected crushing or even a slight spalling which would prove a source of ultimate failure if slippage should be repeated many times; and,

(3) Looseness or "give" at one slab would produce a possible maximum moment in the bar of 3 000 × 0.75 = 2 270 in-lb. This moment would stress a $\frac{3}{4}$-in. round bar to 55 000 lb per sq in. If the bars used are of ordinary mild steel, they may, therefore, be deformed permanently.

The writer calls attention to the approximations involved in the computations presented herein. Much can be learned by such calculations, but they should be taken as significant qualitatively rather than quantitatively. From them the writer draws the general conclusion that the authors' specifications for permissible misalignment may be overly generous if proper dowel action is expected during the entire life of the pavement. Since a practical construction procedure could be devised to eliminate inaccuracy in excess of $\frac{1}{4}$ in. in alignment, this value could be set as a practical standard of workmanship. The importance of this requirement will be evident when it is understood that the stresses accompanying dowel action induced by loads, by heaving of the sub-grade, and by misalignment, may be additive.

Arthur R. Smith,[16] M. Am. Soc. C. E., and **Sanford W. Benham,**[17] Assoc. M. Am. Soc. C. E. (by letter).—In the discussions of this paper attention has been called to some very important considerations in dowel-bar installations and their functioning as a load-transfer device across joints in concrete pavement.

It was appropriately suggested that, in view of the results of the experimental work to determine permissible error, the recommended specification for accuracy was too liberal, particularly since the joints in the experimental slabs were opened and closed with no vertical loads, simulating wheel loads, at or near the joint. If the slabs had been loaded during the tests, it is quite likely that different results would have been obtained since the effect of wheel load and some directions of dowel-bar error are additive. In outlining the program of tests it was the original intention to conduct the tests in this manner on different types of sub-grade and, in addition, to construct experimental slabs for test at a time when pronounced curling was present at the joints. However, time and expense made such an elaborate program impossible. Because of the need for a specification covering accuracy of installation, to correct careless construction practice, the study was necessarily limited to a single phase of the subject; that is, to misalignment alone.

[17] Research Engr., State Highway Comm., Bureau of Materials and Tests, Indianapolis, Ind.

A dowel bar stresses the concrete in which it is embedded because its axis is being bent, due to such causes as traffic load transfer, curling of the pavement at joints, unequal heaving due to frost action, or binding when the joint opens or closes (due to misalignment). With the exception of misalignment all the other causes which tend to bend the bar, thereby damaging the concrete, are entirely independent of the accuracy with which the bar is installed; that is, a misaligned bar across a joint that has not changed in width will transfer wheel loads as effectively as a perfectly installed bar. The coating of bituminous paint (approximate thickness, 0.020 in.) to prevent bond provides a clearance which, although undesirable in load transfer, is of great advantage in permitting some movement of a joint with misaligned bars before the bars begin to bind in the concrete. Although clearance is undesirable as regards load transfer because the bar does not act until the loaded slab has deflected and because it also increases the funneling action of the bar, clearance must be had because, without it, it is not possible to install the bars and hold them in position during the placing and finishing of the concrete with sufficient precision to permit movement without cracking.

The joints in the experimental slabs were opened and closed at the rate of 0.1 in. per min. In practice, movement is very slow. The pavement has attained considerable age before 1-in. expansion joints have closed 0.75 in. (to a width of 0.25 in.). During this period funneling has probably occurred around the dowel bar providing clearance which, with that created by the paint and oil, is sufficient to permit closing of the joint without distorting the bar enough to crack the concrete. This is a possible explanation for the apparently satisfactory condition of the installations shown in Table 1, in some of which the bars are in extremely faulty positions. These installations are now (1938) three years old and all the joints are at present in apparently satisfactory condition.

For these reasons it was believed that a specification for accuracy of installation more rigid than that recommended would add very little to the satisfactory functioning of the joints; certainly not enough to warrant additional cost. Because of the already high cost of joints it is undesirable to specify additional refinements unless it appears rather certain that improved structural efficiency will be obtained. The recommended specification for accuracy, if it had been in effect during the construction season of 1935, would have required the contractor to replace the joints identified in Table 1 as Tests Nos. 1, 10, 11, and 13. Field tests conducted during the following season, when the specification was in effect, showed that the bars were being installed with a degree of precision considerably better than that obtained during the previous year, indicating that the specification resulted in an improvement in construction practice rather than an encouragement of carelessness, as has been suggested.

The question has been raised concerning the tension produced in the pavement due to the resistance to movement of misaligned bars when the pavement is contracting. As was stated in the paper the greatest resistance to the opening of a joint was 3 000 lb per bar which creates 50 lb per sq in. tensile stress in 5-in. pavement in addition to the tensile stress caused by sub-grade friction. The observed loads to open and close joints included, of course, both dowel-bar and sub-grade resistance but the experimental slabs were so short in comparison with slab lengths in actual pavements that sub-grade friction can be ignored. In this instance the dowel-bar error was maximum (1.5 in.). To open the corresponding slab in which the bars were installed perfectly required 2 100 lb per bar, or 35 lb per sq in. tension in the slab. Thus, reducing the dowel-bar error from 1.5 in. to zero (perfect installation) reduced the tensile stress in the pavement 15 lb per sq in. It is believed that this reduction in tensile stress is not great enough to add appreciably to the structural efficiency of the joint; certainly not enough to justify an increase in cost of construction.

It is impossible to state definitely whether or not there was a progressive destructive action during the successive cycles of opening and closing the joints. After the appearance of the first crack or cracks, additional cracks occurred during the remaining cycles of movement in very few of the test slabs, due probably to the partial relief of stress in the slab. This observation is subject to a certain amount of modification since, in some instances, cracks were not detected until after the second or third cycle of movement. It is possible that they were caused by the first movement but did not open wide enough to be seen until after additional cycles. The loads required to open and close joints decreased slightly and rather uniformly with successive cycles of testing which leads to the belief that continuing the tests beyond ten cycles was not necessary.

It has been suggested that vertical errors are more serious than horizontal errors since it would seem that the pavement would offer less resistance to failure of the type shown to the right in Fig. 9 than to the formation of a vertical crack throughout the depth of the pavement as would be caused by a bar having horizontal misalignment. This seems to be a reasonable opinion although failures were about equally divided between the two directions of error.

It is hoped that the interest displayed in this subject is an indication of increased attention to the perfection of load-transfer devices across joints in concrete pavement.

ESSENTIAL CONSIDERATIONS IN THE STABILIZATION OF SOIL[1]

BY C. A. HOGENTOGLER,[2] ASSOC. M. AM. SOC. C. E., AND
E. A. WILLIS,[3] ESQ.

WITH DISCUSSION BY MESSRS. JACOB FELD, DONALD M. BURMISTER, AND C. A. HOGENTOGLER AND E. A. WILLIS

SYNOPSIS

All soil mixtures commonly used for road surfaces and speedways are highly stable at some moisture content. This is equally true of cohesionless beach sands, friable glacial silts, and highly plastic clays. Hence, every possible combination of sand, silt, and clay may serve satisfactorily as aggregate in stabilized soil, provided the right binder is used to cement the soil particles together. Furthermore, the moisture which binds soil mixtures into masses stable enough to withstand the abrasion produced by racing motor cars must have surface tension and viscosity greater than those of free water. On these two facts the entire theory of soil stabilization is based.

The underlying principles involved in soil stabilization and the possible means of its accomplishment are discussed without attempting to evaluate the practical aspects or the relative values of the various methods. Particularly stressed is the application of the collodial phenomena of adsorption and base exchange (21)[4] as they affect: (*a*) Particles of soil, sand, crushed rock, gravel, slag, etc., coated with films of air, water, soluble chemicals, and binders not soluble in water; (*b*) the relative adhesion between solids and films; and (*c*) the effect of the chemical composition of aggregate and binders and the ions on the surfaces of the solid particles.

Construction methods, details of design, and methods of test have been discussed generally in another paper (1*a*) and will not be included herein. Reports listed in the Bibliography (which forms an Appendix

to the paper) furnish more detailed information on the manner of applying the various treatments and making required tests as follows: Graded soil mixtures (2); calcium chloride (3); sodium chloride (4); asphalt emulsion (5), (6); asphalt, sub-oiling method (7); asphalt, mixing method (6), (8); tar (9), (10); Portland cement (11), (12); sulfite liquor (13); molasses (13), (14); calcium silicate (15); electro-chemical treatment (16); application of heat (17); mechanical analysis (18), (19); routine soil tests (18), (19); and Proctor tests (20).

ADSORPTION

Some soil particles have high attraction for air and, under proper conditions, become coated with air films; others have high attraction for moisture and become coated with moisture films. Dried soil clods retain moisture enough to bind the particles into hard and, in some instances, enormously strong masses. On the other hand, air is often adsorbed on soil solids so strongly after a period of drought that drops of rain will roll along on dust without wetting it.

The power that plastic clays possess of retaining their plasticity when mixed with sand or other non-plastic material, is caused by adsorption of one solid by another. The clay is not distributed uniformly through the pores or interstices of the coarse particles, but most of it forms a coating on the non-plastic material and many of the pores remain unoccupied even if there is more than sufficient clay to fill them.

For water or other binder to wet soil particles coated with air, it must displace the air, which means that the particles must attract the liquid more strongly than they attract the air. In like manner clay adsorbs different liquids to different extents; that is, its power of adsorption is selective and under suitable conditions one liquid will displace another in contact with the clay.

Bancroft (21), (22) calls attention to thicknesses of adsorbed moisture films which have been found on different materials as follows (in millionths of an inch): On glass of one kind, 5.1; on glass of another kind, 3.1; on sand (10 mesh), 11.0; on sand (60 mesh), 4.5; and on plastic wet clay, 2.0. The stationary film on copper was observed to be 0.000150 to 0.000225 in. when water flowed rapidly and about three times as much when it flowed more slowly over the copper. The air film between two pieces of glass compressed at 7 grams per sq cm (0.099 lb per sq in.), was found to be 0.000120 in. thick.

FILM MOISTURE IN SOIL

In completely saturated soil, every particle is covered with a coating of film moisture attracted to it more strongly than by the force of gravity. Until enough water is added to the soil to satisfy the condition of equilibrium between attraction of gravity and of the soil particle for water, all the moisture is arranged around the particles as films, with the interstices between the films filled with air.

It is impossible to remove all the film moisture from soils by enormous centrifugal forces exerted by powerful centrifuges. Therefore, it is concluded that much of the film moisture is held on the soil particles by adhesion equal to, or greater than, the enormous forces that fail to remove it. As a result of this great adhesion, film moisture is more viscous or glue-like than water in bulk.

The chemical composition of the soil particles, the nature of ions adsorbed on their surfaces, the moisture content, degree of compaction, and temperature of the soil control the thicknesses of moisture films, which vary widely.

Chemical composition of soil is indicated by the ratio of silica to the combined iron and aluminum oxides. This ratio is termed the silica sesquioxide ratio and is designated by the symbol, $\frac{SiO_2}{R_2O_3}$. Clays high in silica, termed "podsols," consist principally of the highly water-adsorbent, scale-like particles productive of high plasticity and shrinkage. Soils high in iron and alumina, termed "laterites," consist more of the bulky or spherical particles which do not attract water so strongly.

A colloid which holds hydrogen adsorbed on its surface is termed a hydrogen-ionized or H-colloid. One with calcium adsorbed on its surface is termed a calcium-ionized or Ca-colloid. If a substance like hydrated lime, $Ca(OH)_2$, is leached through soil containing H-colloids, the calcium replaces the hydrogen to form Ca-colloids, and the hydrogen thus released combines with the $(OH)_2$ to form water. Such exchange of ions is termed "base exchange."

The potassium ion is representative of those ions which undergo small volume change when alternately wetted and dried. It has a true diameter of 0.000000009 in. and in suspension becomes associated with 16 molecules of water, thus attaining an apparent diameter of 0.000000021 in. The lithium ion is representative of those ions which undergo great volume change when alternately wetted and dried. It has a true diameter of 0.000000006 in. and becomes associated with more than 120 molecules of water thus attaining an apparent diameter of 0.000000040 in. Between potassium and lithium other of the more common metallic ions can be arranged in the order of their attraction for water (36). Therefore, a potassium clay would be expected to undergo the least, and a lithium clay the greatest, volume change under climatic variations. Change of ions on the surfaces of the clay and colloidal particles effects a change in shrinkage, swell, and like properties on which the stability of the soil depends.

The concentration of the hydrogen ions determines the relative acidity of alkalinity. It is indicated by the pH-value which may be defined as the reciprocal of the logarithm of the grams of ionized hydrogen per liter of solution or suspension. The lower the pH-value is below 7.0, the greater is the acidity of the liquid and the greater is its base-exchange capacity.

The moisture content of a clay soil controls the thicknesses of film on the colloids. This, in turn, determines the density to which a particular pressure will compact the soil.

The relation between dry-weight density per cubic foot of samples compressed at equal pressures, to the moisture contents in percentage of the total soil and moisture volumes, at which the samples were compressed, was found by C. A. Hogentogler, Jr. (28) to consist of a series of straight lines with different slopes, as shown by the full lines in Fig. 1. The broken line in Fig. 1 shows the relation the density would have to moisture content if the samples contained no air. At any density, the difference in moisture contents indicated by the two lines represents the percentage of moisture, by volume, required to replace the contained air.

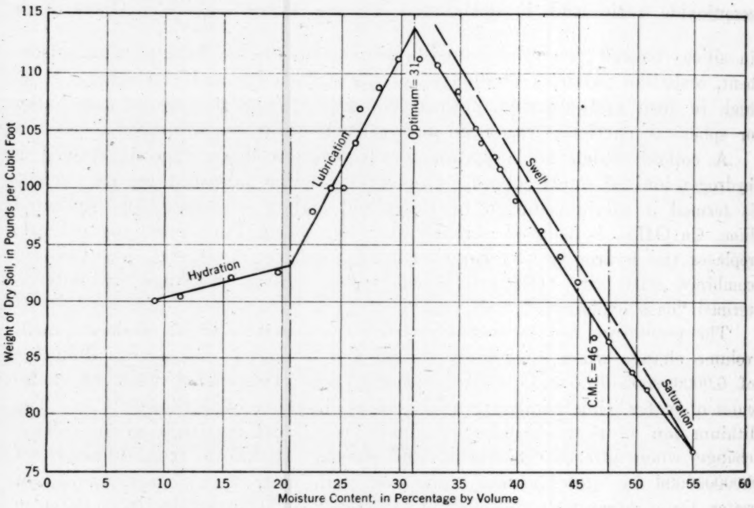

FIG. 1.—RELATION BETWEEN DENSITY AND MOISTURE CONTENT.

The moisture contents at which the straight lines intersect, indicate the limits of four distinct stages of wetting which the compressed samples undergo before their pores become completely filled with water. Wetting up to a moisture content of 20.7% (Fig. 1) may be termed the state of hydration, during which part of the contained water is absorbed by the soil particles, and the remainder is adsorbed on their surfaces in the form of cohesive films.

Moisture contents ranging from 20.7 to 31.1% indicate the stage of lubrication. Part of the contained moisture now acts as a lubricant to facilitate the re-arrangement of particles being compacted without, however, excluding all the air. Water in excess of 31.1% causes the soil mass to swell, although the air content is not further appreciably decreased until a moisture content of 47.7% is reached. Moisture contents between 47.7

and 54.3% represent the stage of saturation, during which practically all the air is displaced and the soil becomes truly saturated.

The moisture content (31.1% in this case) at which maximum density is attained is the optimum suggested by R. R. Proctor, M. Am. Soc. C. E. (20) for use in connection with the construction of earth embankments and dams.

Temperature is an influencing factor because in cold weather the adsorbed films are in general thicker than in warmer weather (1*b*).

Effect of Film Character on Properties of Soil

The free water, or pore water, is that which fills the interstices remaining between the outer surfaces of the adsorbed moisture films and not the pores between the surfaces of the soil particles as such. The flow of water through soil likewise occurs between the films adsorbed on the particles. As a result the speed at which water percolates through soil, as well as the moisture contents indicative of some specific state of stability of soil, varies wherever the thicknesses of the adsorbed films change, in some cases, when the viscosity of the free water changes.

Winterkorn (23), (24), (25) has shown that, due to the change of the kind of adsorbed ions on the particles of one type of soil, the liquid limit varied between 39 and 57, the plasticity index between 16 and 40, and the percentage of colloids between 11 and 28. The moisture content increase, indicating the swell of the samples in the Terzaghi compression device when the pressure was reduced from 3.2 kg per sq cm to 0, varied between 1 and 5 per cent.

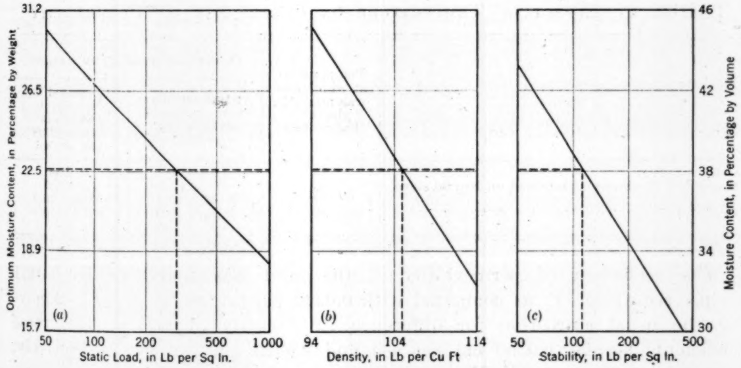

Fig. 2.—Control Curves.

The optimum moisture content (mentioned previously) at which maximum density is attained is not a constant for a particular soil, but varies as the compacting pressure is changed. The relations of optimum moisture content to compacting pressures, attained densities, and stabilities, as indicated by the Proctor plasticity needle for one soil investigated at George Washington University, are shown in Fig. 2.

Change of temperature alone, when other conditions are constant, causes considerable variation in the indicated properties furnished by tests. The test data furnished by A. M. Wintermyer, Assistant Highway Engineer, United States Bureau of Public Roads, and shown in Table 1 disclose no effect of temperature on the liquid limit of Sample S-9616, which is pumice having no plasticity.

TABLE 1.—EFFECT OF TEMPERATURE ON PLASTICITY TEST

Sample No.	Tested at 40° F			Tested at 90° F		
	Liquid limit	Plastic limit	Plasticity index	Liquid limit	Plastic limit	Plasticity index
S-9616	40	..	0	40	..	0
S-9617	57	30	27	49	23	26
S-9618	36	24	12	32	23	9

The liquid limits and plastic limits of both plastic soils (Samples S-9617 and S-9618, Table 1) were higher when the tests were made at the lower temperature. However, the corresponding variations in the plasticity indexes, which are most used for field control in the construction of stabilized roads, are relatively small.

The results of tests performed by Messrs. R. C. Thoreen and F. A. Robeson, of the U. S. Bureau of Public Roads, and shown in Table 2, reveal the relative influence of both viscosity and adsorbed film thickness on coefficients of permeability.

TABLE 2.—EFFECT OF TEMPERATURE ON COEFFICIENT OF PERMEABILITY

Soil	Temperature at which test was made, in degrees Fahrenheit	Coefficient of Permeability	
		At test temperature, in centimeters per second	Corrected for viscosity to 68° F, in centimeters per second
Sand	85	0.0481	0.0390
Passing No. 60 sieve and retained on No. 80 sieve	85	0.0222	0.0375
Clay soil	72 50	6.47×10^{-8} 3.49×10^{-8}	6.13×10^{-8} 4.54×10^{-8}

The coefficient of permeability of the sand was found to be 0.0481 cm per sec at 85° F, as compared with 0.0222 cm per sec at 35° F. Applying the usual correction for difference in viscosity of water (33), these coefficients become 0.0390 cm per sec and 0.0375 cm per sec, respectively, at a temperature of 68° F.

The coefficient of permeability of the clay soil was found to be 6.47×10^{-8} cm per sec when tested at 72° F and 3.49×10^{-8} cm per sec when tested at 50° F. These coefficients, when corrected for viscosity of water at 68° F, become 6.13×10^{-8} cm per sec and 4.54×10^{-8} cm per sec. Permeability tests made on samples of a similar clay at various voids ratios indicate that the decrease in permeability due to the greater film thicknesses at the lower temperatures, shown in Table 2, is equivalent to that produced by reducing the voids ratio from 0.97 to 0.89, which would indicate an increase in the effective volume of the solid particles of about 4 per cent.

The effect of temperature variation on the stability of soil is illustrated by tests on a clay soil compacted in the Proctor cylinder and penetrated with the plasticity needle (20). The data showed (1*f*) that the stability was 1 400 lb per sq in. when compacted at 42° F; 960 lb per sq in. when the temperature of the sample was raised to 130° F; 1 490 lb per sq in. when the temperature was then reduced to 33° F; and, finally, 1 100 lb per sq in. when the temperature was again raised to 118° F.

Types of Soil Stabilization

In the application of information now available on soil stabilization the methods to be used depend largely on the availability of required materials. In some locations, such as the southeastern part of the United States, Nature provided deposits of sand clay and top-soil having the grading and character required in the best of road soils.

In some locations, binder soils and aggregates are available for producing mixtures having the properties of the best of the naturally good soils. In other locations, materials are available for the graduations required in roads, but the binder soil may be of inferior quality. Finally, there are locations where there is deficiency of the aggregate required for properly graded mixtures.

Studies of the best of natural road soils indicate that the design requirement of stable soil mixtures should include the following:

(1) The aggregate should be hard and durable enough to resist weathering, traffic abrasion, and crushing. Sound, tough particles or fragments of gravel, stone, slag, or combinations of them, crushed to the proper size, should prove suitable. Certain types of shales and similar materials that break and weather rapidly when alternately frozen and thawed, or wetted and dried, should not be used.

(2) The soil fines should be of a character such as to provide graded mixtures with the proper balance of capillarity and adhesion without risk of detrimental volume change. It is particularly essential that the fines do not swell enough in the presence of moisture to cause the clay to become a lubricant instead of a binder.

(3) When local materials are available for the proper proportioning of aggregate and binder soil, but the natural clay does not have the binder value required in highly stable road surfaces, a number of admixtures may be used singly or in some combination. There are, first, the chemical salts, calcium chloride, sodium chloride, and magnesium chloride; and second, the waste products of industry, such as sulfite liquor from the manufacture of wood pulp, "blackstrap" from the molasses industry, and huge accumulations of waste sizes of the mineral aggregate industry.

(4) When only fine or poorly graded materials are available, the asphaltic, tar, and Portland cement binders may be utilized to provide stable base courses to be covered with bituminous surfacings. In isolated cases heat treatment has been used.

In the stabilization of fills the Proctor method or some modification is receiving considerable attention and for foundation soils, injection of chemicals and electro-chemical treatment furnish possibilities.

ADMIXTURES AFFECT SOILS IN A NUMBER OF WAYS

Among the ways that admixtures may assist in stabilizing soils are the following:

(1) By absorbing moistures from the air and reducing evaporation from the road surface, some chemicals may serve to keep the roads in a damp condition. This reduces the dust nuisance and facilitates the compaction of the surfaces under traffic.

(2) By electro-chemical action, chemicals and the waste products may serve to increase the density and stability of road mixtures.

(3) By chemical action, the same materials may combine with each other, or with certain of the natural clay constituents, and thus form water insoluble cements of high binding value.

(4) The Portland cement and bituminous materials serve the double purpose of binders and for eliminating the destructive water-absorbent properties of the clay binders.

It is difficult to distinguish between the electro-chemical and the purely chemical actions of admixtures for increasing the stability of soils. However, singly or in some combination they seem to explain not only the performances of soil roads in service, but also suggest relatively simple procedures for future construction.

As primes and fillers, certain soaps, etc., and admixtures of hydrated lime, and certain types of stone dust seem admirably suited for increasing the adhesion of bituminous binders for certain soils.

In addition to their deliquescent and water retentive actions, the chloride salts, by electrolytic action, may cause the compacted mixture to attain densities greater than untreated soils, and they minimize the volume change of the binder which is productive of disintegration of the untreated surfaces with changing moisture conditions.

Mixtures of acidic and neutral materials seem to attain greater stability than that of either one separately. Limestone dust and certain slags seem admirably suited for use as pre-treatments, or with other admixtures to neutralize acid soils. This may be especially desired in the case of siliceous clays. In some base courses now (1937) being contructed, an acid clay is mixed with non-acidic limestone aggregate.

In connection with the formation of natural colloidal cements two types of either rock powders or clays must be considered: Those which on soaking in water or watery solutions soften to the extent that they become, to ever so slight a degree, glue-like, and those materials which do not. To a small extent many of the sandstone, trap, and limestone powders are thus made glue-like by water alone and more so by water-soluble inorganic salts (13).

Experiments have shown that the cementing value of mixtures of the two types of materials (those which soften and those which do not) is considerably greater than the binding value of either material alone. Mr. A. S. Cushman and Prévost Hubbard, Affiliate, Am. Soc. C. E., found (13): (*a*) That by combining a granite with a cementing value of 3 and a limestone with a cementing value of 27, they obtained a cementing value of 110 for the mixture; (*b*) that a granite powder which had a cementing value of 10 when mixed with water alone, had a cementing value of 44 when mixed with lime water; and (*c*) that an amorphous chert which had a cementing value of 6 when mixed with water alone, had a cementing value of 22 when mixed with 4% of calcium oxide and water, and more than 2 000 when mixed with 13% of calcium oxide.

As a result it has been found possible to construct low type surfaces of only waste limestone or slag screenings treated with the chloride salt solutions. With granite screenings the addition of a small quantity of limestone also has been found to be beneficial.

ADMIXTURES OF PORTLAND CEMENT AND BITUMINOUS MATERIALS

Efforts to stabilize fine-grained soils by admixtures of lime and cement materials were made in Iowa and South Dakota as early as 1924 and in Ohio several years later. The results of this early work were not particularly promising, but they should not be considered as indicating the possibilities of such treatments, because the requirements of the thorough distribution of the admixture, the high degree of compaction, and the protective surface treatment now deemed necessary, were not recognized in the earlier work.

More recently (11), (12) research on the use of Portland cement for stabilizing soil bases has been performed in South Carolina by the State Highway Department. The purpose of this work has been to develop a base material that could be constructed at less cost than that required to provide one of properly graded sand clay or top-soil.

The results from these experiments were so promising that a number of similar roads are being constructed in other States. Experimental base courses constructed with available soil materials and the various tars (9), asphaltic emulsions (5), and cut-backs, and oils (6, 8) show similar promise.

USE OF OTHER ADHESIVES

Waste Sulfite Liquor.—Products prepared from the crude liquor have been marked from time to time under various trade names, for use as binding mediums in road construction. As early as 1910 Mr. Hubbard (13) published results obtained by the U. S. Bureau of Public Roads, showing the increase in compressive strength obtained by treating various rock powders with products prepared from waste sulfite liquors. However, the binding base of the adhesives tested was soluble in water, and, as a result, it was found that frequent rains tended to destroy the bond and remove the lignin from the road surface. In order to offset this difficulty attempts were made, at that time, to waterproof or make insoluble the residual base without destroying its binding value by admixtures of asphaltic road oils and deliquescent chemicals, such as calcium chloride.

In 1936 waste sulfite liquor, marketed under a trade name, was used for the treatment of gravel surfaces in New Jersey and experimented with by the State Highway Department of Washington for use primarily as a dust palliative, although the possibilities for its use as a stabilizing agent, especially in well-graded mixtures, have not been overlooked.

Molasses Residues.—A thick, sirupy liquid by-product obtained in the manufacture of sugar from sugar cane is known as "blackstrap" which, when treated with quick lime, forms compounds of high binding value known as calcium sucrates. Blackstrap, in combination with oil and lime, was applied as an experiment by the U. S. Bureau of Public Roads on a road at Newton, Mass., during the summer of 1908 (13), and a molasses-lime mixture was applied as a surface treatment on a section of the Bradley Lane Experimental Road, Chevy Chase, Md., in December, 1911 (29). Within a year, however, rains removed all traces of the treatment, causing the road to take on the appearance of an adjoining section which had been maintained as untreated macadam.

In January, 1936 (14), attention was called to a practice in India in the olden days, when a kind of coarse sugar, made by evaporation from the sap of palm trees, was added to lime to produce an improved quality of mortar. With this as a background, a short length of road surface formed of lime kankar was treated and the results were encouraging. (Kankar is a kind of limestone usually occurring as nodules in top-soil, used for making lime and in building roads in India.) In order to prevent the molasses from being washed away during rains, slaked lime was mixed with it, the claim being that the addition of burnt lime to molasses produces tri-calcium sucrate, which is insoluble in water.

Calcium Humate.—When lime is added to a soil containing humus (24), the calcium replaces the acidic hydrogen in humic acid, forming the more stable so-called calcium humate or neutral humus.

Hilgard (30) points out that there are several humates (of lime, magnesia, and iron) which assist in producing and maintaining crumb structure. When fresh, these substances are colloidal (jelly-like), like clay itself, but, unlike the latter, when once dried, they do not resume their plastic form by wetting. The crumbs thus formed are, therefore, quite permanent and contribute to the looseness of uncompacted soils rich in humus. One part of lime humate is said to be equal in cementing power to eleven parts of clay.

Calcium Silicate.—The insoluble calcium silicate binder is produced by treating soils first with sodium silicate followed by the application of calcium chloride according to the general principle used in the old English method of manufacturing artificial stone (31). Its use in soil stabilization has been principally in connection with increasing the stability of granular soils in connection with the construction of buildings and other structures (15).

TREATMENT WITHOUT ADMIXTURES

Electro-Chemical Treatment.—In a method utilizing electricity for stabilizing soils, described by Endell and Hoffmann (16), metal electrodes are introduced into the soil at appropriate distances, aluminum always being used for the anode and copper for the cathode. Direct current is then allowed to pass between electrodes until the soil is hardened. Experiments were described in which a clay specimen had been brought into its container with an almost liquid consistency, the water content being about 80 per cent. After treatment for some time with a current of 8 to 14 amperes, at 300 to 500 volts, the clay had become so hard that an iron rod, 1 sq cm in cross-section, failed to penetrate it when placed under a load of 10 kg (22 lb). Specimens cut from the side of this block nearest the aluminum electrode neither disintegrated nor swelled during several months of immersion in water.

Application of Heat.—The essential features of this method of treatment are illustrated by a method used in the so-called "black-soil" areas in Australia, in localities where the haul for gravel or crushed rock is excessive (17). A slow-moving, down-draft furnace with a speed of about 10 ft per hr was developed at Sydney, New South Wales, for baking the soil in place and converting it into a brick-like material. The machine (see Fig. 3) is wood-fired, of the air-gas producer type, on a chassis on road wheels, and is propelled under its own power.

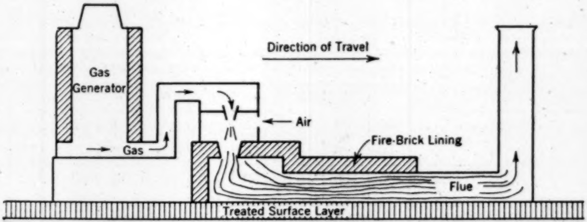

FIG. 3.—DIAGRAM OF FURNACE FOR HEATING SOIL IN PLACE.

Prior to heating, the road is graded to the desired cross-section and the strip to be treated is scarified to a depth of about 4 in. As the machine advances over a particular area, the soil is first subjected to the exhaust gases and then gradually increasing temperatures until the full intensity of the heat of the gases issuing from the generator is reached. Work proceeds continuously day and night, a machine 6 ft wide completing about 500 ft of roadway 18 ft wide per week. The effect of the treatment is noticed to a depth of about 6 in.

When traversed by roller the treated clods are broken down fairly readily. The clay binder is applied to the broken material, the road is shaped up and rolled again, and is then ready to be opened to traffic.

EFFECT OF GRADING AND ADMIXTURES ON DENSITY

The effects of grading and admixtures on stabilized soils compacted by the Proctor method (20) have been described in some detail elsewhere (1), the gradings and physical properties of red clay, Iredell, Arlington, and Manor soils being shown in tabular form (1*e*).

Grading.—The effect of the different gradings on the densities obtained at equal compactive efforts and fairly constant temperatures has been discussed in the earlier study (1*f*) (1*g*).

The red clay (Sample 1, Fig. 4, and Table 3) contains 68% of clay, 20% of silt, and 12% of sand. At the optimum moisture content of 16.7%, the dry weight was 113.0 lb per cu ft as compared with a dry weight of 129.8 lb per cu ft, at 9.6% optimum moisture content for the excellent soil mortar, Sample No. 6.

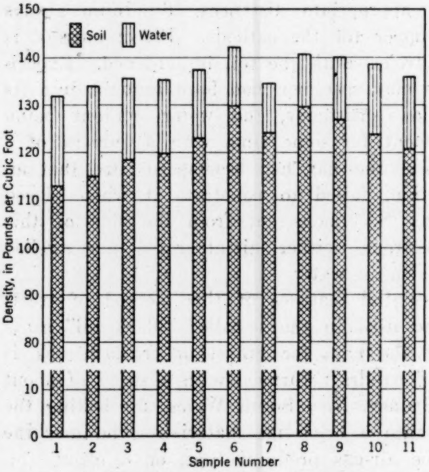

FIG. 4.—EFFECT OF GRADING ON DENSITIES OF COMPACTED SAMPLES.

TABLE 3.—GRADING OF COMPACTED SAMPLES (SEE FIG. 4).

Classification	GRADING (PERCENTAGES), FOR SAMPLE NOS.:										
	1	2	3	4	5	6	7	8	9	10	11
Clay	68	34	21	17	13	8	0	18	18	18	18
Silt	20	60	37	30	23	15	13	5	5	5	5
Sand	12	6	42	53	64	77	87	77*	77†	77‡	77§
Total	100	100	100	100	100	100	100	100	100	100	100

* 24% retained on a No. 20 sieve. † Nothing retained on a No. 20 sieve. ‡ Nothing retained on a No. 40 sieve. § 1% retained on a No. 60 sieve.

Samples Nos. 2, 3, 4, and 5, Table 3, were obtained by adding silt and sand to the red clay represented by Sample No. 1. An attempt was made to obtain proportions representative of the different fractions of Sample No. 6. Thus, Sample No. 5 represents approximately the grading of the fraction of material of Sample No. 6 that passes the No. 40 sieve; Sample No. 4 represents the fraction that passes the No. 60 sieve; Sample No. 3 represents the fraction that passes the No. 100 sieve; and Sample No. 2 represents the fraction that passes the No. 270 sieve.

Fig. 4, with Table 3, shows that as the total sand is decreased from that of Sample No. 6 to that of Sample No. 2, the weight of the compacted mixtures decreases and the optimum moisture contents increase. In Sample No. 7 an attempt was made to approximate the grading of the fraction of Sample No. 6 that was larger than 0.005 mm. As would be expected in the absence of the clay fraction, the optimum moisture content is smaller than that of Sample No. 6, being only 8.5 per cent. The weight of dry soil at maximum density, however, is only 124.1 lb per cu ft, which is 5.7 lb per cu ft less than that of the excellently graded material (Sample No. 6).

In the four samples, Nos. 8, 9, 10, and 11, Table 3, the sand, silt, and clay fractions are constant, but the grading of the sand fraction is varied. The maximum density of Sample No. 8 (with 5% of silt and 18% of clay, and approximately the same sand gradation as Sample No. 6) is slightly lower than that of Sample No. 6. As the coarser sand fractions are eliminated in Samples Nos 9, 10, and 11, and the mixtures approach a more nearly uniform grain size, their densities decrease.

Electrolytes.—In Fig. 5(*a*) are shown the effects of different electrolytes on the densities of compacted samples of the Arlington, Manor, and the Iredell soils. Using the Arlington samples for illustration, it will be noted that admixtures of sodium hypo-sulfite, sodium chloride, ferric chloride, and calcium chloride, effect an increase in weight of dry soil per cubic foot over that of the natural soil with water alone, whereas the weight of the sample treated with sodium silicate is less than that of the sample without admixtures.

Fillers and Adhesives.—In Fig 5 (*b*) are shown the effects produced by other admixtures on the densities of different samples. The fact that films of water-soluble adhesives might be thicker than those of water has no significance with respect to the relative stability of soils treated with the different materials.

TESTS USED IN SOIL STABILIZATION

In practice, the suitability of graded mixtures is determined by means of sieve analysis of the aggregate retained on the No. 10 sieve, combined sieve and hydrometer analysis of the fraction passing the No. 10 sieve, and the Atterberg plasticity tests performed on the fraction of the material passing the No. 40 sieve, an effort being made to combine materials in such quantities that the resulting mixture will conform to the requirements of stabilized road surfaces. To this end, specifications have been prepared on the basis of grading and the plasticity index.

However, any chance combination of two materials that falls within the limits of the specifications may not be the best possible combination. As has been shown by Miller (32), the specifications may call for a plasticity index of between 4 and 12, but for two given materials (aggregate and binder), there is one combination having a definite plasticity index at which highest density may be obtained.

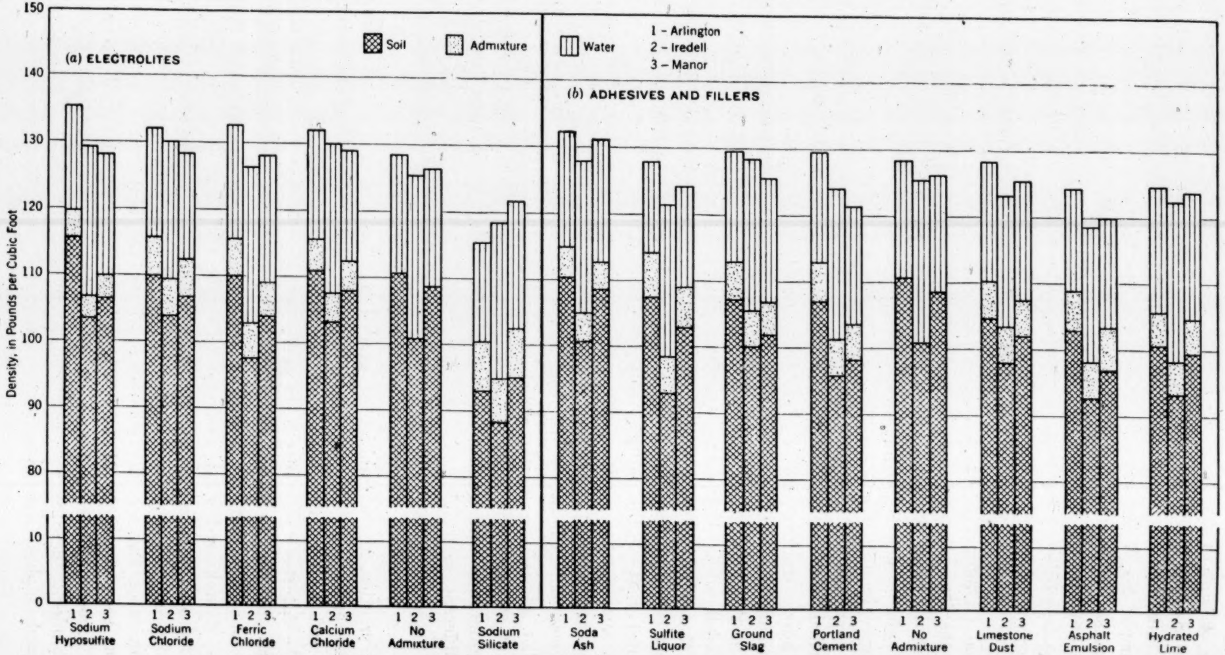

FIG. 5.—EFFECT OF VARIOUS ADMIXTURES ON THE DENSITIES OF COMPACTED SAMPLES.

The curve in Fig. 6 shows the maximum densities obtained in the Proctor test on five mixtures of Potomac River sand and Arlington loam. It indicates that the maximum density will be obtained by combining 30% of the Arlington loam with 70% of the sand. The plasticity index of this mixture is 6 and should be used for control in the field.

For the design of soil base courses in which asphaltic emulsions are to be used, C. L. McKesson, M. Am. Soc. C. E., advocates the use of special tests described elsewhere (5). The moisture content and the quantity of binder required in soil base courses stabilized with Portland cement, tar, and certain asphalts are determined by means of the Proctor tests.

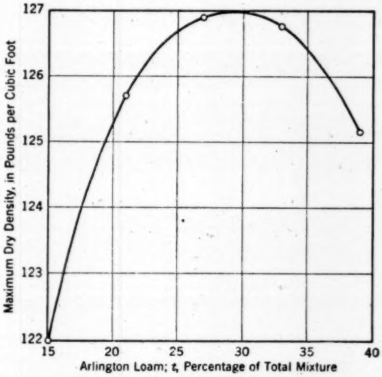

FIG. 6.—MAXIMUM DRY DENSITIES OF COMPACTED SAMPLES.

The Proctor tests are used extensively in connection with the construction of earth dams and embankments. However, it is believed that a modification of these tests, which furnishes data, such as those shown in Fig. 2, allows more latitude of construction procedure. For the compactive pressure to be provided by a given type of equipment, the corresponding optimum moisture content, resulting density, and plasticity needle readings are shown by the curves. Likewise, for any desired embankment density, the equivalent pressure that must be furnished by the rolling equipment, is disclosed.

To illustrate, let it be assumed that rolling equipment, exerting a compactive effort equivalent to a static pressure of 300 lb, is to be used. Then, the soil (Fig. 2) should be compacted at a moisture content of 22.9% of the weight of dried soil; the resulting density should be 104.4 lb per cu ft; and the plasticity needle reading, 117 lb per sq in. If, on the other hand, the embankment is to be constructed at an optimum moisture content equal to, say, the plastic limit (26%), the soil should be compacted at an equivalent static pressure of 130 lb per sq in. The resulting density is 99.2 lb per cu ft, and the plasticity needle reading, 69 lb per sq in.

The slopes of the density-moisture content curves may be quite different, as shown in Fig. 7. Assuming that the moisture content can be controlled in the field within a range of 5%, a variation of 2.5% above and below the optimum would be expected if the control value was set at the optimum moisture content. According to Fig. 7(*a*), densities from 98.4 lb per cu ft to 100.6 lb per cu ft would be expected from this particular soil. The density-moisture content relationship shown in Fig. 7(*b*) has a steeper slope than the one shown in Fig. 7(*a*), although the indicated maximum densities are the same. A variation of 2.5% above and below the optimum moisture content would result in densities between 94.35 lb per cu ft and 100.6 lb per cu ft. By setting the control moisture somewhat above the optimum in the case of the soil with a density-moisture content relationship, such as that shown in Fig. 7(*b*), it is possible to reduce the variation in density. Thus, using moisture contents from 2.5% below to 2.5% above 26.2%, the resulting densities would be between 97.4 lb per cu ft and 100.6 lb per cu ft.

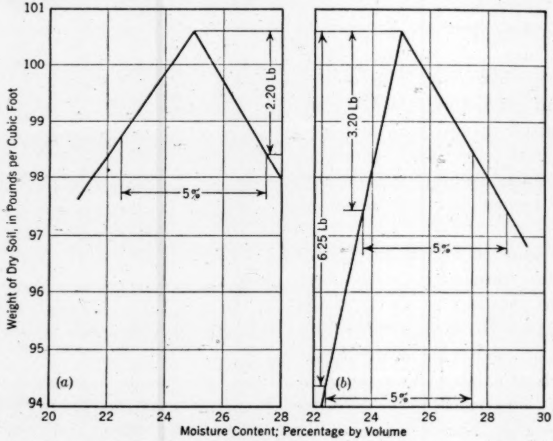

FIG. 7.—EFFECT OF MOISTURE CONTENT VARIATION ON DRY WEIGHT OF COMPACTED SOILS.

CONSTRUCTION VARIABLES

In the mixing of solid binders, such as clay and Portland cement, with aggregate, advantage is taken of the adsorption phenomenon that for thorough distribution it is only necessary for the materials to be brought in close enough association to permit the dry powders to become attached to and coat the aggregate.

Bituminous materials, in contrast, coat the soil more readily after the air films have been removed by wetting the particles. Therefore, water in various quantities is used to obtain the required distribution of tars and asphalts in soil mixtures.

The materials have been mixed by harrowing, blading, etc., by portable plants on the roads, and by means of plants set up at the source of supply of the soils or mineral aggregates.

Asphaltic materials used as stabilizers in Jackson County, Missouri (7), were introduced at desired depths below the surface of the loose road mix by means of a specially constructed "sub-oiler" (1*d*). It is essentially a tooth scarifier, having an oil line attached to the back of each tooth and running nearly to its point.

Graded mixtures have been compacted by rollers supplemented by traffic on roads and by rollers, trucks, etc., in fills. Generally, when the Proctor method of control is used, the prongs of a sheep's-foot or tamping type roller, or equipment that produces a similar effect, are required to penetrate the unconsolidated material and compact the layer from bottom upward, in order that the layer of fine material may be consolidated uniformly throughout its thickness without stratification. Compaction by vibrating the soil is another method being investigated.

SUMMARY

A review of the development of soil stabilization discloses the fact that the principal means followed in practice until several years ago involved the use of granular materials. With the increasing demand for farm-to-market roads the use of water-retentive chemicals was found to be a valuable supplement in the construction and stabilization of properly graded road mixtures. Attention was next directed toward the use of water-insoluble binders, including bituminous materials and Portland cement, for stabilizing poorly graded and fine-grained soils. Data now available indicate that:

1.—Soil stabilization involves film phenomena in one or more of the following steps: (*a*) Removal of the air film by wetting the soil particles; (*b*) making the liquid films stronger and more lasting by use of deliquescent and water-retentive electrolytes; (*c*) use of waste aggregate materials to provide the proper neutrality of the mixtures; and (*d*) replacement of the liquid or air films with bituminous materials, Portland cement, and other insoluble binders in the stabilization of fine or poorly graded soils.

2.—Admixtures which have been found unsatisfactory for treating road surfaces subjected to abrasion by traffic and action of the climatic elements may provide benefit when used in base courses protected from these influences by impervious bituminous surfacings. The use of adhesives is not expected or intended to render the soil sufficiently hard or tough to resist the abrasive action of traffic, but simply to render it resistant to water from capillarity and thus to retain the same stability that the soil had at the density obtained during construction.

3.—Use of natural soil with the thinner films, or chemical solutions to reduce the thickness of the films and thus provide greater density, furnishes three distinct benefits to soil structures in service. The thinner the films the smaller is the quantity of free water that can be released as the soil becomes warmer. Consequently, soils with chemically thinned films retain greater uniformity of stability under changing temperatures.

Reduced film thickness causes soil to attain high density with less compactive effort. This means lower cost for compacting fills, earth dams, etc., and less time required under equal traffic conditions for road mixtures to become stable. The latter is especially important in base-course construction where the highest density is desired in the shortest possible time, in order to prevent additional and, perhaps non-uniform compaction of the base course, after the wearing surface is applied.

The freezing point lowers as the thickness of the film diminishes. Therefore, the denser the soil at relatively low moisture content, the less likelihood is there of the films freezing, even if they consist of water alone. When the contained chemicals also depress the freezing point, a double provision against damage to stabilized soil due to frost is obtained.

CONCLUSION

In conclusion, it should be emphasized that soil stabilization is as yet in its infancy. Laboratory tests are helpful for disclosing the various possibilities of attaining stability of soils, but their value is limited and the constants furnished by them are truly constant only for the conditions of temperature, etc., at which the tests were made.

The plasticity tests disclose primarily only the binder properties of clay due to reversible phenomena. They do not throw light on the presence of colloidal cements that are likely to develop as the soils dry out during compaction under traffic.

The Proctor tests afford a simple and promising means of determining optimum binder contents and degrees of compaction required for the attainment of given densities. The optimum density to which a given soil should be compacted for greatest stability in embankments is not as yet known. It has been suggested that there is a theoretical optimum for a soil in dam construction beyond which tamping may become injurious (35). Meager data obtained in the laboratories of the U. S. Bureau of Public Roads seem to indicate the possibility of a drop in stability after the density of a sample at constant moisture content has been increased beyond a certain limit.

How much the different fine-grained soils will swell, over long periods of time, after being compacted to high density during the construction of embankments, is also a moot question. Generally, the pressure on the soil, at a given location, exerted by the weight of the embankment above it, is considerably less than the pressure at which the soil was compacted. Only colloidal glue action could prevent such soils from swelling. If swelling were likely to occur to considerable degree there would seem to be no reason for compacting the soil with a pressure much greater than that produced by the weight of the embankment the soil is to support.

The fact that some soils are particularly sensitive to small changes in moisture content indicates that from a practical standpoint they are undesirable for embankment construction. Furthermore, such soils when used as binders in stabilized road mixtures will re-act quickly to variations in moisture content with consequent changes in stability and cementing properties. The basic relationships between soil particles and surrounding moisture films are applicable to both embankments and stabilized soil roads, and any tests revealing these relationships are valuable aids in the design and construction of either type of structure.

Unfortunately, tests are not as yet available for disclosing the effects of climatic variables occurring during long periods of time on specially compacted and specially treated soils. As a result much of the desired information on the lasting effects of the base exchange, chemical actions, and especially produced film conditions must await the results of observations on stabilized soil roads and structures in service.

DISCUSSION

Jacob Feld,[5] M. Am. Soc. C. E. (by letter).—A fine summary of soil stabilization is presented in this paper which covers especially the effect of the colloids and moisture films. The real complexity of the subject can only be visualized by a complete definition of the word, "soil," as used in the engineering sense. Such a definition does not yet exist, and an agreement on the meaning of the word would be a great aid in the classification of materials and tests concerning soils. In 1924, the writer[6] enumerated the major constituents of soils and their respective contributions to soil properties as well as the effect on the colloidal constituents of various chemicals and electrolytes.

The farm technologist defines a soil as a porous mass of hard framework plastered over with a jelly containing chemically active matter, plant foods, and unstable organic compounds, the pores of which contain air and water. The farmer classes soils as heavy (clayey) or light (sandy), referring to the predominance of the mineral constituent.

The geologist distinguishes between (1) primitive soils formed by the mechanical loosening and chemical decomposition of rocks (or a combination of both); (2) derived soils formed by the mixture of primitive soils with possible additional weathering, due to water or wind acting as collecting agents; and (3) decayed vegetation mixed with small percentages of minerals forming humus, peat bogs, or similar highly organic soils.

It is quite well agreed that studies on pure sand, pure clay, uniformly grained granular substances, powdered rocks, or any laboratory combinations of these items, with or without water, can help but little, if any, in the solution of a field problem; and the impossibility of reproducing temperature changes, moisture distribution, and other variables, to say nothing of the difficulty of obtaining true soil samples, makes tests on actual soil samples of doubtful value. The foregoing statement would be true even in a uniform soil (a hypothetical and probably non-existent material).

Unfortunately, the problem has been attacked from the microscopic instead of the macroscopic point of view. It is so easy to study the leaves without even becoming aware of the existence of the tree. In the writer's opinion, much more valuable, as well as more rapidly usable, results will be obtained when an agreement is reached to classify soils on the basis of a few quantitatively measured physical properties, found by tests as simple as those now used for testing cement. Standards can then be determined for certain well known classes of soils, such as the list of "Important American Soils" issued by the Department of Agriculture.[7] Without such an agreement, tests on soils made by different men can never be compared, and the accumulation of test data will only be used by those who desire to show agreement between some chosen isolated tests and a "pet" theory.

Donald M. Burmister,[8] Assoc. M. Am. Soc. C. E. (by letter).—An excellent and comprehensive summary of soil stabilization, particularly the important physico-chemical surface phenomena, has been presented in this paper. The authors have shown that the grading and proportions of the fine and coarse materials, admixtures and chemical treatment, and temperature and film character have an important effect on the density, optimum moisture content, and stability of compacted soils.

The primary purpose of such investigations is to build a fund of knowledge on soil stabilization, so that the experiences and knowledge gained may be of practical value, and serve as a guide in solving such problems. In order to accomplish this purpose more completely, soil behavior must be translated into terms of soil character, which means that the soils in each case must be described, accurately and systematically, on the basis of a few quantitatively measured physical properties, so that they can be identified unmistakably, and classified. This would make possible comparisons and reliable correlations with soils from other localities.

In addition to the basic principles of soil compaction established by Mr. Proctor (see heading, "Bibliography," Reference (20)[9]), and the principles emphasized by the authors, there are a number of important physical relations which the writer believes are fundamental, because they bring into a more unified and consistent pattern many of the physical factors governing the behavior of soils. Five of these relations are as follows:

(1) There is a general tendency for a decrease in the maximum density and an increase in the optimum moisture content with increasing fineness of the soil, the degree of fineness being designated by a mean grain size or a size factor[10] which correlations show to be a practical and useful measure of fineness.

(2) The important influence of the grading of soils and the proportions of mixtures on density (that is, the grading-density relations[11]) can best be expressed in terms of the type of grading curve and the range of particle sizes,[10] there being consistent relationships at the optimum condition of compaction even to the finest materials.

(3) The plastic characteristics of the fine fraction of the soil, expressed in terms of the liquid and plastic limits, and the plasticity index relations, give a valuable clue to the physical character of the soil, because the plastic characteristics are influenced by the same physical factors that determine density and stability—namely, wetting characteristics, plasticity, mineralogical nature, binder, or cohesive qualities, etc.

(4) The proportion and the characteristics of the coarse fractions of the soil, particularly the wetting characteristics and the grading-density relations,[11] have an important influence on the moisture-density relations and on the stability of the whole soil. If the proportion of coarse materials is large, the fine fraction acts as a filler and binder, and the character of the coarse material predominates. If the soil is predominantly fine, the moisture-density relations and

[10] *Proceedings*, Am. Soc. C. E., February, 1938, p. 397.

[11] *Loc. cit.*, p. 365.

stability are determined almost entirely by the plastic characteristics of the fine fraction of the soil.

(5) There appears to be a fairly narrow range of clay content (finer than 0.005 mm) necessary to obtain both maximum density and stability, particularly for stabilized earth roads, where permanent stability is essential in both the wet and dry condition. Where there is a deficiency of clay (that is, less than about 5%) and where the soil is non-plastic, with a plasticity index less than about 4, the density at the optimum moisture content is materially less, and the soil has insufficient binder qualities. The optimum moisture content may be less, but there is a larger quantity of entrapped air. Clay content in excess of 35% to 40% and a plasticity index greater than about 15 to 20 are undesirable from the standpoint of stability of rolled-earth dams and fills, although the compacted soil may be very dense. The requirements for stabilized earth road soils, of necessity, must be defined more closely because of the extreme service conditions.

A study of compaction tests on different soils and an analysis of the compaction test data from a great many sources[12] show that these fundamental relations and those stated by the authors form the basis for correctly interpreting and evaluating the influence of many physical characteristics of soils on their density and stability. The writer wishes to suggest the following simple, systematic method of presentation and analysis of the data given by the authors in Fig. 5 and Table 3, which is intended to reveal and focus attention on the characteristic features of the soils under investigation, or soils from any given locality, so that the influence of their individual similarities, or differences, and qualities can be learned; and so that the inter-relationship of all physical factors can be studied in an attempt to trace their influence on density and stability. Although general statistical relationship is valuable, it is believed that the emphasis should be placed on the particular character of the individual soils. Differences in physical characteristics then become of equal importance with similarities of soils as reflected in density.

In Fig. 8, the mean grain size or size factor,[10] as a significant physical characteristic of soils, is used as the plotting argument. All related data for each soil are then plotted on a vertical line through the mean grain size in the different component parts of the diagram. This method of plotting serves to focus attention on the particular characteristics of the soils, and the confusion of superimposing a large number of grading curves is eliminated.

Size Characteristics.—The distribution of grain sizes is indicated for each soil by projecting and plotting certain soil fractions as, for example, percentages finer by weight than 5.0, 0.5 (approximately No. 40 sieve), 0.05, and 0.005 mm on to a vertical line through the respective size factors or mean grain sizes. A closer sub-division such as log 6 or log 2 intervals might have been chosen. The distribution of these fractions, or grouping (bunching above or below the 50% size) is characteristic and serves to indicate both the type of grading curve, which is designated by letter in Fig. 8, and the range of particle sizes.[10]

---

[12] "The Physical Characteristics of Soils, with Special Reference to Earth Structure," by D. M. Burmister, Assoc. M. Am. Soc. C. E., *Bulletin No. 6*, Research Laboratory, Dept. of Civ. Eng., Columbia Univ., June, 1938.

A broken line traced through the respective fractions shows clearly the tendency in these soils for increasing clay content and decreasing coarse material with increasing fineness. The peculiarities of any particular soil with respect to the distribution of grain sizes are now indicated by the departures from the general trend of these fractions.

It is to be noted that for the soils in Group 1 the range of particle sizes decreases with decrease in mean grain size, and the type of grading curve changes from the wide-range, coarse *F*-type to the narrower range *F*-types (almost the *D*-type) and, finally, to the fine *E*-type. Soils in Group (2) have a constant proportion of fine material and vary only in the coarseness and

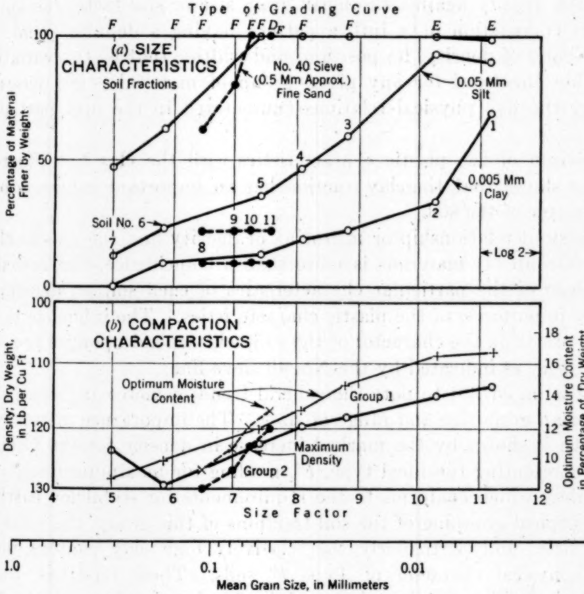

FIG. 8.—THE GRADING-MOISTURE-DENSITY RELATIONS OF FINE-GRAINED SOILS

range of the coarse fraction, and they change from the typical *F*-type to the D_F-type.

Compaction Characteristics.—These characteristics of the soils are now reflected in the maximum density and optimum moisture content. First, there is a decrease in density with decreasing mean grain size; and, second, this decrease is also associated with a decrease in the range of grain sizes and a change in the type of grading curve for these soils. The importance of the range of grain sizes is shown in Group (2), where change in the range of the coarse fraction alone causes a marked decrease in density. The decrease in density of Material No. 7, due to deficiency of clay content (or decrease in the range in the fine sizes), is very noticeable, but the optimum moisture content is also less, showing that there is a larger quantity of entrapped air.

However, the size characteristics alone are insufficient to describe and identify soils. The plastic characteristics give much more valuable and specific information on their true character. Fig. 8, therefore, is extended for the analysis of certain groups of soils in Fig. 9 to include the plastic characteristics of the fine fractions of the soil passing the No. 40 sieve (0.5 mm, approximately), which are defined in terms of the liquid limit and the plasticity index.

A study of the density relations at the optimum condition discloses consistent relationships with the specific characteristics of each soil. This method of plotting the density against the mean grain size or size factor, as an argument, brings compaction data into a pattern having a definite trend. The slope of the band of density, its position, and width—that is, the variation of density within the band for any given group of materials—are determined primarily by the five physical relations enumerated in the first part of this discussion.

A comparison of the plastic characteristics with the clay line (finer than −0.005 mm) shows that the clay fraction has an important influence on the general character of the soil.

The consistent relationship or mirroring of density and the plastic characteristics for Group (4) materials is more than a coincidence, but reveals the direct influence of the particular characteristics of each soil on density, and indicates the importance of the plastic characteristics. The influence that the fine fraction exerts on the character of the soil, will depend upon its proportion of the whole soil, as indicated by the No. 40 sieve line.

Again, it is important to note the general trend of increasing density with increasing mean grain size and range of sizes. The importance of the type of grading curve is shown by the marked increase in density for the Group (6) materials, representing the ideal type, *F′*, grading for maximum density—the Talbot grading, which conforms to the requirements for stabilized earth-road soils. The typical grouping of the soil fractions of this group, the wide range of particle sizes, and particularly the relatively high clay content indicate clearly the physical character of Type *F′* soils. These relations, together with the relatively high plasticity index of the fine fraction (passing the No. 40 sieve), represent the ideal requirements that must be satisfied in order to obtain maximum density. In general, where the plasticity index is lower than the trend the density is lower, and where it is higher, the density is greater, an inverse relationship, which is quite consistent.

Equally consistent relations are indicated for the Iredell, Arlington, and Manor soil of Group (3), which the authors used in their investigations (see Fig. 5). In view of the fact that the plastic characteristics reflect, consistently, the influence of the physical factors of the fine fraction that determines density and stability, the specific influence of admixtures, electrolytes, and chemical treatment, except bituminous materials, may be determined and correlated by their specific effects on the liquid limits and plasticity indices of the particular soils, because these substances affect primarily the wetting characteristics,

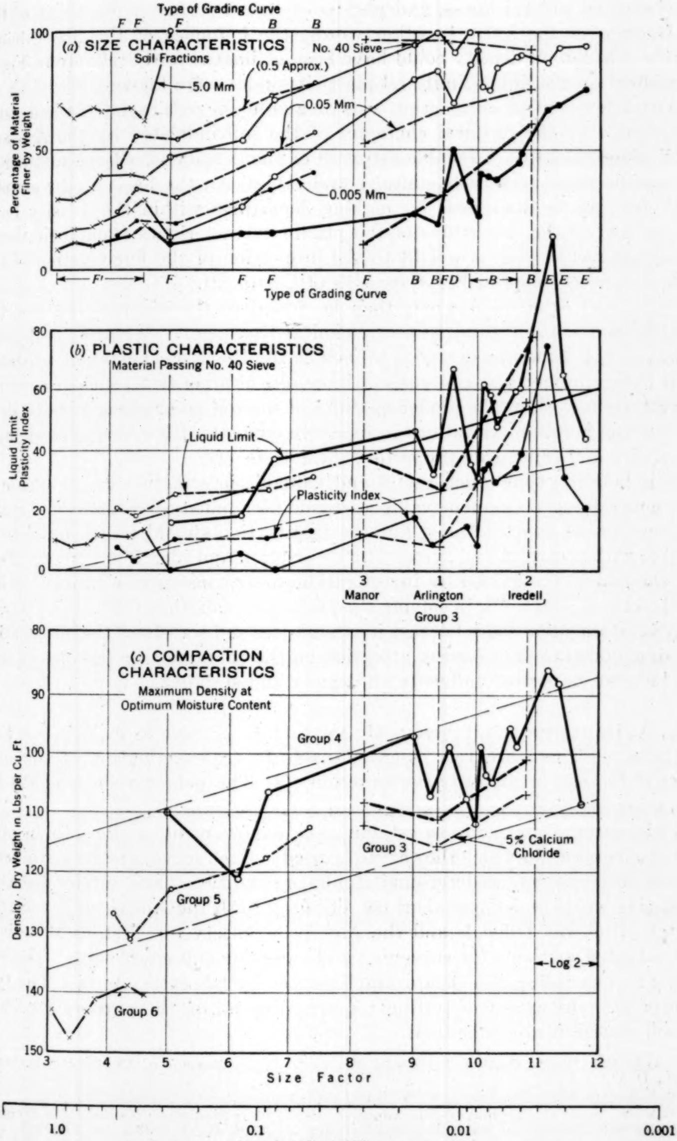

FIG. 9.—THE COMPACTION CHARACTERISTICS OF SOILS SHOWING THE INFLUENCE OF SOIL CHARACTER ON DENSITY

film character and thickness, and physico-chemical surface phenomena of the fine fraction of the soil. In other words, the influence of the 5% calcium chloride solution on density could have been estimated fairly reliably in Fig. 9 if the effect on the liquid limit and plasticity index were known.

With a few control compaction tests on a group of soils to define the density band, and with the physical character of the soil indicated by the size and plastic characteristics, a reliable estimate of the density of a large number of soils can be made more economically and rapidly on the basis of the simpler liquid and plastic limit tests by making departures within the density band proportional to the departures of the plastic characteristics from their trend, and by giving the proper weight to the proportion of the fine fraction of the whole soil, as revealed in Fig. 8 for soils of Group (2).

Additional sub-divisions may then be added to the diagram showing the quantity and kind of admixture or chemical treatment. Where it is deemed advisable, Fig. 9 may be extended to include the Proctor penetration resistance at the optimum moisture content, or the results of other tests, such as crushing strength tests to show the binder qualities of the soil and slaking tests to show how the soil reacts to variations in moisture content with consequent changes in stability and cementing properties, shear tests, etc.

It is believed that much useful and valuable information can be made of more general and permanent value as a guide for rolled-earth dams and stabilized earth-road constructions; but the information should be as complete as possible with a careful and systematic description and identification of soils so that the experience gained by investigation or by construction in one locality may be of practical value in solving the problems in another. The soil diagram affords certain advantages because it summarizes and correlates the information in a single diagram and focuses attention on the characteristic features of soils that have an important influence on density and stability.

C. A. HOGENTOGLER,[13] ASSOC. M. AM. SOC. C. E., AND E. A. WILLIS,[14] ESQ. (by letter).—There are two essential parts to an examination of soil as a material for use in highway construction: (1) The field survey, and (2) the laboratory analysis.

Field surveys are made to establish the environment of the soils in place or in the locations in which they are to be used. Such surveys include studies of climate, topography, underground drainage conditions, and service behavior of existing roads under prevalent conditions. Both the American Association of State Highway Officials and the American Society for Testing Materials[15] have adopted methods for surveying and sampling sub-grade soils. The surveying and sampling of soils are supplemented by laboratory tests. The type of tests and the extent of testing required depend on the purpose for which the soil materials are to be used.

[15] A. A. S. H. O. Method T-86, Adopted, 1934; Standard Specifications for Highway Materials and Methods of Sampling and Testing, A. A. S. H. O., 1935, pp. 213–221; also, A. S. T. M. Designation: D 420–35T, pp. 940–949, *Proceedings*, 38th Annual Meeting, Vol. 35, 1935.

In the paper, emphasis was placed on the character and properties of the soil materials as revealed by laboratory tests. It was assumed that satisfactory field conditions would be accomplished.

Highway engineers have been accustomed to select aggregates almost exclusively on the basis of their hardness, durability, and grading. These aggregates are mixed with Portland cement and bituminous binders with the expectancy of equal serviceability, this being possible because the designs utilize average strengths of groups of materials instead of the maximum strengths of the best mixtures individually; but in soil stabilization engineers strive for the maximum strengths of individual mixtures of soil aggregate and binder. They study films of air, moisture, chemical solutions, and insoluble binders; their relative adhesion to soil particles; and how their strengths and thicknesses are influenced by traffic, climate, and admixtures. Both Mr. Feld and Professor Burmister have indicated the desirability of a generally accepted system of soil classification for engineering purposes. Professor Burmister has described in his excellent discussion the multiplicity of factors which must be considered in any such grouping.

The authors are convinced that the practical method of attack is to group soils on the basis of performance for each particular engineering use. Simple tests may then be used to identify the individual members of each performance group.

Four groupings of soil materials based on performance when used for a particular purpose in highway construction have been adopted. They are: (1) A grouping for sub-grade materials; (2) a grouping for embankment materials; (3) a grouping for graded materials for use in base or surface courses; and (4) a grouping for fine-grained soils stabilized with Portland cement or bituminous material. On the basis of the test data, the soil samples are classified according to these groups and studied further in an effort to improve on the test result limits tentatively established.

The general grouping for sub-grade soil materials in which eight groups are recognized is widely used by State highway departments. The tests used for the identification of these materials are: (*a*) Mechanical analysis; (*b*) liquid limit; (*c*) plastic limit; (*d*) shrinkage limit; (*e*) field moisture equivalent; and (*f*) in some cases only, the centrifuge moisture equivalent.

A grouping for embankment materials has been adopted as a standard specification for the American Association of State Highway Officials.[16] The specification includes six groups for embankments less than 10 ft in height, and five groups for embankments greater than 10 ft in height. The tests used for identification in these groupings are: Liquid limit; plastic limit; and maximum weight, per cubic foot, as determined by the compaction tests.

The grouping for graded materials for surface and base course construction has been adopted as a standard for the American Association of State Highway Officials.[17] Seven groups—three for surfacing materials and four for base course materials—are included. These materials are identified by the liquid limit and plastic limit tests, and the mechanical analysis.

---

[16] Standard Specification M 57–38, A. A. S. H. O.

[17] Standard Specifications M 61–38 and M 56–38, A. A. S. H. O.

The grouping for fine-grained soils stabilized with Portland cement and bituminous materials has been submitted to the American Association of State Highway Officials in part. Two groups of materials, differentiated in the case of stabilization with Portland cement by wetting and drying, and freezing and thawing tests, are recognized. The compaction test is used to determine the quantity of water to add during construction.

Results of check tests conducted during the nine years, 1929–1938, by the Bureau of Public Roads in co-operation with the various State highway testing laboratories show that tests for identifying the members of the various soil groups have been developed to an entirely satisfactory status.

The widespread usage of these groupings has indicated that they are of practical value and that the employment of specifications based on them are workable and produce results which are more satisfactory than those previously attained.

SOIL REACTIONS IN RELATION TO FOUNDATIONS ON PILES

By R. M. Miller,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Hibbert M. Hill, George P. Stowitts, George A. McKay, Chandler Davis, Harry E. Sawtell, J. Stuart Crandall, and R. M. Miller.

Synopsis

Technical literature dealing with foundation problems contains voluminous reports on the properties of clay, silt, and mud, and the reactions of these soils to loads transmitted through round or square plates of varying sizes. There has also been as much written on the properties and reactions of sand and other permeable soils under various conditions of loading. Seldom, however, does one find a clear analysis of the behavior of a combination of many soils, a condition that is encountered so frequently in the construction of foundations. Even less frequently does one discover a publication that is written for the practical use of the designer and the construction engineer who are seldom equipped for this highly specialized branch of the profession. It appears possible that if more attention were directed to the application of theory rather than to theory itself fewer foundation failures would result. The attempt has been made in this paper, therefore, to use the construction field as a source of information, and to correlate the collected data on pile foundations under varying soil conditions so that the reasons for success and failure become evident.

The data presented herein may tend to show that the "science" of pile foundations can be called a science only when the piles are driven to rock, gravel, hardpan, or other substantial sub-stratum. Very little is known of skin-friction values or of the distribution of loads to the subsoils and, therefore, not much is known about the correct spacing of piles. It will be evident that in soils of clayish characteristics, and even in saturated sands, the dynamic pile-driving formulas are only a poor indication of the carrying capacity of a single pile; and that the carrying capacity of a cluster or mat of piles seldom equals the value of a single pile multiplied by the number contained within the cluster.

Note.—Published in June, 1937, *Proceedings*.

[1] Project Engr., PWA, Cincinnati, Ohio.

AVERAGE PRACTICE

Records collated from 250 pile-driving projects, well distributed over the United States, form the basis of this paper. The analysis is interesting in that it reveals the variety of soil combinations extant and the average treatment, by practicing engineers, of this complicated problem. As recorded from the boring data the soils were of such an infinite variety of mixtures and in such an infinite variety of proportions that only three examples will be noted: (1) 5 ft of sawdust, old paving blocks, and general refuse, on 25 ft of very soft and slushy mud, changing gradually to 5 ft of firmer blue mud on sand; (2) 6 ft of sand and clay, on firm sand and silt, on coarse sand and quicksand, on medium coarse gravel; and (3) 20 ft of hydraulic sand-fill, on 25 ft of mud, on 5 ft of peat, on marl. During the construction of the foundations for the Laurel Homes Housing Project, Cincinnati, Ohio, in an area of 35 by 150 ft, loam top-soil was found on soils which may be described by the terms, clay, "bull liver," and quicksand. Within the same area were found twelve cesspools and one spring flowing strongly during the drought of the summer of 1936. Imagination cannot picture a mathematical treatment of such a problem. With no apologies, it should be stated that such inexact terms as quicksand, clay, the dirt movers' "bull liver", etc., are used throughout this paper as describing the soils more clearly to the minds of most engineers and contractors than the correct technical terms. No piles were driven for the Laurel Homes Project.

The driving of piles in the widely varying soils indicated by the foregoing, develops reactions as diverse as the soils themselves. In some instances a heave as much as 6 ft resulted, and, in others, settlement followed. Added resistance to driving after rest resulted in some cases and lessened resistance to driving after rest in others. Frequently, shorter piles were required as more were driven in a cluster, due to the consolidation of the surrounding soil, and at times longer piles were required as driving progressed.

The solution of this problem may be demonstrated by average data computed from the aforementioned records. If the assumption is made that the design load must be carried by the soil below the pile-points, and if the average design loads are divided by the area represented by the pile-spacing, comparative loads per square foot on the several types of subsoils can be ascertained. It is understood, of course, that whereas only average values, are being compared concentrations of loads may often occur beneath pile-points greatly in excess of the average.

From Table 1, it is evident that, in spite of errors in assumptions, most of the serious settlements of foundations on piles in America should occur on projects where the pile-points rest in clay or other plastic subsoils. It is also evident that average practice is at times wasteful where the pile-points rest on firmer sub-strata. It would appear, therefore, that where piles have been driven in plastic soils, the average design load per pile has been too much, or the spacing of the piles has been too small, for the

the average design load. It would also appear that where piles have been driven to rock or other hard strata advantage should be taken of the possibilities, such as increasing pile diameter, pile spacing, the design load per pile, and the unit load on the hard sub-strata. In addition, it must be apparent that end-bearing piles driven to solid sub-strata present comparatively little difficulty.

TABLE 1.—BEARING VALUES FOR PILE FOUNDATIONS

Soil beneath pile-points * (1)	Design Load, in Tons per Pile			Average load upon subsoil, in tons per square foot (5)	Assumed safe load, in tons per square foot † (6)
	From: (2)	To: (3)	Average (4)		
Soft clay	12	35	25.0	2.8	1.0q
Sand	6	45	28.4	3.2	4.0‡
Gravel	14	40	28.7	3.2	6.0
Firm clay	20	39	29.5	3.3	3.0q
Rock	18	70	36.4	4.0	30–100.0§

* Average pile spacing equals 3 ft. † Building Code of Cincinnati, Ohio. ‡ Average for fine clean sand and coarse compact sand of Cincinnati Building Code. § Building Code of Boston, Mass.

Examination of the records indicates that the results are due in many instances to incorrect, incomplete, or a total lack of, sub-soil data, to misinterpretation of the results of preliminary investigation, and often to too much dependence placed upon standards of pile loading and spacing.

SOILS

Research and experience have brought to light soil characteristics that serve as a basis for the understanding of their reactions during the driving of piles. However, variations in the water content or imperceptible quantities of other soils in combination change the results so that at times predictions as to reactions are embarrassing.

In general, it may be said that: (1) Soils, to-day, are considered as solids definitely elastic in some degree; (2) compressibility varies from sand and gravel at the one extreme to gumbo and peat at the other; (3) sand under load compresses almost at once, whereas clay of low permeability from which water can only escape slowly under pressure, requires a long time for permanent deformation; and (4) undisturbed clay recovers considerable of the depth of its settlement when the load is removed, depending on the duration of application of the load.

THE BEHAVIOR OF IMPERVIOUS SOILS

The phenomenon of the compression and rebound of soils has been illustrated so many times by investigators, by means of compression and rebound curves, that additional curves are superfluous. It will be instructive, therefore, to examine a fairly common phenomenon that may serve to illustrate the behavior of the more impervious soils.

One of the railways in the East was built through red and yellow clay, with miles of clay cuts and fills. Large carloads of coal are hauled by heavy locomotives, producing heavy wheel loads. Observation of the track under traffic indicated that the clay sub-grade was originally very elastic, the deflection of the rails under the passing wheels being considerable, and the rebound being apparently equal to the deflection. For years after construction was completed, more and more ballast was added, and the track was lifted time and again, until, finally, for valuation purposes, the ballast was measured, and it was found that the road bed immediately under the ballast had assumed the shape of a ditch, 3 ft or more deep in places. This would mean that the repeated application of loads over a long period of time gradually compressed the clay until, after many load applications, permanent deformation was reached. Some evidence was discovered of side movement of the soil into cut ditches and of mixing of ballast and sub-grade.

The time required for driving of piles, however, is usually a matter of minutes and the application of comparatively few blows. If a clayish or impervious soil is considered as elastic, it should compress momentarily with the blow of the pile-hammer and rebound at once; or if the reaction is viewed as the displacement and flow of a plastic material under pressure the result in either case is movement upward or in the direction of the least resistance. This is known as "heave", and is less in soils containing larger proportions of sand or water. If the soil happens to be sand, the surface is more likely to subside than to heave. If the sub-soils are alternate beds of clay and sand, both heaving and subsidence may occur. No definite rules can be stated, but it is possible, from the examples that follow, to trace some similarity in the reactions of soils.

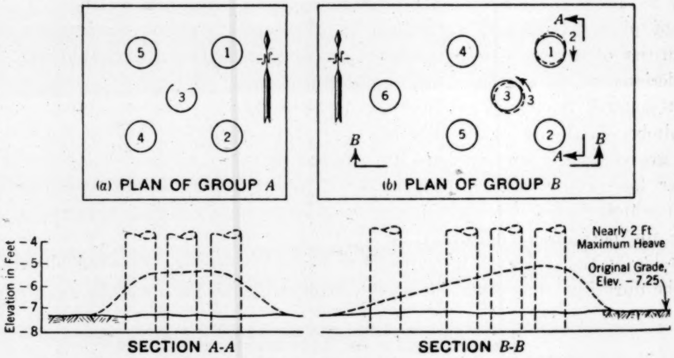

FIG. 1.—ARRANGEMENT OF PILES AND ORDER OF DIVISION.

Example 1.—During the spring of 1932, some interesting pile tests were made on the site of one of the larger Government Buildings in Washington, D. C. (3)[2] Two groups of piles were driven: Group A, of five piles, having an average length of 20 ft; and Group B, of six piles, having an average length of 13.6 ft. The piles in each group were spaced at 2.5-ft centers, and the two groups were separated by about 200 ft. All the piles were of straight shaft, uncased, compressed concrete, with a diameter of 15 in., and all but one (see Fig. 1, Pile 6, Group B), had a bulb or pedestal at the bottom.

---

[2] The numerals in parentheses denote references to the Bibliography in the Appendix; thus: (2(*e*)) refers to Item No. 2, November, 1933, p. 1461.

From Table 2 it is evident that the soil had consolidated around the piles of Group A as the driving progressed, and the piles, therefore, had to be shortened. The ground was thrown vertically upward during the early part of the penetration of each pile; and yet, the maximum heave was only 0.5 ft. Fig. 2(*a*) shows that the strata penetrated consisted of a mixture of permeable and impermeable materials, the reactions of which were slightly on the side of the impermeable materials. Table 2(*b*) shows that, in Group B, the soil had not tightened up sufficiently to cause shortening of the piles as the driving progressed. The heave amounted to a maximum of 2 ft, equal to approximately 70% of the displacement of the piles in the clay and silt. It is evident, therefore, that the soil around Group B was of the clayish order (see Fig. 2(*b*)), as shown by its heaving reaction and small amount of consolidation. It is also evident that the soft concrete of the closely driven piles was more likely to become distorted in this group. This proved true; when the piles of Group B were excavated to the gravel stratum, 1 ft above final penetration, Piles Nos. 3, 4, and 5 had a tendency toward a

smaller sectional area in the clay just above the gravel and a slight lateral deflection, in the direction of least resistance, outward and away from the most highly compressed soil.

Example 2.—On the construction of the Union Terminal, at Cincinnati, Ohio, a large proportion of the pile foundations were in clays and combinations of clays, in which the heave at times amounted to as much as 3 ft. Many of the footings were supported by encased, cast-in-place, concrete piles, placed by driving a pipe or casing containing a core. On withdrawing the core, a corrugated iron pipe was placed in the casing and filled with concrete, after which the outer casing was withdrawn, leaving an annular space of 1 in. around the corrugated iron pipe. On one occasion the corrugated iron pipe was ordered removed after the casing had been withdrawn. Due to unavoidable delay, the orders were not followed until a few hours when it was found that the clay had gripped the corrugated iron pipe so tightly that it could not be removed without destroying it, illustrating perhaps the rebound of elastic material when the pressure is removed. For the same purpose Example 3 is given.

Example 3.—At Potomac Park, Washington, D. C., three test piles were driven in 1934. One was a composite pile with a steel-encased concrete action section, 16 ft long, and a lower wooden section, 30 ft long. The second, driven 15 ft away, was a steel-encased, cast-in-place, concrete pile, 53 feet long, and similar to those mentioned in Example 2. The third test pile was a standard, wooden, peeled pile, 52 ft long. They were each driven through 10 ft of hydraulic fill, 30 ft of Potomac River mud, and then, at 2 in. per blow for 3 ft and 1 in. per blow for 1 ft, tightening up to four blows per inch through the next 5 ft.

The steel-encased, concrete pile had been provided with a steel center bar, 1 in. square, so that the pile could be subjected to an upward pull. On removing the casing, the usual 1-in. annular space was left. Static load tests were made on the three piles, so that several days elapsed before a pull test could be undertaken. Hydraulic jacks were used in pulling, which applied an upward pull of 47 500 lb upon the 1-in. center bar before it parted. Deducting the weight of the pile, a net pull of 40 000 ft had been applied, which was equivalent to a frictional resistance of at least 243 lb per sq ft, giving an indication of the grip upon return of a very plastic soil.

Clayish or fine-grained soils usually heave in some degree during driving, depending upon the water content and mixture with other soils. After rest they regrip the pile with added resistances, at times amounting to as much as 2.5 times in 12 hr, and even 4 times in 24 hr. Whether the cause is attributed to the rebound of an elastic soil against the pile or to the readjustment of the internal structure of the soil after remoulding is not as important as the facts themselves. Either explanation may be true at different times.

Reactions of More Pervious Soils

The addition of sand or coarse-grained mud to soil combinations changes the results in a surprising fashion. Charles Terzaghi, M. Am. Soc. C. E., refers (1(*b*)) to the driving of piles in fine-grained saturated sand, and notes that the surface of the sand subsided 1 ft due to the driving. Victor A. Endersby M. Am. Soc. C. E. (1(*c*)) describes the driving of piles in sand to satisfactory resistance on one of his projects. The piles were allowed to rest until the following day. When driving was resumed, it was discovered that they had lost 40% of their bearing power.

Example 4.—During the construction of the extension of Concrete Pier No. 314, Navy Yard, Charleston, S. C., under the supervision of the United States Bureau of Yards and Docks (5*a*), a number of 18-in., square, wooden, test piles were driven through 10 ft of silt and into stiff blue mud, apparently quite coarse-grained. At from 43 ft to 57 ft the test piles developed a resistance to driving of 40 tons, soon thereafter "fetching up" at virtual refusal. After a rest of from 3 hr to 2 days, driving was resumed, showing a marked decrease in resistance. The decreases in specific cases were from 43 to 21 tons, 45 to 32 tons, 47 to 39 tons, and 39 tons to 25 tons.

Example 5.—The following, to much the same purpose, is reported by Lieut. J. N. Laycock, U. S. Corps of Engineers (4*b*): Four timber test piles 18 in. square and 80 ft long, were driven at Balboa, Canal Zone, through soft silt to − 28 ft to − 43 ft; then through fairly compact and uniform blue clay, the blue clay extending well below the pile-points. With each of the four test piles, driving was suspended several times, the delays varying from a few minutes to overnight, and in every case of suspended driving, there occurred a loss of resistance. These losses varied from 3 000 lb for Pile No. 1, for a 15-min delay, to 48 000 lb out of 90 000 lb for Pile No. 4 for an overnight delay. Such losses follow so closely those of the test piles driven at the Charleston Navy Yard that both soil combinations must have been very coarse-grained, comparing in reaction to a saturated sponge placed suddenly under compression.

Example 6.—At the Naval Supply Depot, United States Naval Operating Base, San Diego, Calif. (5*b*), a number of concrete and wooden test piles were driven through 7 ft of soft plastic mud, carrying a small quantity of sand and shells. Beneath the mud lay strata of sandy clay and sand. A wooden test pile, 20 in. by 20 in. square, was driven to virtual refusal. The pile was allowed to rest 24 hr and driving was resumed. In the first few inches of re-driving there was a decrease in resistance, but the pile was again driven to refusal, after the driving had progressed 1 ft. It should be noted that Examples 4 and 5 refer to coarse-grained muds or more permeable materials. Example 6 refers to permeable sand and shells and impermeable mud, in which sufficient sand was present for the combination to act in a similar manner but in a lesser degree.

During the same tests at San Diego, an 18-in., precast, concrete pile was pulled, and brought up a natural shoe of compacted material on the point of the pile. The report states (5*b*) that "it consisted apparently of samples of the various materials through which the pile had passed, and was as hard as, and had the appearance of, soft rock." This phenomenon is not uncommon, as it has been noted many times in the driving and pulling of test piles in sand and shells. The possible explanation is that a permeable saturated soil such as sand under pressure, loses its water content rapidly, and is consolidated quickly. Piles in saturated sand will drive to virtual refusal, quickly forcing out the water in the sand immediately surrounding the pile-points and forming a bulb of solid material. The water in the sand surrounding the consolidated bulb having a means of ready escape, the pressure will be quickly dissipated during rest. Following rest, the pile and its sand bulb having no longer high pressure to work against, will drive with lessened resistance. Continued driving, however, accompanied by further consolidation, at length, brings the piles to final refusal.

Example 7.—Resort has been had to the artificial consolidation of soils for the support of structures since the dawn of history. The Egyptian sand pile has been, and still is, used successfully for this purpose in many parts of the world. This pile consists in driving a hole in the ground, filling it with sand, and tamping the sand to refusal. This process provides a satisfactory foundation, provided the soil can be consolidated. For example, into the sub-soils beneath the Federal Legislative Palace, in the City of Mexico, Mexico (6), consisting of an extremely unreliable mixture of volcanic ejections and alluvial matter, were driven 150 000 sand piles, 8 in. in diameter on 20-in. centers. The displacement of the piles could have caused a heave of 5 ft, if no consolidation had occurred. As the heave averaged only 1 ft, however, consolidation in the amount of four-fifths of the displacement had taken place. However, when water cannot quickly be lost from fine-grained impermeable soils under quickly applied pressure, very little if any consolidation occurs. Increase in soil pressures, due to the driving of piles, may be temporary, whereas consolidation of the soil is of permanent value in increasing bearing power. It must be obvious, therefore, that the driving of piles in moist to wet soils that cannot be consolidated for a long time leads to uncertain results.

Skin Friction

Perhaps no factor in the design of pile foundations has been as fruitful of foundation troubles as skin-friction values and their relation to the problem. Offering no ready-made solution or convenient tabulation that will apply to all conditions, the attempt will be made to indicate by illustration the wide range of values that may be secured and the reasons why the assumptions are of such small use.

In the absence of better information, engineers have been forced to use the best data available. The friction between pile and soil has often been computed from the results of static load tests, deducting assumed point resistances with no allowance made for temporary soil pressures.

Much better than the average of published data are the values shown in Table 3. It can be seen that: Either the soil terms are not clear; the point-resistance deductions may have been in error; temporary soil pressures may have affected the result; or, perhaps, the surfaces of the piles themselves have been important factors; for example, compare Items Nos. 1 and 2 of Table 3, both of which are for soft blue clay.

Example 8.—Exhaustive tests were conducted by the Whangpoo Conservancy Board during the Shanghai Harbor investigation in China, in 1920–1921 (8). The friction value (in pounds per square foot) of blue clay at that time was reported variously, as follows:

Timber pile, 10 in. by 30 ft	340
Timber pile, 20 ft long	360
Round Douglas fir pile, 45 ft long	650
Rough-surfaced concrete pedestal pile, 33 ft long	650

The report also indicates a slight decrease in skin friction for the longer piles and an increase of 10% in friction values during the subsequent twelve months.

TABLE 3.—VALUES OF SKIN FRICTION

Item No.	Soil	Friction value, in pounds per square foot	Point resistance deducted	Location
1	Stiff blue clay	1 850	No	Hull. England
2	Soft blue clay	740	Yes	Portland. Me.
3	Soft muddy clay	370	Yes	Tunis, Algeria
4	Mud. sand, and clay	370	Yes	Proctorville, La.
5	Soft clay	295	No	Rhine Valley, Germany
6	Soft mud	130	No	Rhine Valley, Germany
7	Mud	130	Yes	17th Street and North River, New York, N. Y.
8	Silty microscopic sand	130 to 900	No	Shanghai. China
9	Fluid mud	95	Yes *	Aguis Creek, Va.

* 15 per cent.

Example 9.—In 1933, in connection with the Sewerage and Sewage Disposal Plant program in Columbus, Ohio (*9a*), it was decided to drive precast concrete piles and to test for uplift. Eight piles, 15 ft and 20 ft long, were driven through loam, clay, sand, and gravel. Ground-water level was quite near the surface. The eight piles were pulled with the following results:

Piles	Depth below the ground, in feet	Frictional resistance, in pounds per square foot
1	11	538
2, 3, and 4	14	557
5, 6, 7, and 8	19	613
Average of eight piles	16	582

Evidently, the skin friction had been increased with depth in contrast to the results reported by the Whangpoo Conservancy Board (see Example 8).

Example 10.—Pull tests were also made for the Water Supply and Filtration Plant, at Fort Wayne, Ind. (*4c*), 4 600 conical concrete piles, averaging 16.8 ft in length being driven through dark yellow clay, fine sand, and coarse sand. Later, five piles were subjected to pull tests with hydraulic jacks. The friction value developed by these pull tests, averaged 755 lb per sq ft for steel on clay, fine sand, and coarse sand.

Example 11.—The sinking of caissons in the underpinning of the Naval Aircraft Building, at the League Island Navy Yard, Philadelphia, Pa., also developed data contrary to that furnished by the tests at Shanghai as to the relation of friction values to length of piles. Records were kept by the U. S. Bureau of Yards and Docks of the pressures necessary to move the caissons at various depths. The caissons penetrated silt and sand to gravel and cobble at 50 ft to 60 ft. Making allowance for the upward pressure of the air, it was found that the pressure necessary to move the caissons plotted in nearly a straight line for the upper depths and then tended to a flattened parabola for the lower depths. The friction values increased from 100 lb per sq ft at a 15-ft depth to 305 lb per sq ft at a 60-ft depth.

Example 12.—To illustrate the relative skin-friction values of rough and smooth pile surfaces, it may be interesting to compare the results of the load test on Pile No. 6 of Group B, Example 1, with those made on the precast concrete piles that ultimately became a part of the building foundation. The precast piles were $13\frac{3}{4}$ in. in diameter and cylindrical in shape. Eleven of them scattered in the vicinity of Group B were test loaded. These precast piles (of 12.6-ft average length, for a settlement of $\frac{5}{64}$ in.) were supporting loads averaging 31 tons. An exact comparison cannot be made with the settlements of $\frac{3}{32}$ in. used in connection with the piles in Group B. However, $\frac{5}{64}$ in. is close enough for reasonable comparison. Since the point-bearing area of the precast pile was approximately equal to that of the bulbless Pile No. 6, Group B, it would appear that the friction values of the precast piles were equal to $\frac{81}{50}$ times that of the rough-surfaced bulbless pile in the same soil.

For the same purpose it should be added that a part of the Potomac Park tests (Example 3) consisted in test loading both the wood pile and the corrugated encased concrete pile described. The wood pile failed at a test load of 32 tons whereas the concrete pile stood successfully a test load of 45 tons, indicating that the surface and perhaps the shape of the pile are important factors.

Summary.—Skin friction cannot be assumed as a factor that in itself supports a structure, but rather as the means of spreading the load to the strata below the pile-points. Knowledge of friction values, therefore, is of use in determining the bearing value of the pile and surrounding soil and whether or not the soil below the pile-points is overloaded due to concentration.

Friction values may be affected by variation in the soils, combinations of several soils, variation in water content, the length and surface of the pile, and the time that has elapsed since driving. It must be evident, therefore, that any tabulation of friction values that is intended to cover all possible conditions must be accepted with reservations. Dependable results can be secured by the driving of test piles of the type selected and by pull testing, at a lapse of time. This delay will be discussed herein under the heading, "Load-Carrying Capacity and Static Load Tests." The results are equally valuable when, as occasionally happens, the shearing strength of the soil, and not the pile surface, is the vital factor because if the former is the case the pile surface must be sufficiently rough. If the pile surface is the vital factor a pile with a rougher surface can be selected.

LOAD-CARRYING CAPACITY AND STATIC LOAD TESTS

There appears to be general agreement that the dynamic pile-driving formulas give only approximations of the carrying capacities of piles under static loads when driven in fine-grained impervious soils, but that the formulas are reasonably accurate when the piles are driven in sand or other pervious soils. As to the dependence generally placed upon the results of static load tests upon single piles, the results thus obtained are unreliable indications of what may be expected of the group or mat, of which the single pile forms a part. This applies, however, only to piles driven on close centers or in fine-grained impervious clayish soils. To illustrate how static load tests on single piles may mislead the engineer, a few examples will suffice.

Example 13.—The piles described as Group A in Example 1, were subjected to a final static load test of 250 tons, and Pile No. 5, of Group B, was loaded to 70 tons (see Fig. 1). Group A was loaded to 125 tons for 24 hr. The load was then increased to 250 tons, and allowed to remain for 5 days. The settlement was $\frac{5}{32}$ in. Pile No. 5, Group B, was test loaded to 25 tons for 24 hr, to 50 tons for another 24 hr, to 62 tons for 36 hr, and to 70 tons for 24 hr, with a total settlement of $\frac{1}{8}$ in. (see Fig 3). At a settlement of $\frac{5}{32}$ in., the piles of Group A were carrying an average of 38 tons each, and Pile No. 5, Group B, was carrying 62 tons.

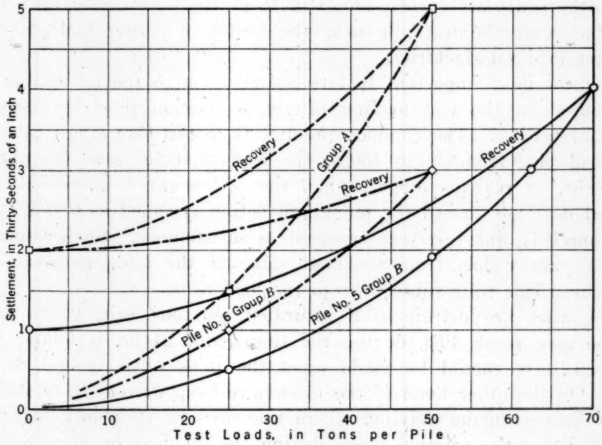

FIG. 3.—COMPARATIVE LOAD-SETTLEMENT CURVES; TESTS OF PILES SHOWN ON FIG. 1.

Comparative static load tests between single piles and groups of piles are very rare, due to the expense of making the tests and the speed usually demanded. In the absence of additional test results, the engineer must use the best information available bearing on the subject.

Example 14.—In 1918 and 1919, concrete piles to the number of 411, averaging 17.7 ft in length, of the compressed concrete pedestal type, were driven for an industrial building of the Texas Oil Company, at Providence, R. I. There are no records of the borings taken. The driving record indicates that the piles should develop, according to the *Engineering News* formula, from 41 tons to 83 tons, the average being 53 tons each. The structure was designed for a final loading on the piles of 30 tons each. Static load tests of 45 tons were applied for 24 hr on one pile of a group and on an isolated pile. The test results showed practically no settlement. There seems to have been no trouble with the piles themselves, but check levels taken on the completed structure since 1925 showed a settlement of from 1.75 in. to 3.75 in.

Example 15.—For the grain elevator at Portland, Ore. (4*d*), fourteen wooden test piles were driven, well distributed over the construction area. These test piles as well as the permanent wooden piles were driven to a resistance of 25 tons (as determined by the *Engineering News* formula) through soil of considerably fluidity, to — 41 ft, the elevation of the pile-points. One test pile at the southeast corner of the Storage Annex was satisfactorily load-tested to 40 tons. The foundation consisted of a 3-ft concrete mat cast upon the wooden piles, which were spaced 2.5 ft center to center. During construction, marked settlement was noted, and when the load per pile, under the Storage Annex, had reached 9 tons, the building had settled 1.96 ft at the northeast corner, 0.76 ft at the southwest corner, 1.4 ft at the southeast corner, and 1.72 ft at the northeast corner, in spite of the fact that the test pile near the southeast corner had supported a 40-ton test load satisfactorily.

One of the most important factors contributing to the misleading results often secured in the test loading of single friction piles is disregard of the time of testing. The common practice is to test-load single piles to the design load plus from 50 to 100%, the loads resting upon the piles from 24 to 48 hr, or perhaps longer, when the settlement is measured. If the settlement does not exceed the maximum (often specified as 0.01 in. per ton of load applied), the tests are accepted as satisfactory. Such results, however, may vary widely from the final value of the piles, as great changes often occur in the soils subsequent to the load tests.

If the piles are driven in a saturated pervious soil, where losses in resistance may reach 40% during the subsequent 24 hr, it follows that no static load tests should be made upon the piles until several days have elapsed. On the other hand if the piles have been driven in an impervious soil that heaves during driving, where increases in resistance may amount to several times the original value during the 30 days or more that follow driving, it seems useless to make static load tests upon the pile during that time. The problem, however, is not quite as simple as the foregoing implies, because piles often penetrate several types of soils, in which both "heave" and consolidation may occur. As boring data are not always sufficiently accurate guides, it would seem best when there is uncertainty to consider the soils as impervious and to test-load accordingly. In addition, if the test loading of single piles were replaced by a group test loading, beneficial results would follow.

SPACING FOR FRICTION PILES

The correct spacing of piles is of importance for two reasons: (1) For cast-in-place concrete piles too close spacing in some soils is likely to cause distortion in the partly set concrete of contiguous piles if the driving is carried in rows continuously; and (2) for friction piles the correct spacing of a group or mat allows for the maximum load-carrying capacity of each pile. Under such conditions the pile and the surrounding soil are acting as a unit.

Numerous examples could be given of the distortion of cast-in-place concrete piles driven in different soils and with different spacing, if the information would be of any value. There appears to be no basis, however, for the derivation of formulas to cover the proper spacing of piles in relation to length, diameter, and soil conditions, in order to prevent distortion. However the simple device of driving alternate rows and reforming over the same ground to complete the unfinished rows is successful in preventing distortion and cracking if sufficient time has elapsed.

Reference has been made herein to the work of the Whangpoo Conservancy Board (8) in soil investigation and pile tests. Mr. H. F. Meyer, commenting on the Shanghai findings states (9):

> "As soon as two piles are so near each other that the two volumes of influence cut into each other, the question becomes more complicated. The size of the affected prism of soil is so large that, in all ordinary cases under a footing or a foundation, they will overlap. The soil will thus be under greater pressure than when only a single pile is involved, the angle of friction will be smaller and the skin friction of the piles will decrease. By spacing the piles nearer than the spacing as given by the formula (developed by the Whangpoo Conservancy Board) no additional safety against settlement is gained, and the builder who has carefully test loaded every single pile and found that they would sink only ¼ inch for a load of 400 lb per square foot skin friction on their surface, will, to his astonishment, observe that his whole densely piled building settled more than a foot when completed, in spite of the fact that the piles are not nearly loaded up to their 'full capacity'. The distance from center to center of the friction piles driven next to each other, should never be less than half the circumference of one pile, if the whole friction area is to be utilized; the two piles, taken as one unit, will then present the same friction surface as would each of the two piles individually added together. If there are more than two piles, the circumference of the whole cluster of piles, should be bigger than or equal to the sum of the circumference of the individual piles in the cluster. The same should apply to any part of a cluster. Thus, in case of a rectangular foundation with equal distances between piles, and all piles square, and of the same size with sides 12″, the length of the entire foundation being 'A' and the width of same 'B', the distance 'Z' between piles will thus become: A and $B = 10'$; $Z = 4.5'$: A and $B = 100'$; $Z = 11.1'$; $A = 100'$; $B = 40'$; $Z = 8.7'$."

Such spacing is apparently intended for use only in the plastic clay to be found in Shanghai. Even in that soil, it appears to be sketchy indeed to engineers in the United States. On the other hand, the average spacing for friction piles used in the United States as discussed under the heading, "Average Practice", would appear to be the other extreme.

The transmittal of the load in part through friction tends to spread it upon the sub-soil and, therefore, has an important relation to pile-spacing and bearing power. If the spacing of the piles is such that the distribution of the load through skin friction to the sub-soil is uniform, the result is a "block load", and the piles and the soil surrounding them are acting as a unit. Obviously, the pile which (through side thrust or the roughness of the surface) transmits the largest percentage of the load to the surrounding sub-soil, will develop the least concentration of load under the point. Such piles, therefore, may be over-spaced and still act as a unit with the soil.

If the characteristics of the different soil strata that lie beneath the site are known, Boussinesq's analysis can be used with variations for the determination of the distribution of pressures to the sub-soils. Having solved for the pressure distribution on the crucial stratum, the proper spacing of the piles can be computed for uniform distribution of pressure. Although this practice would be a great improvement over some of the "hit-or-miss" methods, it is believed that in the hands of the inexperienced foundation engineer an actual test by means of driven and test-loaded groups of piles would be a more reliable method for securing this information.

Any group test intended for use in effecting uniform settlement in a pile foundation must cover such different conditions as changes of soil on the site and the difference in size and shape of the pile foundations.

Whether one or more group tests are made, the first step is a thorough exploration of the sub-soils by the use of core borings. From this information approximate pile lengths and the type of pile to be used can be selected. A test group can then be driven on centers preferably of two pile diameters and arranged so that the same loading platform can be used for the test loading of piles on centers of two diameters, four diameters, and for single piles.

To allow for the readjustment of the internal structure of the soil, the piles should rest after driving from a few to thirty days, depending upon the character of the soil. If, after the rest period, a single pile is test-loaded by increments, followed by the test load of the piles on four diameters and, finally, by the test loading of the piles on two diameters with the settlements recorded as the increments of load are applied, data may be had that will indicate the carrying capacities of the piles of a mat, the diameters, and the spacing for an assumed settlement.

The fact that so many foundation settlements are dish-shaped indicates that the spacing between the piles toward the perimeter may be farther apart than the spacing toward the center of the structure. Without doubt an answer will be found to this part of the problem similar to that used in the design of the foundations (6) for the Federal Legislative Palace, in the City of Mexico (Example 7), in which Boussinesq's suggestions were followed in the plotting of an ellipse, the ordinates of which represent soil pressures at any given point.

Experience indicates that the expense of preliminary work for the analysis of soils, pile types, and economical spacing, will usually effect a sufficient saving in the first and later costs, to more than justify the expense. This is particularly true of large foundation projects. It should be added, furthermore, that by using satisfactory load tests, the dynamic pile-driving formulas can be useful in selecting pile lengths and in comparing varying soil conditions. They need no longer be the "yardstick" for measuring bearing capacities, upon which so much has always depended.

SOME PILE FOUNDATION SETTLEMENTS AND THE CAUSES

The intention in selecting examples of settlement of structures on pile foundations has been to present the case fairly from available records. It must be freely admitted, however, that all foundation settlements are not due to the use of friction piles in plastic soils, as might be inferred from the following examples.

End bearing piles driven to hard sub-strata act as columns and may be limited only to the bearing capacity of the sub-strata and the pile itself. However, at times the weakest link may be the column, because some of the piles may be over-driven, or cast-in-plate concrete piles may, at times, be deformed or even pinched off. Local settlement on a pile or cluster may occur, but the records of such settlement are difficult to secure. Besides, injury to piles in placing is usually due to poor planning and supervision and is avoidable.

The following statement would appear to be a fair interpretation of the fundamental thought of the publications of Edmund A. Prentis and Lazarus White, Members, Am. Soc. C. E. (11): "It would seem elementary to state that each horizontal stratum has to support the total load above, including the overlying strata and the structures erected thereon." In the case of a pile foundation it is equally true that the soil strata below the pile-points must support the loads placed upon them, or settlement, and possibly failure, will follow. This principle is so fundamental and so clearly sensible that even the layman should be able to understand it. It would appear from the examples that follow, however, that this simple axiom is not generally recognized.

Most of the foundation settlements that will be described, fall into one main group, the causes and conditions of which are nearly identical. Perhaps the most common has followed the making of new land by filling in an old lake, swamp, or slough with a very soft bottom. Often the conditions that existed before filling, have been completely forgotten. When, years afterward, it is proposed to erect a structure upon the filled land, exploratory borings may or may not be taken. If piles are decided upon and are not driven through the compressible stratum at the bottom, or if spread-footings are used, settlement often results corresponding to the depth and compressibility of the soft stratum below the points of application of the loads. Later, when a complete survey of sub-surface conditions is made, the cause of the trouble is only too apparent. With this in mind, note the recurrence time after time of compressible sub-soils and particularly peat in the following examples.

Example 16.—For a great steel structure built not so many years ago, a creosoted timber bulkhead was driven in a bay. An hydraulic dredge filled the area contained within the bulkhead with sand to a depth of approximately 20 ft. About 500 ft away, a structure somewhat similar to the one proposed had been in operation for a number of years, and no appreciable settlement had occurred. Apparently, soil conditions on the site of the proposed structure were identical with those of the older structure and, therefore, no preliminary soil explorations were made. As a part of the inshore foundations, pedestal footings were planned, each to rest on twenty-one wooden piles, 40 ft long, carrying 15 tons each. These piles were to be driven into the hydraulic sand fill mentioned.

The pile-driving began, and apparently satisfactory results were being secured, as measured by the *Engineering News* formula. The engineer in charge, however, felt something to be wrong and increased the number of piles and the lengths from 40 to 45 ft, then to 50 ft, and, finally, to 60 ft. The concrete for the pedestal foundations was poured, and shortly before the time for erecting the steel upon the pedestals, the tops were checked for elevation. It was seen at once that instead of bush-hammering, some of the pedestal tops were an inch or more below elevation, indicating settlement. Upon rechecking, it was found that during the following weeks, the same pedestals, even without load, had continued to settle at an alarming rate.

Test borings were taken, the results of which will be seen in Fig. 4. The cause of the trouble was obvious at once. The heavy sand fill had been placed upon sand, underlaid by very compressible soils. The piles were driven through the sand fill and the original sand, and developed the required resistance. However, inasmuch as the piles did not penetrate through the compressible soils and into the substantial strata beneath them, the added weight of the new fill caused settlement and the piles, of course, settled with the fill.

The steel superstructure was erected, although the pedestals continued to settle, compensation being made by means of driving steel wedges and placing plates under the column shoes. The settlements of the several foundations will be seen by referring to Fig. 5. However, after some months devoted to a close study of the problem, it became evident that the increments of settlement were decreasing and that, without corrective measures, settlement would finally cease.

If the plotting of the soil strata (Fig. 4) can be assumed as correct between the points at which test borings were taken, and if the settlement is assumed to be proportional to the thickness and compressibility of the strata beneath the pile-points, very little, if any, settlement might be anticipated in Foundations *S*5, *S*10, *S*11, *N*5, and *N*11. By the same reasoning the maximum settlement might be predicted in Foundation *N*10, diminishing in the following order: *S*7, *S*6, *N*9, *S*8, *S*9, *N*7, *N*6, and *N*8, which is very close to what occurred.

It should be added that any type of pile that did not reach the stratum described as "sandy marl", under the compressible peat, sand and peat, sand and mud, etc., would have proved as ineffective as did the wooden piles. Had the test borings been taken before construction, longer wooden piles would

have been used at an additional cost that would have been small compared to the several millions of dollars spent on the project.

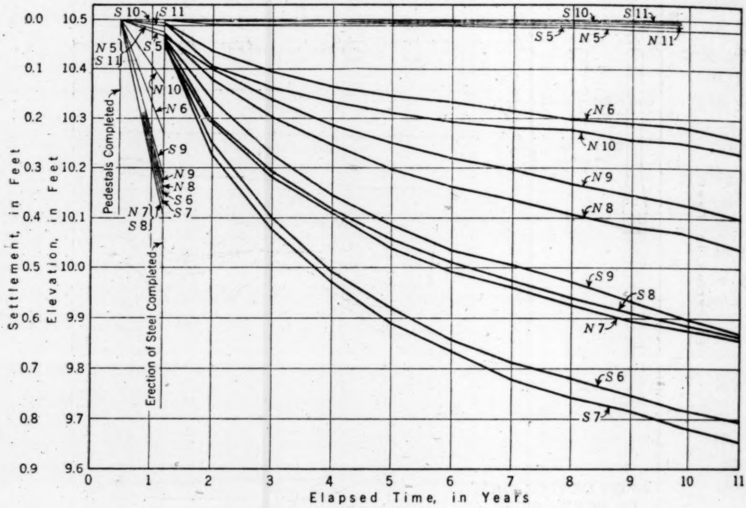

FIG. 5.—SETTLEMENT HISTORY, EXAMPLE 18.

Example 17.—During the rush construction period of 1917, an 11-story concrete warehouse was erected in the Brooklyn, N. Y., Navy Yard (5*c*). Due to the speed demanded, there was no time for sub-surface exploration. Piles were driven for the foundation from 10 ft to 34 ft in length into a fill over an old marsh. During the erection of the building, serious settlement occurred, which continued after completion. Subsequent investigation showed a stratum of peat 1 ft to 7 ft in thickness, at a depth of 30 ft to 40 ft below the surface, subjected to a load of approximately 35 lb per sq in. Tests on sample cubes of the peat gave a compression of 35% for this load. As such a condition is obviously disastrous, a part of the foundation was underpinned with steel pipe piles, filled with concrete. It is scarcely necessary to emphasize that had the times been normal, test borings would have been taken before construction, and piles would have been selected of sufficient length to reach good bearing below the compressible peat.

Example 18.—The original borings for the 12-story building of the Westinghouse Company, in Philadelphia, Pa. (4*e*) showed 8 ft to 10 ft of fill underlaid by uniform clay and sand to rock at 45 ft. Conical concrete piles, 25 to 30 ft long, were driven. Before the building was completed, settlement was noted. Investigation then disclosed that the soils were composed of 27 ft of loose fill, 4 ft of peat, 1 ft of gravel, 15 ft of silted peat, 8 ft of silt, and 2 ft of sand and gravel on hard mica schist. However, the strata were not uniform in thickness and the compressible peat lay mostly under the east side of the building, where 4 in. of settlement occurred. The west side of the building did not settle, again demonstrating that the thickness of the compressible sub-soils corresponds to the settlement. There appears to be but one answer to such a problem—underpinning. It appears certain, however, that if dependable test borings had been taken before construction, and the piles driven to the same bearing reached by the underpinning, no settlement would have occurred, and considerable money would have been saved.

Example 19.—At the League Island Navy Yard, in Philadelphia (5*d*), during the rush of the World War, two projects were constructed on concrete piles under fairly similar conditions as to soil. In one case, conical, cast-in-place concrete piles were used, and, in the other, the straight shaft, compressed, uncased, cast-in-place concrete pile with a bulb at the bottom. This Navy Yard is situated at the west end of the Horse Shoe Bend of the Delaware River. The eastern part of the reservation has been built up by an alluvial deposit of river silt and organic matter overlying an earlier deposit of coarse sand, gravel, and cobble. The sub-soil formations under the two structures, a concrete storehouse and a 175-ft chimney for the Naval Aircraft Factory, are described as follows: For the storehouse six borings showed silt to a depth from 35 ft to 55 ft below mean low water. Sand and gravel were found under the silt, sloping from a high point at the northwest corner of the building to the low point at the southeast corner (see Fig. 6(*a*)). For the stack, the sub-soils correspond roughly, except that the compressible silt is deeper under the stack than under the storehouse.

(*a*) CONTOURS OF TOTAL SETTLEMENT, TO FEB. 1922 (CONTOUR INTERVAL, 0.1 FT)

(*b*) CAISSON IDENTIFICATION AND ANTICIPATED BOTTOM CONTOURS

FIG. 6.—AIRCRAFT STOREHOUSE, U. S. NAVY YARD, PHILADELPHIA, PA.

The storehouse is a six-story concrete building, divided into ten bays, east and west, and nine bays north and south. Under the column footings, cast-in-place conical concrete piles, 30 ft long, were driven, designed to carry 30 tons each. In driving these piles, only a small number were driven to a resistance corresponding to that required by the design. It was discovered, however, that the resistance increased considerably after rest, and as this factor has been the salvation of many projects under apparently similar conditions, construction was continued.

In June, 1918, load tests on one pier, equivalent to that required by the design, were made. The pier settled 3 in. in 45 days, but the increments of settlement decreased rapidly after the first week. Check levels were taken weekly on all the columns during construction, which showed decreasing increments of settlement, even though the column loads were increasing as construction progressed.

Several months after completion, settlement cracks appeared in each floor. In January, 1919, the total settlement varied from 6 in. to 16 in., corresponding to the depth of the compressible silt below the pile-points, modified by the characteristic cup-shaped settlement. Note the similarity of the contours of Fig. 6(*a*) relating to settlement and Fig. 6(*b*) referring to depth of compressible material.

The storehouse was subsequently underpinned successfully, but, of course, at considerable cost. Had war conditions not existed, and had there been an ample supply, wooden piles of sufficient length to reach into the sand and gravel undoubtedly would have been used.

Example 20.—During the same period the 175-ft chimney was constructed. The foundation rested upon 64 cast-in-place, uncased concrete piles, 36 ft long, with a bulb at the bottom. The penetration of the piles during driving was steady, and the resistances, according to the *Engineering News* formula, indicated an average safe load of 130 tons.

The foundation of the chimney was built in 1918. In October, 1919, settlement was detected through the leaning of the chimney toward the power house on the north. The angle of leaning was reported as 9 on 1. Records of the increments of settlement showed that they were decreasing and that the movement would cease in time, if the structure were left alone. However, corrective measures were undertaken, consisting of the construction of a concrete ring foundation on 71 wooden piles, designed to carry 15 tons each, but driven to solid bottom through the compressible silt.

Example 21.—The settlement of the new Navy Building, at Washington, D. C. (5*e*) is another example of the use of piles too short to reach a substratum of sufficient bearing power to carry the loads. Conical concrete piles were driven through a recent fill over an old marsh. Upon the piles a head-house was constructed 200 ft in length, with rear wings. It settled a maximum of 4 in. The loads on the piles at the face and under the interior piers are reported as conservative, but subsequent analysis showed that where the wings meet the head-house, the piles under the piers were overloaded. The piers did not settle most, however. The greatest settlement occurred in the area of the greatest depth of fill where the settling of the fill itself carried down with it, the piles and the structure.

Example 22.—In 1905 an armory was built in Minneapolis, Minn. (4*f*). The site originally had been swampy ground, reclaimed by filling with sand

and gravel, so that, at the time construction began, the soils from the surface downward consisted of 15 to 20 ft of sand and gravel fill, 6 in. to 41 ft of mud on sand and gravel, with ground-water level at 1.5 ft below the pile cut-offs. Wooden piles 30 to 40 ft long were driven for the building, 189 ft by 218 ft, and some of them passed through the sand and gravel fill and through the mud into the hard sand and gravel sub-stratum. This was the case at the southeast corner. At the northwest corner, however, although the piles were driven through the sand and gravel fill and into the mud stratum, there was perhaps 10 ft or more of mud between the pile-points and the solid sand and gravel. A fairly good picture of sub-soil conditions may be had from the settlements that occurred over a period of several years. The southeast corner settled not at all, the southwest corner, 3 in., the northeast corner, 0.5 in., and the northwest corner, 37.5 in. As such unequal settlements are disastrous, in 1913 the west side of the building was condemned. It is probable that if test borings had been taken before construction began, and some extra money spent for longer piles, nothing would ever have been heard of the settling of the Minneapolis Armory.

Example 23.—The factory buildings of the Jurgens Oil Mill Works between the River Maas and the Dike at Zwyndrecht, Holland, were constructed on made land, consisting of sand fill, hydraulically placed. In 1915, the Jurgens Margarine Company (12) decided to erect on the site an oil mill to contain heavy machinery, tanks, etc. Since it was evident that piles would be necessary, test piles, 20 m (65.6 ft) long, were driven. The piles were driven to a resistance of 30 blows for the last 30 cm (11.8 in.), or theoretically, to a static load equivalent to 50 tons per pile. Inasmuch as the piles were to be loaded to only 5 tons each, there was apparently a factor of safety of 10. Creosoted wooden piles, 20 m (65.6 ft) long were driven. In fact, it appears from the accounts that longer piles could not have been placed under continuous driving, as they crushed at the heads under the driving resistance of 30 blows for the last 30 cm (11.8 in.). The soils through which the piles were driven were saturated and consisted of 4.5 m (14.8 ft) of sand fill, 13 m (42.7 ft) of peat and some clay, and 5 m (16.7 ft) of fine sand on coarse sand and gravel. From this, it may be seen that the pile-points reached into, but did not penetrate, the stratum of fine saturated sand, and fell short of the substantial stratum of coarse sand and gravel. Had the piles been allowed a period of rest and had driving been resumed, it appears probable that longer piles might have been driven farther and into the sand and gravel.

In 1916, the factory was completed, and by 1920 the Oil Hardening Building had settled so badly that collapse was threatened. Near the center, the structure had settled 70 cm (27.6 in.). For most of the building the load per pile did not exceed 3 tons although, under the tower and tank, the loads per pile were as great as 18 tons. The external loading on the piles, however, must have had little to do with the settlement, as the maximum did not occur where the piles carried the heaviest external loads. In fact, the piles under an extension of the floor outside the building, carrying almost no loads, settled in the same manner.

The engineering report contained the statement that the hydraulic sand fill, with its high friction value, was settling into the bed of 17 m (55.8 ft) of compressible peat and clay. By its grip upon the piles the fill was pushing them through the peat of comparatively low friction value, and thrusting the points farther into the bed of 5 m (16.4 ft) of saturated fine sand which was incapable of carrying the loads. The load of the hydraulic sand fill was estimated at 15 tons per pile, which still would have left an ample factor of safety, had the dynamic pile-driving formula been of any value.

CONCLUSION

In the past, the design of pile foundations in plastic soils has, in the main, followed standards that do not take into consideration all of the many factors involved in these complicated problems. Although most of the serious settlements of foundations on piles have taken place in plastic soils even there the results have, in the large majority of cases, been surprisingly successful. At times, however, foundation settlements occur that are very expensive to the owner and are no credit to either the architect or contractor.

Even when the best of core borings have been taken, classification and predictions as to reactions of soils on sight by the average engineer is extremely difficult, if not impossible. Soils into which piles are driven range from those that heave and do not consolidate easily to those that subside and consolidate almost at once. Within this broad range occur mixtures and combinations in infinite variety, the reactions of which are further complicated by variations in the water content. Physical analyses of course, can develop the nature of the soils and the proper classification can be made, from which experience can usually predict the result. For the average or inexperienced foundation engineer, however, a more reliable answer can be had from a combination of core borings and pile-driving and loading tests in the field.

The engineer who depends upon some convenient tabulation of friction values, who expects a static test load upon a single pile multiplied by the number of piles in his foundation to equal the total load-carrying capacity, who relies upon the results of static load tests made too soon after driving, or who places complete dependence upon the *Engineering News* formula under all conditions, may be not a little surprised, at times, at the results.

Standard pile spacing as accepted in the United States is usually too close for the loads applied upon them when the piles are driven in plastic soils. If the proper spacing is used corresponding to the length, size, shape, roughness of the pile surface, load, and the soil characteristics, greater loads can be placed upon the piles with less settlement. Mathematical analyses for pile spacing and the distribution of loads to sub-strata would undoubtedly be an improvement over the usual practices; but group test loadings approximating the conditions of construction and final soil consolidation should prove more dependable. When this is done, the dynamic formulas may be regulated to a position of secondary importance.

Had a sufficient number of borings been taken over the sites, and had the borings been accompanied by clear descriptions of the sub-soils, it is reasonably certain that only a few of the foundation settlements described in this paper would have occurred, since the piles in most cases would have been driven to virtual refusal upon satisfactory sub-strata. However, where the piles have been driven short of sub-strata on the theory that friction piles would support a structure in spite of overloaded compressible strata beneath, it can only be stated that such a saving in first cost is very expensive. If any of the compressible strata are suspected of being peat, or combinations of peat, and the peat bed is of appreciable thickness, disregard of such a warning is to invite disaster.

Reliable core borings should always be made in sufficient number to disclose the nature of the sub-soils beneath the entire site. When it is discovered that that strata upon which the pile-points are to rest are perhaps insufficient to carry the loads to be placed upon them, thorough analyses and pile-driving and loading tests should be made. In a word, convenient tabulations of values or standards should be viewed with distrust, because each pile foundation presents a new problem. No two are exactly alike.

Acknowledgments

For the furnishing of a report of the Whangpoo Conservancy Board, the writer wishes to acknowledge thanks to Dr. Herbert Chatley, Acting Engineer-in-Chief; for data published in Public Works of the Navy and for suggestions, to Captain George A. McKay (C.E.C.), U. S. N., M. Am. Soc. C. E.; and for reports of tests, and of the construction, of projects, to The Western Foundation Company, The Raymond Concrete Pile Company, and The MacArthur Concrete Pile Corporation; and for suggestions and criticisms, to Major H. P. Burrel, of the Western Foundation Company, and to A. E. Cummings, M. Am. Soc. C. E., of the Raymond Concrete Pile Company.

DISCUSSION

Hibbert M. Hill,[3] Assoc. M. Am. Soc. C. E. (by letter).—A very interesting series of examples is presented in this paper and the author's deductions from his study of them are exceptionally clear cut. After reading the paper, however, the writer has an impression that Mr. Miller makes it appear that more weight can be given to pile-driving and loading tests than is actually the case. Such tests are of value for specific purposes (as, for example, to determine whether a pile will develop frictional resistance sufficient to transfer its load to the surrounding soil, or, in the case of piles reaching a hard stratum through soft material, to test the strength of the piles as columns), but in the usual case it is impossible to test load an area comparable in size to the foundation. Therefore, in the usual case, the results of test loadings, in plastic materials especially, cannot be relied upon to indicate directly the settlements to be expected in the finished structure.[4]

The author places great emphasis, and rightly, on a thorough exploration of the underground by borings. It is not a flattering commentary on the state of the art that this point requires emphasis. The writer has had experience involving the design and construction of eight locks and dams on the Upper Mississippi River. These structures were founded on piles in undergrounds containing sand, silt, and clay, complicated in some cases by rock at depths of about 15 ft. Borings by various methods, driven test piles, and loaded piles were used to explore these foundations. The period of construction of the project as a whole was of sufficient length to provide settlement data for comparison with the test results from some of the structures before the final structure was completed. At the termination of this experience, the writer summarized in his notebook what he had learned about foundations. The red letter entry in this notebook is:

> "By far the most important foundation information is a thorough knowledge of the material in the underground to a depth of about twice the width of the foundation; to greater depths if soft beds might exist at those depths. For all explorations use a method which will obtain a whole sample of the material, from ground surface to bottom of boring, and where compressible materials are encountered, obtain undisturbed samples for laboratory shear and consolidation tests."

An expert, it is true, can forecast future behavior quite accurately by inspection of undisturbed samples, but the expert will reserve his opinion until he has the laboratory results before him. Only the inexpert are courageous enough to proceed, where compressible materials are involved, on the basis of inspection of ordinary boring samples.

George P. Stowitts,[5] M. Am. Soc. C. E. (by letter).—This discussion of the behavior of pile foundations in mixed soils, with its wealth of example and data, seems to the writer to make for clarification of certain basic considerations in the design of pile foundations.

---

[3] Supt., St. Anthony Falls Water Power Co., Minneapolis, Minn.

[4] For a discussion of this subject see, "The Science of Foundations," by Charles Terzaghi, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 93 (1929), pp. 288–291

[5] Regional Engr., PWA, New York, N. Y. Mr. Stowitts died March 5, 1938.

In mixed soils, piles must still be primarily point bearing or primarily friction bearing. Where there is within reach an underlying stratum of sufficient bearing capacity, the nature of the superimposed strata becomes relatively unimportant, and the case may be considered as point bearing; it becomes entirely proper to resort to a spacing as close as driving conditions permit. It is then important that the piles be of as nearly a uniform cross-section as possible. Where there is no such underlying stratum within reach, which will carry the load of a normal footing within its own area, the piles must be considered as friction piles. A friction pile is one which depends on the cone of pressure to reduce the unit load at and below its point to a value capable of being supported by the available strata. If these cones of pressure intersect and overlap too much there is a waste corresponding to the overlap. Thus, in the case of friction piles, the spacing is the controlling factor.

Although the spacing called for by the Whangpoo formula (see heading "Spacing for Friction Piles" in the paper) is extreme, none the less it is based on sound logic. Spacings of 2.5 ft or 3.0 ft, perfectly correct with point-bearing piles, must usually be very wasteful when used with friction piles; 3.5 ft to 5.0 ft would represent the most usual practical answer. This will usually call for a larger foundation area; but not always, as the unit value of the piles will be higher and more uniform.

It seems to the writer that Mr. Miller has drawn the wrong conclusion from the dish-shaped settlement (see "Spacing for Friction Piles"). These necessarily reflect an overloading of the underlying sub-stratum; and, consequently, are more affected by the size of the foundation than by the exact number of piles. The interior piles may well be given a fairly generous spacing; crowding in more piles will have no effect one way or the other. Close spacing in the outer ring will often have the further effect of establishing a cleavage plane, so that it becomes difficult to get the full value of the supporting soil outside the pile cluster. Where one of these settlements has occurred it can be ascribed more often to the foundation being too small rather than to its having too few piles.

Where there are many piles under a footing, much can be done to make their value high and uniform by beginning to drive in the center and working out toward the edge. This throws the heaving and compacting outward where one will be relatively harmless, the other helpful. Starting at the edge makes the piles more and more difficult to drive, needlessly increases the trouble with heaving, and decreases the capacity of the piles.

All the foregoing comment involves essentially, a friction-pile problem; such phenomena can scarcely happen where the piles are entirely end bearing. It may be worth noting in this connection that tapered piles, regardless of their material, are at their best as friction piles. In an end-bearing pile, the useful column material (for load carrying as distinguished from driving) cannot be much more than double the lower half. In heaving ground it is important that the pile, as driven, have abundant tensile strength; that is to say, that cast-in-place concrete (one of the best possible materials in compressible soils) is out of place in an incompressible soil.

Much can be done to control heaving by the sequence of the pile-driving. Often there is one side of a foundation where heaving will be relatively harmless. By starting the driving on the side with the greatest resistance (the one against the bank, if there is one), and progressing back and forth over the long rows, the heaving can be mostly thrown away from the driving to where it will make the minimum of trouble. This takes more cribbing, and more moving of the driver, but will often save several times this extra cost.

Loss of bearing capacity after driving often occurs, but so does gain. Along the New Jersey shore, opposite about 50th and 65th Streets in New York City, there is a peat deposit as deep in places as 210 ft; 85-ft wooden pier piles driven with a 3 900-lb drop hammer must be watched closely lest they go below the cut-off. They will often be going down 3.5 in. at the last blow with a 10-ft drop; but the next day these same piles can scarcely be started with the same hammer. These piles are loaded successfully to 15 tons, despite the alarmingly small value given by the *Engineering News* formula. It has seemed to the writer that the nearer one comes to a pure friction pile, the less reliable are the results given by this formula.

GEORGE A. MCKAY,[6] M. AM. SOC. C. E. (by letter).—An important phase of foundation engineering which has received insufficient consideration, is treated in the paper by Mr. Miller. In contrast with the more exact determination of strength of the various parts of the more familiar superstructures, the fixing of the size and character of foundations has too often been a matter of rough approximation based on the limited information available as to the action of somewhat comparable constructions in somewhat comparable soils. If the structure stood, it was evidence of sound judgment, and if it settled, there was generally a self-satisfying excuse as to unknown, unusual, and unforeseeable subsurface conditions which, when investigated, were given but little publicity.

Although improvement in practice has been steady, there is, and there always will be, a long way to go before engineers can approach the confidence with which other better known and more easily studied elements of structural engineering are treated. In dealing not with pile strengths or pile formulas, but with soil behavior under pile loads, this paper marks a step toward focusing attention on this vital but comparatively neglected factor in safe construction.

There was a time, and not so many years ago, when the average engineer, in the course of designing a medium heavy structure on somewhat questionable soil, would cease to worry over possible serious settlement when he decided to use pile footings rather than spread footings. Such a decision, he felt, eliminated the uncertainties as to soil settlements from spread footings under load and rendered the design exact enough to fall safely within the factor of safety used in standard pile formulas, which with easy calculation convert a penetration from a dynamic blow into a static safe bearing value. Following such a decision, the remaining foundation design was easy. The estimated bearing value per pile, divided into the total load, gave the number of piles, and the size, shape, and depth of the foundation followed after consideration of other allied economic and easily analyzed conditions.

---

[6] Capt. (CEC), U. S. Navy (*Retired*), Miami, Fla.

In general, two vital considerations were overlooked, and both fall within the scope of the paper and are illustrated by examples given therein. One was the limit which could be placed on the supporting power of the soil itself to carry the loads passing either from end bearing of the pile-points or from skin friction to the soil surrounding the pile. A false feeling as to the security of pile foundations had gradually developed from observed and published examples applicable to isolated pile behaviors, such as heavy loads supported by pier piles driven on, say, 8-ft to 15-ft spacing in soft mud where such piles safely carried much heavier loads than the standard pile formula indicated would be safe. Engineers knew that piles in the process of being driven were often, in some manner, lubricated, and that, in general, after rest the skin friction increased, and the piles showed higher resistance and increased bearing strength when driving was resumed. They knew that piles received support from end bearing and from skin friction, but they did not know, with certainty, what proportion of resistance arises from each pile, nor what changes in these proportions occur after rest and under load. These changes follow the slow return to equilibrium of the materials displaced by driving and the slow adjustment of increased water content pressures within the contracted voids in the disturbed and loaded areas.

The important point which was not stressed early enough was that it added nothing to the supporting power of a pile foundation to drive additional piles after the area affected had had inserted in it a sufficient number of piles to produce soil settlement from superimposed loads. Numerous examples of settlement trouble can be traced to this cause.

The second point was a lack of appreciation that under certain conditions the soil surrounding a pile from which support was expected, in cases where such soil was compacted or settled from other causes, would re-act through skin friction on the pile and overload it and carry it down. Ordinarily, settlements from this cause are entirely distinct from the superimposed load of the structures which the pile foundations are designed to support. They may be caused by compression and gradual settlement of new fill through which the piles are driven. One serious case arose from the placing of a heavy fill surrounding a concrete stadium which was properly enough designed, with sufficient concrete piles to carry, safely, the calculated loads from the structure, but these piles were unable to carry the added load arising from the settlement of soil compressed by the much greater load from a fill placed outside of, and around, the structure.

Somewhat more difficult to foresee was the settlement of batter piles driven to resist the outward movement of a quay wall constructed in 30 ft of water in a heavily silt-laden tidal stream. In this case the sheet-piles for retaining the fill below and to the rear of the relieving platform were driven 40 ft back of the face of the wall, thus exposing the batter piles under the relieving platform to the accumulation of silt deposits from the stream. Routine and frequent dredging along the face of the wall would leave banks of soft mud under the wall held by the piles against rapid sloughing down into the stream. This added load from skin friction on the batter piles produced settlement of the piles, and instead of resisting the outward movement of the wall they actually assisted in pulling it forward so that years later, after the wall had moved out-board several feet and was being reconstructed for other reasons, excavation showed open joints between the batter-pile heads and caps, with about an inch of drift-pin exposed.

It is by pointing out cases in which current practices are faulty that their limitations can be better visualized and appreciated. More literature along such lines will be helpful. Much light can be thrown on this problem by engineers who are fortunate enough to combine with their work of design and construction other duties of maintenance, alteration, and repair of old structures. The exposure of parts incident to reconstruction provides an opportunity for examination of members subjected to the test of years and often reveals conditions, the study of which demonstrates the accuracy or error of past standard practices. It is the accumulation of such facts which gives an engineer a background of experience leading to safer construction, and inasmuch as specific concrete examples are more easily visualized and remembered than abstract rules, young engineers, by the perusal of such examples, can more quickly gather from the experience of others that knowledge of what to avoid and what limitations must be kept in mind which insures safe and permanent construction.

The examples cited in the paper and the lessons drawn therefrom are useful; they focus attention on the need for such subsurface exploration of soils around and below the piles as the importance of the structure warrants, and also the need for recording permanently such data for future use by others. In the case of less costly constructions where the expense of subsurface exploration is not warranted, they help to accentuate the importance of spreading pile spacings and analyzing possible future physical changes in surrounding conditions so as to avoid excessive or irregular settlements of soil in contact with, or below, the piles, and thereby assist in safe design.

The paper alludes to the possibility, in some cases, of securing savings through reduction in the number of piles where pile-points reach hardpan or rock. In any consideration of such savings careful attention should be given to the advisability of increasing the size of the pile-point in the end bearing and the possibility that such points may have been damaged in driving. It is also of interest in this connection to appreciate that foundation engineers know less than they should of the permissible increase in safe compression unit values and in end-bearing values for piles driven in firm soil where the pile particles are restrained against the lateral expansion and disruption incident to the application of compressive loads. As this side restraint increases with the depth to which the piles penetrate, the safe unit load for compression and the resistance to crushing in wood and concrete must increase materially, depending, of course, on the character of the soil penetrated. Such increases in permissible safe compression are undoubtedly considerable in sandy or firm soil and possibly sufficient where piles have moderate tapers to permit the carrying capacity to be determined by the safe bearing on the fibers at the top of pile. Scientific investigation along this line would probably bring into closer agreement present practices in permissible loads on piles as compared with small caissons sunk to rock or hardpan bearing.

Present practices are conservative as far as piles driven to firm bearing strata are concerned. Not much trouble is encountered on pile foundations in sand or gravel where these materials are confined against possible future lateral movement. It is the compressible silts, mud, clay, and peat strata either below the piles or surrounding them, which should be investigated more thoroughly and studied cautiously.

Following thorough subsurface exploration much can be accomplished in certain soil combinations through the more scientific study of soil reactions and in the placing of piles to take economic advantage, safely, of any favorable factors which may be present. By securing a better distribution of loads to soil through a greater use of batter-piles, by lagging piles to secure controlled lengths and greater bearing at predetermined elevations, and, in certain cases involving lateral reactions, a more intelligent use of tension piles, a closer approach to the more exact methods used for the design of superstructures may be secured. A case illustrative of possible savings through use of lagging on piles exists at the U. S. Training Base on San Clemente Island, in California, where it is desired to extend a steel-pile pier to deeper water. The piles pass through successive layers of softer rock and sandy soil before hard rock is encountered. If carried to bed-rock, the steel piles at the outer end would be long and heavy; still it would not be safe to stop the narrow steel pile-points in any of the upper, softer, rock strata. Test piles show the strata to be fairly uniform and dipping toward the sea, and it is quite feasible to lag the piles with wooden fillers and secure safe bearing on one of the higher layers of softer rock. Somewhat similar would be the conditions encountered in coral where carefully planned use of lagging might reduce to reasonable figures what otherwise would be prohibitive costs of construction. In softer soils lagging, under certain conditions, would avoid the use of long composite piles. Such lagging, however, is feasible only for cases such as in pier construction, etc., where piles are single and not closely spaced in clusters, and not where the piles without lagging carry all the load the soil would support. In other cases, lagging will increase the effectiveness and value of piles subjected to tension.

The attainment of the objective of improving pile foundation design practice so as to bring it closer to the more exact methods used for superstructure design, however, is being retarded by the uncertainties surrounding and affecting the interpretation of standard pile-driving formulas which seldom take into consideration such vital and important factors as the thickness of, or material used for, cushions, the effect of jetting, speed of driving, and vibrations from hammer or soil irregularities, and from methods of holding a pile, etc. In time, some of these uncertain elements will be better investigated and better understood. A simple contrivance developed by Commander W. Mack Angas (CEC), U. S. N., M. Am. Soc. C. E. (used experimentally in the driving of a 20 by 20-in. concrete test pile for a Navy pier at the Supply Depot in San Diego, Calif., in 1927), secured such remarkably accurate data as to promise definite progress in the investigation of certain factors.

This apparatus consisted of a revolving cylinder, 15 in. in diameter and 18 in. high, mounted on a platform adjacent to the concrete test pile being driven, and a pencil inserted in a socket near the head of the pile and bearing against a small spring at the base of the socket. This pencil traced a line on a sheet of paper mounted on the revolving cylinder surface, with the result that a record was secured of the exact movement of the head of the pile for each successive blow of the hammer. Time increments could be read to less than one-hundredth part of a second. With a similar cylinder, 6 ft long, the exact behavior and velocities and rebound of the steam hammer were recorded and could be read in equally fine time increments for all parts of the stroke. The graphs secured showed clearly the considerable rebound of the concrete pile-head to the shock of the hammer blow and, by proving the temporary occurrence of tension in the pile, explained certain horizontal cracks in piles driven through hard coral on a previous pier constructed at Pearl Harbor, Hawaii. It was the intention to use the apparatus in the study of the effect of variable cushions commonly used in pile-driving apparatus, but this was prevented by lack of time, money, and opportunity for further experimentation. However, the possibility of accurate analysis was established, and some day this interesting and important element will be investigated further. Any company or engineer in a position to carry this study further, either in analyzing hammer actions or efficiencies or pile behaviors can undoubtedly secure from the Bureau of Yards and Docks, U. S. Navy Department, Washington, D. C., details of the apparatus, and information and charts covering the data secured in San Diego in 1927.[7]

CHANDLER DAVIS,[8] M. AM. SOC. C. E. (by letter).—Quite properly, Mr. Miller warns designing engineers not to depend on "some convenient tabulation of friction values." A thorough study of the underlying soils is required. This is especially true in New York Harbor, where the most varying and peculiar conditions are encountered.

The late G. S. Greene, Jr., M. Am. Soc. C. E., Engineer-in-Chief of the Dock Department of the City of New York, confronted with these difficulties, designed his well known floating wall.[9] However, each authorized section was thoroughly studied before work was begun and the final design of the quay wall determined. Table 4 contains some of the observations made over the area of the West 23d Street, North River Section. This section extends from 10 ft south of the north side of West 23d Street to the north side of West 30th Street, about 1 944 ft.

* With gravel, sand, and shells.

Table 5(*a*) shows the penetration per blow at various depths at the foot of West 26th and 27th Streets, North River. In this case all the piles were straight, free of bark, and equipped with a cast-iron shoe. Blows were struck with a 1.5-ton hammer, falling 8 ft.

As shown in Table 5(*b*), the piles tested are part of the completed pier at the foot of West 26th Street, North River. At the time of the observations the pier had been completed about one year. All the piles tested were in the interior, each supporting about 16 tons; they were about 75 ft long, and the points were about 65 ft below mean low water. According to Table 5(*a*) the penetration per blow at this depth is about 6 in. and, by the *Engineering News* formula, the safe load is 3 tons per pile. The piles, however, were loaded to 35 tons per pile without damage to the pier. They are true friction piles and depend on the skin friction to support the working loads.

Whenever a large ship is breasted into the slip around an outer corner a perceptible movement of the pier is observed. The piles move and bend under the pressure of the vessel, acting as long columns of indefinite length. About 7 ft of their upper ends are braced securely and are fixed both laterally of the pier as well as longitudinally, and they act as one unit. At which point below the mud-line the lower ends are held immovable is indeterminate. The distance varies; each time the pier moves the mud grip is broken and the column length is increased by an unknown amount. However, as time goes by, the river bottom under the pier is built up; material in suspension in the river water is gradually deposited; the increased weight on the dock mud compresses it and renders it more dense, and thus the area over which the skin friction acts is increased and the pier becomes more stable. The writer removed a pier at the foot of Broad Street, East River, where the surface of the mud under the pier was level with mean low water. This deposit was of a very stiff consistency.

The foregoing are a few of the numerous observations made in New York Harbor on piles, all of which were not driven to refusal but are supporting their working loads. The pile-driving formulas are not applicable in these cases.

The observations and study of the river bottom in New York Harbor made by the Dock Department, covers more than 65 yr. The thorough study made by Mr. Miller of soil reactions in many countries bears out the foregoing findings and deductions. He further stresses the necessity of a thorough investigation of the subsoil and a complete understanding of the facts obtained; that is, Mr. Miller emphasizes the fact that experience is an important factor in such studies, particularly in the case of piles that are not driven to "refusal", and are friction piles.

Harry E. Sawtell,[10] M. Am. Soc. C. E. (by letter).—In the Synopsis the author states his purpose "to use the construction field as a source of information, and to correlate the collected data on pile foundations under varying soil conditions so that the reasons for success and failure become evident."

The success of his attempt, when citing different examples of construction, depends largely on the accuracy with which the conditions that surround each piece of construction are reported. This accuracy is not always present. The writer has elsewhere called attention to a case in which inaccurate assumptions led the investigators into some curious errors.[11]

Mr. Miller discusses soil reactions due to driving piles into clay, but does not cite examples of the remoulding effect on clay. The writer does not think that the results of actual construction or any published experiments can justify any assumption that driving piles into soft or medium clay will completely or largely remould it. In and around Boston, Mass., it has been the practice to support foundations by driving piles into clay, and the comparatively few cases of bad building settlements no doubt are caused by the slow but sure compacting of underlying clay beds due to the additional loads placed upon them.

Driving piles into clay cannot be compared to remoulding a clay sample in the laboratory. In fact, the usual close spacing of piles gives an area of soil around each pile of about 5.5 sq ft, and assuming a pile well above the point to be 7 in. in diameter, the pile is found to occupy less than 5% of this area.

To add an example to Mr. Miller's citations showing "Soil Reactions to Foundations on Piles," the writer wishes to cite the soil conditions, assumptions for design, and some results of the foundation design for the Eastman Laboratory, a Chemical Research Building for the Massachusetts Institute of Technology, built in 1931.

Soil.—This building is supported on piles which were driven through about 20-ft of low-grade fill (silt) and which stopped in a good sand bed under the northerly half of the structure; but for the southerly part the piles were driven through a loose sand bed, an average of 3 ft thick, and about 23 ft into a stratum of medium blue clay. Under the tips of the piles the clay was about 47 ft thick where boulder clay is reached. The clay has some small quantity of sand in it, in the form of layers or lenses, but the layers are seldom continuous.

Design of Pile Supports.—The basic idea of the design was to spread the load reaching the plastic (medium) clay over as great an area as possible, in order to impose upon the clay as small an additional loading per square foot as possible. The piles were spaced so that the pressure bulbs (having a small diameter in clay) did not overlap. The piles were designed to carry small loads and were deeply embedded, in order to transfer the load to the clay with a surface frictional value of about 300 lb per sq ft.

Load Tests.—To develop the value of skin friction certain piles were loaded covering a period of 200 hr. One pile was driven through a stratum of loose sand and into 22.7 ft of clay; and after being allowed to set, it was given a test load of 40 000 lb applied slowly, without causing failure. This pile (one of a group) settled less than $\frac{5}{16}$ in. and recovered to a total settlement of $\frac{3}{16}$ in. when the load was removed.

---

[10] Structural Engr., Care, Charles T. Main, Inc., Boston, Mass.

[11] *Proceedings,* Am. Soc. C. E., November, 1933, p. 1467, *et seq.*

The original condition of the clay, evidently, was not changed by driving to such an extent as to destroy the elasticity and grip on the piles. The recovery at unloading was somewhat more than one-third the maximum settlement under the load of 40 000 lb. The working load is about 14 000 lb per pile in this foundation.

Surface Friction.—At the foregoing loadings, the pile showed a surface friction resistance equal to about 900 lb per sq ft for the total test load, and about 300 lb under the proposed working load.

Tests to determine the probable frictional value of a pile in soil under load show whether or not the actual working load upon a pile can be transferred to the surrounding soil safely. This is correct whether or not the pile is a part of a group. The effect of group action under certain loads is largely a question of what settlement occurs under the total loading of the group over a long period of time in which the moisture content of the clay may be pressed out into the surrounding soil. The question of how much settlement is permissible must be answered by other considerations, and must be suited to the surroundings, connecting buildings, or other structures.

To demonstrate, in another manner, the effect of driving piles into this kind of clay and the possible deformation and remoulding of the clay, a series of re-driving tests were made upon piles driven for the support of this Laboratory.

Re-Driving Pile Values.—Re-driving values, after hours of rest varying from 0.5 hr to 32 hr, have been reported in detail elsewhere.[12] The same formula and a single-acting steam hammer were used in both driving and re-driving and, therefore, the results were comparable. The clay was a so-called "medium" grade, but was inclined toward the soft-medium. No evidence of remoulding of clay was shown; nor was the elasticity of the soil destroyed as would be the case if the clay was remoulded much when the piles were driven.

Action of Clay During Driving of Piles.—Another demonstration of the action of clay soil, at this same building, when driving piles, was observed, namely, one end of this Eastman Laboratory (Building 6, Fig. 7) joined one of the other buildings (Building 2) of the group, also supported on piles driven into the soft-medium clay. The piles under Building 2 were 45 ft long, whereas those under the new Laboratory are 50 ft long, with the tips of the new piles 5 ft deeper than the old piles.

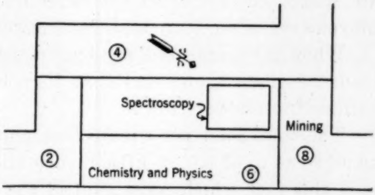

FIG. 7.—KEY PLAN, NEW EASTMAN LABORATORY.

After driving the new piles adjacent to the old ones, it was found that the wall and near-by corridor of Building 2 had been raised $\frac{3}{16}$ in. After two years had elapsed Building 2 settled back to its original level and has remained there.

---

[12] *Journal*, Boston Soc. of Civ. Engrs., October, 1933, Table 1, p. 166.

The ground surface heaved around the new piles during the driving, but equalled less than one-half the displacement of the piles.

The lifting action and the displacement of soil around the piles indicate that the clay around the new piles was not appreciably remoulded but resisted compression to such an extent as to exert a positive pressure on the clay around the new, and especially around the old, piles under Building 2. It was evident that the clay had sufficient stability and density to transmit the upward component of the compression force to the old piles and to raise the building slightly.

This favorable action cannot take place except when piles are properly spaced, deeply embedded, and have a large reserve value of surface friction.

Pile Formulas.—There appears to be no one pile formula suited to all, or even to any two types or combinations of, soils. The engineer will use many times, therefore, the formula best known and recorded for its deviations and limitations when applied to the largest combination or types of soil.

No formula is used by the writer as a rule, but occasionally, the *Engineering-News* formula is favored as a yardstick or gage only, and seldom to obtain correct pile values directly. No other formula is so well known in regard to its faults and limitations, and, therefore, so safe when used as a gage.

Elastic Properties.—All the writer's research in soils seems to confirm the repeated statement that soils are somewhat similar to "weak solids" having elastic properties, and must be considered as such in foundation design.

Economic pile design is one in which just enough piles are used to distribute the load uniformly and properly to the highest stratum capable of carrying the total load without producing an unwarranted settlement.

Each pile corresponds to a small isolated footing or unit and has its own bulb of distributed pressure. Therefore, the most economical spacing of piles is one in which the pressure bulbs are far enough apart to prevent overlapping of the substantial pressure lines, thus using the entire area to good advantage and producing a fairly uniform pressure on the soil under such piles. If piles are spaced too far apart the subsoil pressure is uneven and permits upward movements of moisture and clay between piles where there is no pressure.

When piles are used in medium or soft clay, it is imperative that small loads be given them, and that they be given deep embedment to keep the surface friction very low.

The total load per square foot under the entire pile group must be kept small so as to obtain as little deformation or future settlement as possible, and it is this fact which must control the design of foundations on compressible soil rather than any result of a single pile-load test.

Examples of Settlement.—The material beneath the Laboratory has been described herein under the heading, "Soil." The design of the superstructure was based upon the idea that the unit loading on the deep bed of clay would be about the same (about 1 500 lb per sq ft additional pressure) whether piles were embedded in the clay or in the sand bed above it. This basic idea was used in the design of the original buildings as it was known at that time (1914) that the actual settlements would result from the consolidation of the clay bed below all fill or sand which might be found above it.

The settlements of this building have been recorded occasionally since its erection in 1931 and now (1937) amount to about 1.25 in. at the southerly end and about 2.25 in. at the other end, but with a somewhat greater settlement at the center of about 2.5 in. A greater settlement was anticipated at the center of the building and was allowed for by cambering the building.

The ends of the building were butted up to, but had no physical connection with, older buildings beneath which it was assumed that the subsoil was consolidated to a greater extent than would be the case in the center away from the old buildings (see Fig. 7).

The older buildings which surround this new Laboratory were built from 1914 to 1916 and the soil and foundations were similar to those described herein for the new Laboratory. These older buildings have settled almost exactly 6 in., one having shown no further settlement since 1927, and the others have had no appreciable settlement since 1932. It is anticipated that some time in the future, these buildings, which appear to have ceased settling, will show some slight additional settlement due to the small but continued consolidation of the clay.

The interesting point regarding these examples is that, from the very first, settlement was anticipated, and the foundations were designed so that the settlement would occur in the clay by consolidation and not at the piles or as a result of driving piles.

The proof of the soundness of this design is that under a number of the buildings of this group where a part of the piles were stopped in a sand bed above the clay, and a part were driven deeply into the clay (the sand did not extend under all the full length of each building), the settlements under both ends of the buildings were found to be almost exactly the same.

The author's "Conclusion" is quite proper and justified, as it clearly states the case as developed from actual work done. The writer agrees with most of the conclusions, but wishes to contend that, when designing foundations, engineers should insist on having authority to make more thorough soil investigations than is customary. The comparatively small extra cost of making more explorations, including the taking of "undisturbed" samples by boring machines or open pits, should not stand in the way of obtaining all the information possible, especially if the soil is stratified or includes compressible material. Such thoroughness not only results in a safer foundation for a structure, but frequently saves more than the extra cost of complete exploration.

A case in point was the foundation for the Baltimore (Md.) Plant of the American Sugar Refining Company. A sufficient number of borings were taken to permit a closely spaced contour map being made, showing the surface of the sub-stratum which was capable of supporting all the piles under this group of large heavily loaded buildings. This map was used by the contractors when ordering piles and when driving them, and they estimated their savings at many thousands of dollars in less waste of piles and in smaller cost for the routine handling of the piles on the job.

The writer wishes to emphasize the positive danger of using prepared tables either for driving values of piles or of following pile-driving formulas, or of using values showing safe friction per square foot of surfaces of piles for different kinds of soils. These values should be determined by investigation and study for each job.

Such a study should include certain developments brought forward by the science of soil mechanics, but caution should be exercised to use only those which have been substantiated and proved to be applicable.

J. STUART CRANDALL,[13] M. AM. SOC. C. E. (by letter).—Many sources of data are cited by the author and these should be helpful in permitting more logical design of foundations, and particularly pile foundations. The accumulation and careful interpretation of such information are vital to a proper checking of the assumptions now made or to be made in theoretical analysis. Many of the apparently antagonistic results can be interpreted readily with present knowledge of soil mechanics. Some require further research.

The elapse of time under the dynamic load, during the driving of piles, is very short as compared with the period of actual static load. Therefore, during driving the only data of value are those which give some measure of the behavior of the foundation or any part of it under static load. In a pile foundation:

(1) Each pile must have adequate strength to resist the stress developed in driving (usually several times the static load);

(2) Each pile must have adequate resistance against movement with relation to the soil; and,

(3) The load on the soil, created by the entire group of piles, must not cause dangerous or excessive differential settlement.

Requirement (1) depends on the size and the materials comprising the pile and on the actual stress caused by driving. Much over-driving of wooden piles has been due to the use of drop hammers and the application of the *Engineering News* formula in determining so-called safe loads, which may have a factor of safety of 12, or more, thus stressing the piles beyond the ultimate strength of the material. Requirement (2) is measured by a dynamic pile formula, or by a load test; and Requirement (3) depends on the net weight of the structure and the nature of the underlying supporting soil. As a maximum over the entire area, this imposed load is the weight of the structure per square unit, and this unit load can be reduced only if piles permit spreading the load over a larger area and provided that no loads are imposed by adjacent structures, present or future. As the author intimates, there is no doubt that many foundation difficulties have been due to blind reliance on Requirement (2) and complete neglect of the others. Too frequently this second requirement has been determined by the *Engineering News* formula, the primary merit of which is that the uninitiated can work out a result, however far it may be from reality.

One of the most logical driving formulas is that of Alfred Hiley[14] which is in current use in England:

---

[13] Pres. and Chf. Engr., Crandall Dry Dock Engrs., Inc., Cambridge, Mass.

[14] "Pile-Driving Calculations," by Alfred Hiley, *The Structural Engineer*, London, England, Vol. VIII, July and August, 1930.

$$R_d = \frac{e\,W\,h}{s + k} \times \frac{W + n^2\,W_p}{W + W_p} \quad \text{(1)}$$

in which R_d = dynamic resistance to driving; e = efficiency of the hammer; W = weight of the striking parts of a hammer; h = the drop, or length of stroke; s = penetration of pile per blow; k = one-half the elastic rebound of the pile-head after blow; W_p = weight of pile; and n = Newton's coefficient, or coefficient of restitution. Inasmuch as for the materials in contact the values of n are usually small, the writer proposed[15] eliminating the term, $n^2\,W_p$, and has suggested the formula:

$$R_d = \frac{e\,W\,h}{s + k} \times \frac{W}{W + W_p} \quad \text{(2)}$$

If the actual resistance may be determined accurately, a factor of safety of 3 should be adequate. Applying such a factor with the usual efficiency of hammer (namely, 0.75 for a drop hammer overhauling the fall and drum; and 0.90 for a single-acting steam hammer), measuring drop, in feet, and penetration, in inches, the allowable load is:

For a drop hammer,

$$R_a = \frac{3\,W\,h}{s + k} \times \frac{W}{W + W_p} \quad \text{(3a)}$$

and for a single-acting steam hammer,

$$R_a = \frac{3.6\,W\,h}{s + k} \times \frac{W}{W + W_p} \quad \text{(3b)}$$

These formulas appear in the proposed new Boston (Mass.) Building Code.

In Equations (3) the term, k, is a measure of the energy loss due to elastic compression of pile and soil. Evidently, for any given pile, soil condition, and hammer, there is a certain height of fall below which the pile does not move, h_0, which is also a measure of this energy loss due to elastic compression. Based on this fact the writer has suggested the following formula[16]:

$$R_d = \frac{W\,(h - h_0)}{s} \times \frac{W}{W + W_p} \quad \text{(4a)}$$

Making the same assumptions as for Equation (3a):

$$R_a = \frac{3\,W\,(h - h_0)}{s} \times \frac{W}{W + W_p} \quad \text{(4b)}$$

in which h_0 is the maximum drop of the hammer below which there is no penetration. The value of h_0 for any particular case may be determined readily in the field. Measuring the penetration accurately for, say, four different heights of fall, plotting the penetration as abscissas and the drop as ordinates, these points should fall on a straight line whose intercept with the Y-axis gives the value of h_0. If the points do not fall in a straight line the test should be repeated. As h_0 varies as the square of the dynamic resistance, therefore, these determinations should be made when at the probable desired resistance.

---

[15] *Journal*, Boston Soc. of Civ. Engrs., May, 1931, p. 176.

[16] *Loc. cit.*, Equation (14), p. 181.

Furthermore, the determination of h_0 permits a verification of the theoretical calculations of the values of k, because,

$$k = \frac{h_0 s}{h - h_0} \qquad (5)$$

The value of h_0 was determined by the writer, at Boulogne-sur-Mer, France, in 1933,[17] for 35-ft greenheart piles driven into sand with a 3 080-lb hammer for a safe load of 25 metric tons (factor of safety = 6), giving a value of 1 ft. Applying these data in Equation (5) gave a value of k equal to 0.06 in. as compared with a theoretical value of 0.12 in. Recently, a similar determination was made of an oak pile driven at the Massachusetts Institute of Technology.[18] The pile was 26 ft long, driven into sand with a 3 000-lb hammer for a safe load of 22.5 short tons (factor of safety = 3). The value of h_0 was determined as 2.2 ft, giving, by Equation (5), a value of k equal to 0.35 in. as compared with a theoretical value of 0.30 in.

A sound driving formula can give only the resistance to rapid penetration or, in other words, the load on the pile during driving. This is of value in determining the driving stresses in a pile. Furthermore, in soils where the resistance to rapid penetration is the same as that to slow penetration, such formula can give the resistance of a pile to movement in the soil under static load. This is true of sands, gravels, and such permeable incohesive soils, but is not true for such soils as clays and silts.

In clays and silts the remolding and disturbance of the soil during driving tends to reduce the frictional resistance which in most cases again sets up after an elapse of time at even a greater value, although on rare occasions the opposite occurs. In these soils there is no known relation between dynamic and static resistance. Therefore, it would appear that the logical procedure in such cases is to base the resistance to movement in the soil on the frictional resistance. An equation for this condition would take the form:

$$R_a = \frac{A_s f}{3} \qquad (6)$$

in which A_s = the area of contact surface; and f = "skin" friction per unit area. In Table 3 the author gives certain values[19] for friction which apparently are taken from the writer's paper. It should be pointed out that the soil at Hull, England (Item No. 1) was not soft clay, but actually stiff blue clay which makes the tabulated value of 1 850 lb per sq ft appear more reasonable. Furthermore, the writer verified certain data of pile-pulling tests at Boulogne-sur-Mer, France, where a value equal to, or greater than, 1 800 lb per sq ft was found for stiff clay. In some tests the friction per unit area decreased with depth; in others, it increased, and then became constant. Therefore, friction tests should be made for each locality and for the lengths of pile used unless other tests are available for the same soil and locality. Even then, corroboration by test is advisable for any important foundation.

[17] Four piles in railway dry dock designed and constructed for Service des Ponts et Chaussées.

[18] By Stone & Webster Eng. Corp., October, 1937, Pile Z 240, New Architectural Bldg., Cambridge, Mass.

[19] *Journal*, Boston Soc. C. E., May, 1931, Table 4, p. 185.

To this point the writer's remarks have been concerned with the stress in individual piles and the resistance of individual piles to movement in the soil. The results of driving formulas and of load tests can give no indications of the action of a group of piles under static load. The load from a single pile stresses the soil over a fairly wide area. With a group of piles in close proximity these zones of stress overlap, causing more important stress concentrations at greater depths. The writer cannot agree with Mr. Miller regarding the value of load tests on a group of piles. Admitting that such tests on single piles can give no measure of the settlement of an entire pile foundation, particularly where underlaid by compressible soils (because the load caused by a single pile is distributed over considerable area so that the time-settlement effect is infinitesimal), the same is true of load tests of small groups of piles forming part of a larger foundation, although to a different degree. The settlement for the group would be greater than for a single pile, but it would not be comparable to that of the entire foundation. Assuming a structure of infinite extent, the additional load on the soil, whether or not piles are used, would be equal to the weight of the structure per square unit, less the weight of any excavation. If the weight of material excavated is equal to the weight of the structure there would be no additional load and, hence, no comparative settlement. On the other hand, if there is a net load increase and the structure is underlaid by such compressive soils as clay and silt, then there will be settlement. The magnitude of this settlement can be predicted only after an accurate exploration of the soil and a settlement analysis based on undisturbed samples.

The author has cited cases in which the soil has "heaved," others of subsidence, and, again, cases of no evident movement. This action is a result of the soil structure. The voids of clays and silts are usually filled with water and, being relatively impermeable, cannot be compressed during the short period of pile-driving, so that the soil must be displaced equivalent to the volume of the embedded piles, resulting in "heaving." In compact sands and gravels, piles cannot be driven without displacing the soil, causing "heaving" either by the driving process alone or with the aid of jetting. In loose sands, gravels, and fills, the action of driving tends to re-arrange the soil particles into a more compact structure. This may result in some subsidence of the surface, which would depend on the degree of volume change by reason of the reduction in voids. Where layers of several kinds of soil are penetrated, a combination of these effects may take place.

In cases where piles are driven through incompletely consolidated soil to a bearing in a more resistant one, there are certain special conditions to be considered. The imposed load on such a pile would be transferred through friction in the upper layer, and largely through end bearing in the lower one. However, as the upper layer continued to consolidate under its own weight, eventually it would cause an additional load on the pile through friction, so that the load carried by the point would amount to the superimposed load on the pile plus the total frictional load imposed by this consolidating layer, and thus cause settlement. This has been observed in Holland and is a factor in design.[20]

The profession has given much attention to refinement in the design of structures, all based on certain assumptions as to rigidity of foundations, while all too frequently the foundations are only superficially considered and empirically designed; yet the settlement of these foundations may completely vitiate the assumptions in the super-structure design. It seems to be particularly this point which Mr. Miller desires to emphasize and which merits serious thought. The mere driving of piles to some resistance does not, by itself, constitute a solution. The question of foundation design and its limitations should be the first consideration, after which definite conditions affecting super-structure design can be logically determined.

R. M. MILLER,[21] M. AM. SOC. C. E. (by letter).—One of the most interesting experiences that can come to the engineer is to have repeated contacts with engineers and architects of every professional status, who have piling foundation problems to solve. Perhaps no other work has been given as little actual study by the mass of engineers and architects and in no other field are mistakes repeated so persistently. The very general attitude seems to be that brains are needed to design and build a structure but that almost any one can drive piles into the ground, and that once driven the matter is settled for all time. The courage of ignorance has been so general that the writer was tempted and wrote "Soil Reactions in Relation to Foundations on Piles" in the hope that he might emphasize in simple terms, and in readable form, why some of the commonest mistakes occur. If he has made a few of the most dearly cherished fallacies seem questionable, something may have been accomplished. The discussion of this paper has been most considerate although by no means in entire agreement.

Mr. Hill feels that the writer gives more weight to pile-driving and loading tests than he should. Perhaps the thought was not well expressed. In substance, it should have been much as follows: In impervious soils or combinations of pervious and impervious soils, the commonly used "yardstick," the dynamic pile-driving formulas are of but small value whereas the test loading of single piles is not much better; nor is the test loading of single piles, a cluster or mat in such soils, if done too quickly after driving. If, however, a cluster is test-loaded after a sufficient lapse of time to allow for some re-arrangement of the soil particles, even if the cluster is not of an area comparable in size to that of the foundations, the results will more nearly approximate those of the foundations than those indicated by the dynamic formulas, single-pile load tests, or load-testing the cluster, or mat, immediately after driving. Test-loading a group as suggested should offer an improvement over the usual methods, but not the complete answer.

---

[20] *Proceedings*, Conference on Soil Mechanics and Foundations, 1936.

[21] Project Engr., PWA, Cincinnati, Ohio.

The writer wishes to concur particularly in the closing sentence of Mr. Hill's discussion which states that "only the inexpert are courageous enough to proceed, where compressible materials are involved, on the basis of inspection of ordinary boring samples."

Mr. Stowitts advanced the thought that the order in which piles are driven is an important factor in the final result. Such matters appear to be lost sight of in favor of apparently more important considerations; but, if mishandled, they may become of as much importance as any other factor of the problem. The sub-soils underlying any two projects are never exactly alike: In one, it may be advisable to drive alternate runs of piles and return a second time over the same ground; in another, as suggested by Mr. Stowitts, it may be well to begin driving at the center and work outward toward the edges; and in another, it may be best to work uphill rather than down, or *vice versa*. In any case, careful consideration should be given to the control of heave and to lateral movement. Broken, cracked, or pinched piles have resulted from this cause in sufficient number to warrant thoughtful planning.

The writer agrees with Mr. Crandall that the dynamic pile-driving formulas should be used only where piles are driven in sands, gravels, and such incohesive soils, and also that his modification of Hiley's formula offers more dependable results than can be had from the generally used *Engineering News* formula. On the other hand, he feels with Mr. McKay that the unknown effect of the use of the several kinds of driving cushions of different thicknesses and different materials should be more thoroughly examined. That this factor affects the results in considerable but unknown degree cannot be doubted, and, yet, how many engineers give the matter consideration?

The use of Equation (6) for the resistance to movement of a pile through clays, silts, etc., appears logical provided the friction value of the soil and the type of pile are known within reasonable limits. Mr. Crandall states that "friction tests should be made for each locality and for the lengths of pile used unless other tests are available for the same soil and locality."

Sub-soil formations may lie fairly uniformly under a project site, or they may change radically within a comparatively small area. If the former is found to be the case one friction test should be sufficient; but if the latter is true the number of friction tests should be governed by the conditions. As an example, refer to the writer's description of the sub-soils underlying one of the buildings of the Laurel Homes Housing Project, in Cincinnati (see heading "Average Practice"). In the space given as 35 by 150 the use of Equation (6) would insure equal settlement, or no settlement, only if at least six or perhaps more friction tests were made. However, as equipment installations represent a large part of the cost of such tests a few added tests would affect the cost very little.

Mr. Sawtell states that the writer has cited no examples of the effect of the remoulding of clay during pile-driving upon subsequent settlement. This is quite correct, due to his inability definitely to connect effect to this cause. In fact, he agrees with Mr. Sawtell that "driving piles into clay cannot be compared to remoulding a clay sample in the laboratory," and that "he [Mr. Sawtell] does not think that the results of actual construction or any published experiments can justify any assumption that driving piles into soft or medium clay will completely or largely remould it." In fact, the writer's observations incline him to the belief that, although some remoulding of the clay surrounding a pile undoubtedly occurs during driving, the soil particles re-adjust themselves after driving so that, in time, the effect of any remoulding disappears. Furthermore "the slow but sure compacting of underlying clay beds" is a characteristic of this type of soil and furnished a more logical reason for settlement than the remoulding theory.

Although insistence should come from engineers that more thorough soil investigations be made than is customary, it should go further than that. So long as contracts for borings or open-pit explorations are let through competitive bidding to the low bidder, with little regard for his knowledge and experience, so long will much of the foundation work be based on inexact information.

Occasionally, the contractor's superintendent or foreman in charge of such preliminary investigation is competent to secure representative samples and to classify soils; but many times this is apparently not the case, judging from results. It has been the writer's experience, so many times, to work with boring records that subsequent construction has proved to be inaccurate that he looks with suspicion upon any records of soil exploration unless he is sure that competent men have been in charge. Results indicate that too much care can scarcely be taken to secure sufficient and accurate preliminary information.

MEASUREMENT OF DÉBRIS-LADEN STREAM FLOW WITH CRITICAL-DEPTH FLUMES

By H. G. Wilm,[1] Esq., John S. Cotton,[2] Esq., and
H. C. Storey,[3] Esq.

With Discussion by Messrs. R. L. Parshall, Martin A. Mason, Edwin S. Fuller, Harold K. Palmer and Fred D. Bowlus, Harry F. Blaney, R. L. Stoker, J. C. Stevens and H. G. Wilm, John S. Cotton, and H. C. Storey.

Synopsis

Heavy burdens of erosion débris in streams of the San Dimas Experimental Forest, in California, have been found to cause substantial errors in measurements of discharge at some of the gaging stations. Stream-flow records are kept at a number of points throughout the Experimental Forest. Furthermore, there are two sets of triplicate water-sheds, each shed having an area somewhat less than 100 acres, immediately below each of which is located a Parshall flume, a V-notch weir, a small reservoir, and a flat-crested weir over the dam forming the reservoir. The flow from these water-sheds is first measured through either the Parshall flumes or V-notch weirs, according to the volume of flow. Its débris content can then be measured in the reservoir, and the clear water can be measured as it passes over the flat-crested weir of the dam.

However, there are numerous other points on the water-sheds below which the entire dependence is placed on the Parshall flumes or V-notch weirs for the determination of stream flow. Due to the presence of large quantities of eroded material in all heavy flows, the results at these points have been somewhat erratic. This was due largely to deposition of débris on the level approach to the throats of the Parshall flumes during the falling stages of the stream flow, and to the filling of the weir boxes with silt which soon put the V-notch weirs "out of commission."

The experiments described in this paper were conducted with the consultation and under the supervision of E. W. Kramer, M. Am. Soc. C. E., as Regional Engineer (California Region, United States Forest Service) now (1937) Regional Director (Federal Power Commission, San Francisco, Calif.) and

under the authority of Professor E. I. Kotok, Director, and C. J. Kraebel, Project Leader, of the California Forest and Range Experiment Station (United States Forest Service). The objective was to improve the present gaging stations so that they would yield reasonably accurate results with bed-load material present in the stream measured. Included in the study were also tests of the Parshall flume as constructed in the Experimental Forest, to check its accuracy with clear and loaded flows.

Introduction

The California Forest and Range Experiment Station has instituted an intensive program of investigations for the purpose of solving problems concerning the inter-relationship of mountain vegetation and water, with the objective of developing methods of water-shed management which should provide a maximum yield of usable water with a minimum of soil erosion. These studies are largely concentrated in the San Dimas Experimental Forest, a chaparral-covered mountain area of 17 000 acres in the San Gabriel Mountains, approximately 30 miles east of Los Angeles, Calif.

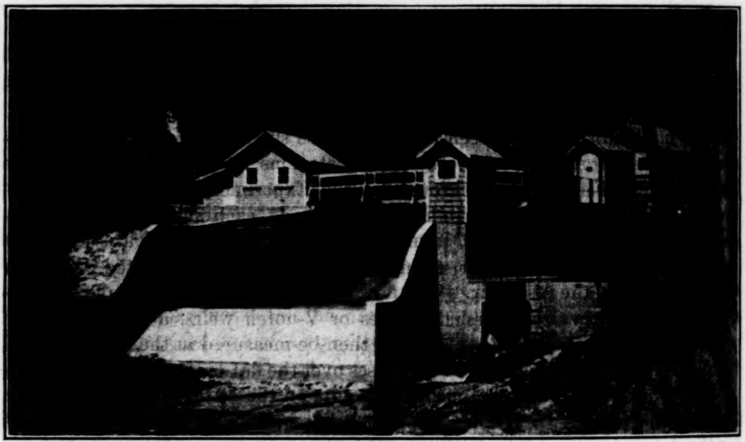

Fig. 1.—Large Gaging Station, San Dimas Experimental Forest; Parshall Flume and 90-Degree V-Notch Weir

In connection with studies of other phases of the problems, analyses have been made of rainfall-run-off ratios in seventeen drainage basins of various areas, from 0.06 sq mile to 14.1 sq miles.

Rainfall averages for these water-sheds, obtained by means of a system of nearly 400 standard rain gages and 15 intensity gages, are known to be accurate within 5 to 10% for the large areas, and from 3 to 5% for the small, intensively studied water-sheds. To date, however, stream-flow records have been of greatly inferior accuracy, due to the presence of quantities of eroded material in all storm peak flows. Deposition of this material results in erratic and undependable volume measurements in the gaging stations.

Sixteen of the seventeen gaging stations completed at present (1937) were constructed during the course of a single dry season from designs based on the best existing practice. (To the writers' knowledge, no control flume or weir had been designed previous to this time, which would operate as well as the Parshall flume in measuring silt-laden flows.) In each case a Parshall flume,[4] of throat width (3 ft to 30 ft), sufficient to handle the largest probable flows, was built to operate in conjunction with a 90° V-notch weir, intended to measure small continuous flows. Measurement of water stages in each is made by a continuous time-stage recorder.

In the design of Parshall flumes for the Experimental Forest, several minor modifications had been introduced, in order to increase their capacity and improve their efficiency in measuring silt-laden flows. The rising floor section down stream from the throat (see Fig. 1) was replaced by a downward sloping floor, the converging sections were lengthened, and the walls were increased in height.

Storm flows during the first rainy season following construction soon demonstrated the inadequacy of this type of control in measuring flows containing a substantial bed load. Even small post-storm streams carried enough sand and gravel to fill weir boxes quickly, and to build up a deposit on the flume floors so that they no longer functioned as critical depth meters. It is believed that the flumes should still measure large flows with reasonable accuracy, as the effect of bed load would constitute a much smaller percentage of the total flow; but as the stations stand at present they fail to give a satisfactory measurement of small and intermediate débris-laden flows, which form the run-off resulting from most storms.

Below the gaging stations, at each of the smallest, intensively studied water-sheds, is a cement-lined débris reservoir. The water depths measured in this basin and over the broad-crested weir spillway afford an efficient check on stream-flow measurement, in some cases furnishing the only reliable data on flow from the water-sheds studied.

PURPOSE OF THE INVESTIGATION

At the request of the Regional Engineer, the experiments described in this paper were set up in March, 1935, with two major objectives: (1) To test the effect of construction modifications on the rating of Parshall flumes in the San Dimas area; and, (2) to adapt the present stations to measurement of flows of all sizes, either by improving the débris-transporting characteristics of the Parshall flume, or, failing this, by attempting to develop a control flume that would function satisfactorily under a wide range of conditions and might be used in conjunction with the present stations to measure flows of intermediate volume.

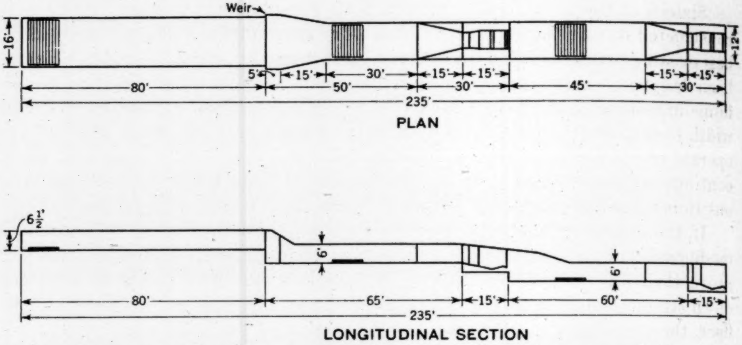

Fig. 2.—Plan and Section of San Dimas Experimental Flume, Showing Position of Sharp-Edged Control Weir, Experimental Flumes, and Raft Baffles

control) Reservoir was made available for experimental purposes, in any quantities desired up to 250 cu ft per sec.

Below the outlet gates in this dam was constructed a water-tight timber flume, lined with tar-paper, 16 ft wide, 6.5 ft deep, and 80 ft long, beyond the end of a short concrete channel leading from the sluice-gates. At the end of this section of flume was installed a 16-ft sharp-edged, steel suppressed weir, set level with a maximum variation of ± 0.001 ft. By the installation of additional bulkheads and short vertical sharp edges, this weir could be shortened to form a contracted weir of any desired length.

Beyond the weir the structure was continued, narrowing to a width of 12 ft, for 155 ft. At the weir, the floor of this section is 4.5 ft below that of the

Fig. 3.—General View of Flume as Seen from Top of San Dimas Dam

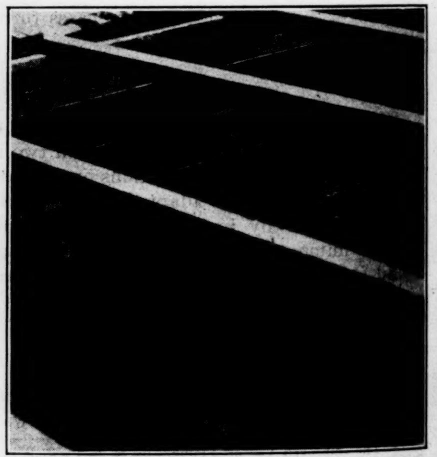

Fig. 4.—Wall of 5-Foot Parshall Flume, Showing Arrangement of Metal Strips Used in Plotting Water Surface Curves

weir channel; and a second drop of 6.8 ft occurs in the middle of the lower structure. Experimental flumes were installed here and at the down-stream end of the structure. Figs. 2 and 3 show the design and a general view of the entire installation.

Water depths over the weir and at both experimental controls were measured in 1-ft iron stilling-wells, by means of milliammeter point gages designed by the Staff of the Experiment Station, and accurate within ± 0.001 ft. In addition, water-surface curves were plotted by the use of metal strips tacked to the walls of the flumes being tested, at horizontal intervals of 1 ft and at vertical intervals of 0.1 ft (see Fig. 4).

CONTROL FLUMES STUDIED

In every test made, at least two flumes were rated simultaneously at the two stations constructed in the large test flume. Tests made with various experimental structures in the San Dimas test flume, listed in chronological order, and noting the length of weir used as a control for each test, are as follows:

I.—Tests of Modified Parshall Flume.—

(*A*) Five-foot flumes (rating with clear water), with 16-ft suppressed weir as control, using flows from 14.08 cu ft per sec to 234.5 cu ft per sec: (1) Same design as that adopted in the Experimental Forest gaging stations, with level floor in converging section; and (2) same design as that adopted in Experimental Forest gaging stations, except that the floor of the converging section was given a 5% slope.

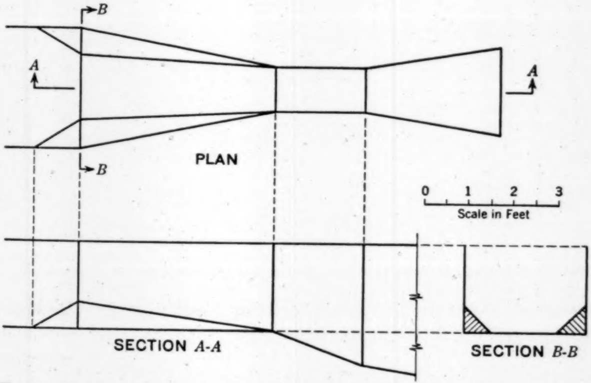

FIG. 5.—PARSHALL DESIGN, 45-DEGREE FILLETS IN A 1-FOOT PARSHALL FLUME

(*B*) One-foot flumes with 3-ft contracted weir as control, using flows from 0.11 cu ft per sec to 16.0 cu ft per sec: (1) Rating with clear water: (*a*) Level floor in converging section; 45° wing-walls extended from up-stream end of flume to walls of 12-ft channel; (*b*) floor of converging section on 5% slope; (*c*) floor of converging section on 3% slope; (*d*) level approach floor, with fillets installed on this floor from the throat back to the up-stream end of the flume, and set at an angle of 45° from the floor to the converging side walls (Section *B–B*, Fig. 5). This fillet design was suggested by Mr. Parshall[5] for the purpose of improving the efficiency with silt-laden flows; and (*e*) level floor in converging section, wing-walls extended parallel to each other from the up-stream end of the flume for 10 ft, instead of diverging as 45° wing-walls. (2) Rating with débris-laden flows: Same installations as in Item *B*–1.

(*C*) Six-inch flume, with a 3-ft contracted weir as control, using flows from 0.20 cu ft per sec to 2.71 cu ft per sec. The purpose of this test was to ascertain the effect on the rating formula of entrance conditions radically different from standard. This flume was installed in the side of the main structure below the lower 1-ft flume, and with its axis at right angles to that of the main structure. The result was considerable turbulence and an abrupt change in flow direction.

(*D*) Three-foot flumes with an 8-ft contracted weir as control, using flows from 0.62 cu ft per sec to 53.52 cu ft per sec: (1) Level floor, but with a series of low fillets along the floor. These fillets were triangular in cross-section, tapering in height from 4 in. at the up-stream end of the flume, to 1 in. at a point 1 ft up stream from the flume throat. Sloping ramps were constructed on the ends of each fillet.

II.—Experiments with Other Critical-Depth Flumes.—In the course of the studies, a new type of measuring flume was developed, which functions as a broad-crested weir in which water depths are measured at a point in the flume down stream of the section in which critical depths occur. In Fig. 6, for example, b_f denotes width of measuring flume; b_a = width of approach channel $= 3b_f$; h_a = height of structure in the approach channel $= \frac{\text{maximum flow}}{5\,b_f}$; L = length of the measuring flume $= r + 2h_a$; and r = radius of the transition $= b_f$. The object of this design is to provide for measurement of flow at critical or super-critical velocities, sufficient to transport débris rapidly through the flume and to keep its floor scoured clean. This flume differs in function, design,

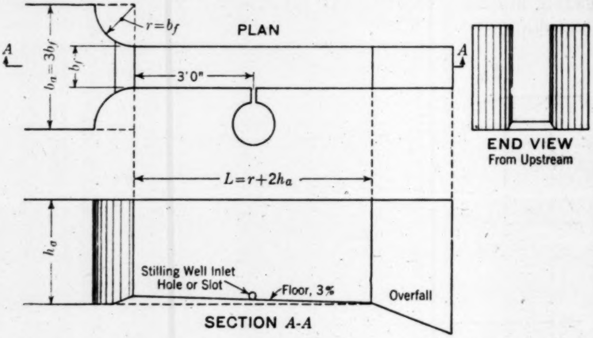

FIG. 6.—GENERAL DESIGN FOR SAN DIMAS RECTANGULAR CRITICAL-DEPTH FLUME

and point of depth measurement from the Venturi flume described by H. K. Palmer and F. D. Bowlus, Members, Am. Soc. C. E.[6] The meter described by Messrs. Palmer and Bowlus would not function satisfactorily for measuring flows containing bed-load, as measurements made up stream of the "critical" section must necessarily be affected by changes in approach velocity, caused by deposition of transported material in the back-water zone above the flume's entrance transition. Because of the necessity of measuring loaded flows, no conventional broad-crested weir could be used, as its contraction would soon become obliterated by accumulated débris. Therefore, a standard flume transition was constructed in the new flume to replace the bottom contraction.

---

[5] Memorandum concerning the effect of fillets placed against the walls of the converging section of a 1-ft Parshall measuring flume, by Ralph L. Parshall, U. S. Bureau of Agricultural Engineering, Fort Collins, Colo., March, 1935.

The transition is the cylinder quadrant (see Fig. 7), described[7] by Fred C. Scobey, M. Am. Soc. C. E., in 1933, with a radius of curvature equal to the width of the flume. This type of transition was adopted because of its simplicity and relatively short length; and because, according to Mr. Scobey's experiments, the head loss through it should, in most cases, be no greater than in more complex transitions, such as the reversed curve described[8] by Julian Hinds, M. Am. Soc. C. E., in 1928.

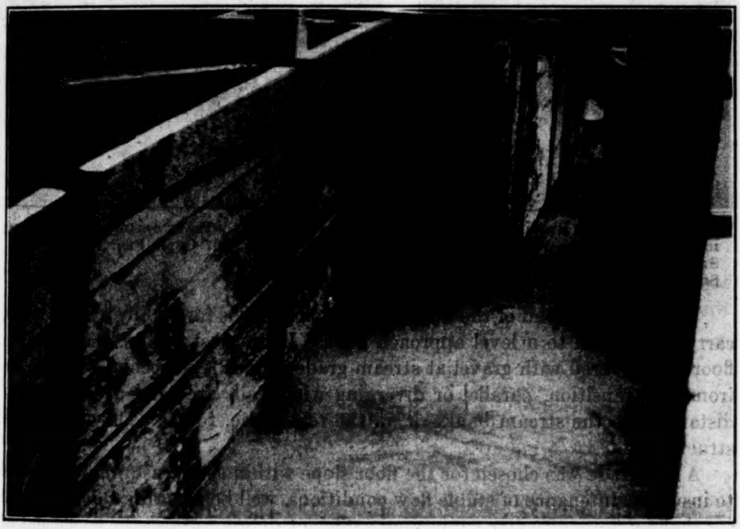

FIG. 7.—VIEW FACING DOWN STREAM; 1-FOOT RECTANGULAR, CRITICAL-DEPTH FLUME; FLOW, 2.71 CUBIC FEET PER SECOND

Below this transition the measuring flumes tested were either rectangular, as shown in Fig. 8, or trapezoidal in cross-section, with a floor laid on a 3% grade. The trapezoidal flumes had a wall slope of 1 on 0.25 (see Fig. 9), the object of this cross-section having been to increase capacity while retaining accuracy for low flows, and to attempt to hold critical depths at points close to the "crest," or to the down-stream end of the entrance transition.

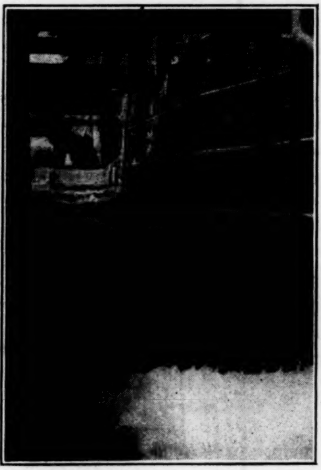

FIG. 8.—THREE-FOOT RECTANGULAR CRITICAL-DEPTH FLUME; VIEW FACING UP STREAM; FLOW, 12.68 CUBIC FEET PER SECOND

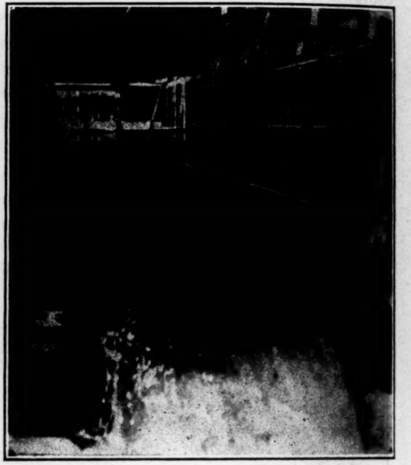

FIG. 9.—TWO-FOOT TRAPEZOIDAL CRITICAL-DEPTH FLUME; FLOW, 22.97 CUBIC FEET PER SECOND

The up-stream end of the 3% floor in each flume is formed by a short ramp, carrying over on to a level approach floor. In the test flumes, the approach floor was covered with gravel at stream grade (about 3 per cent). Up stream from the transition, parallel or diverging wing-walls are carried back a short distance into the stream banks or, in the test flume, to the walls of the main structure.

A 3% grade was chosen for the floor slope within the measuring flume so as to insure maintenance of stable flow conditions, well below critical depths, even for shallow flows of water containing sufficient débris to raise the coefficient of hydraulic friction of the flume as high as $n = 0.025$. Although this allowance may seem liberal, it was considered necessary because of present inadequate knowledge of the quantitative influences of transported material on flow characteristics in flumes. The only disadvantageous effect of such a floor slope lies in its increasing velocities which tend to reduce the sensitivity of the instrument to small changes in flow. This effect may be minimized, however, by locating the stilling-well inlet reasonably close to the section in which critical depths occur. Furthermore, any such reduction in depth variation per unit of volume variation is largely compensated in practice by the facts that any error in measurement of head causes only approximately 1.3 times that error in computed volume; and that velocity of approach has no effect, theoretically, upon the flume's rating.

Preliminary ratings have been made for three sizes of flume in both the rectangular and trapezoidal designs: 1, 2, and 3-ft widths in the former, and

0.5, 1, and 2-ft bottom widths in the latter. The 1-ft flumes were rated by 3-ft and 8-ft weirs; the 8-ft weir was used also for the larger widths of the flume. A 1-ft rectangular flume with a level floor was also tested, in order to verify the similarity in discharge behavior between this type of control flume and a broad-crested weir.

Experimental Procedure

In each test run, gate-openings in the dam were controlled by a staff member of the Los Angeles County Flood Control District, who was in continuous communication with a co-ordinator at the test-flume structure. To start the run, the gate was opened enough to fill all the basins in the test-flume structure, and then lowered to a small fixed opening. When the flow had reached stability, as indicated by constant point-gage readings at the lowest experimental flume, a signal was given and six to ten depth readings were made by separate observers at each point-gage, noting times of reading to the nearest $\frac{1}{4}$ min. Other observers plotted the water-surface curves in each flume being rated, and recorded the water depths in the channels up stream. Staff gage readings were also taken at the weir as a check on the point-gage, and current-meter velocities for the larger flows were measured to check the weir rating. After the completion of point-gage readings for each stabilized flow, the gate-opening was increased and the entire operation repeated until enough different volumes had been measured to insure the procurement of reliable rating curves. For the 6-in. Parshall flume only seven points could be taken; but for each of the others ten to fifteen separate volumes were measured.

Complete stability of flow through the gate was insured by the large head of water available behind the dam. Formulas used for the control weirs were:

For the 16-ft weir (Bazin's formula):

$$Q = \left(0.405 + \frac{0.00984}{H}\right)\left(1 + 0.55\left[\frac{H}{Z+H}\right]^2\right) L\,H\,\sqrt{2gH} \;\ldots\ldots (1)$$

and, for 8-ft and 3-ft contracted weirs:

$$Q = 3.33\,(L - 0.2H)\,H^{1.5} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which Z = the height of the crest above the bottom of the channel. Although no volumetric or other completely reliable rating could be made of these weirs, their accuracy is believed to be well within limits required for the study (± 2% to 3%), as demonstrated by their close correspondence with volumes computed from current-meter measurements, and by the agreement of observed discharges with points determined by formula.

In testing the behavior of débris-laden flows in the small Parshall and rectangular San Dimas flumes, a stream-bed mixture of gravel and sand was dumped as rapidly and continuously as possible by six men with two wheelbarrows into the channels just up stream from the flumes tested. In each case, water depths in the flumes were measured first with a stabilized flow of clear water; then, with the same rate of flow, débris was added as rapidly as possible, and the depths were remeasured.

Later, in testing the trapezoidal San Dimas flumes, bed-load material was added from large bunkers constructed above the flume structure just up stream from each flume. It was found difficult, however, to feed the débris uniformly from the bunkers, because the material became packed.

In computing results, all point-gage readings for each stabilized flow were averaged and checked with the corresponding staff-gage reading or the water-surface curve, and rating curves and formulas were obtained from the resulting average points. Variation of individual readings from their average seldom exceeded 0.01 ft.

Computations were made of velocities and energy gradients within each flume, in order to determine energy losses attributable to the transition and to friction and turbulence within the flume. The results were not satisfactory, probably owing to centrifugal effects in curved flow. However, as nearly as could be determined, losses through the transition and flume appear to be small.

All calculations were made with a 50-in. slide-rule and an electric calculator. Computed discharges obtained by "least squares" were checked against a straight line drawn through logarithmically plotted, observed discharges.

RESULTS

Rating curves and formulas were computed for the flumes tested, and compared with Parshall's ratings of his flumes. The significant results of the experiment are shown in Tables 1 to 3, and summarized as follows:

Modified Parshall Flumes with Level Floor in Converging Section.—

(*a*) The logarithms of all rating points fit a straight line closely, with deviations which exceed 5% only in the 6-in. flume.

(*b*) For a 6-in. flume,

$$Q = 2.13\, H_a^{1.47} \qquad (3)$$

Increasing the length of the entrance section of the Parshall flume and depressing the floor of the outlet section have little effect, if any, on the discharge characteristics of the flume.

(*c*) Flow in Parshall flumes, at depths as great as twice those originally rated, conformed with no increased error to computed rating formulas.

Alterations of the Parshall Flume.—The rating with clear water may be described as follows:

(1) A 3% to 5% slope in the floor of the converging section resulted in shooting flow at low stages. As depths were increased a hydraulic jump passed through the flume. All larger quantities flowed at depths greater than the critical, giving smooth rating curves with discharges for all heads considerably higher than standard.

(2) Introduction of fillets of either design resulted in discharges somewhat in excess of standard ratings. In the 3-ft flume with multiple fillets, low flows occurred at shooting velocities, and at all stages a slight drop was perceptible at the up-stream end of the fillets.

Effect of Débris on the Altered Flumes.—Excellent transportation of bed-load resulted as long as shooting velocities occurred. At higher stages, however, with normally slow velocities, débris movement was greatly reduced. The introduction of fillets somewhat improved the transportation of fine material, but failed to be effective for bed-load ranging above fine gravel in coarseness.

When bed-load was present in the flow, observed discharges were erratically in excess of normal values for the flumes at all stages tested (see Table 1).

20	1.645	12.11	12.31	−0.20	− 1.6†	13*a*	0.968	21.33	21.41	−0.08	− 0.4

* Observed head is for flows containing bed-load material; observed discharge is based on control-weir measurements; and computed discharge is based on San Dimas ratings for clear water. † Channel above flume built up to 25% with bed-load material.

These findings support field observations made at Experimental Forest gaging stations, where it was found that bed-loads are transported through Parshall flumes only at high discharges. Low flows carrying loads cause deposits of sand and gravel on the approach floors of all these flumes, and prohibit the use of notch weirs by similar deposition. These facts result in serious errors and gaps in flow records.

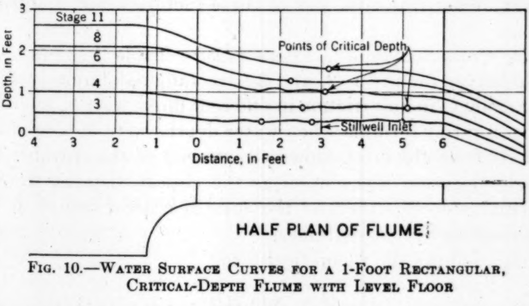

FIG. 10.—WATER SURFACE CURVES FOR A 1-FOOT RECTANGULAR, CRITICAL-DEPTH FLUME WITH LEVEL FLOOR

High-Velocity Flumes (San Dimas Design): Rectangular Cross-Section, Level Flume Floor.—Surface waves occurred in this flume (see Fig. 10), because a level floor does not supply gravitational energy to replace that lost in friction; therefore, the depths fluctuated at about the critical, within the flume. The resulting points lie on either side of a curve represented by the formula,

$$Q = \sqrt{g}\, H^{\frac{3}{2}} \qquad (4)$$

which is the theoretical formula for a broad-crested weir. The rating is unsatisfactory, as deviations of individual points from the curve are as great as 15% (see Fig. 11). Furthermore, addition of débris immediately caused the flow to jump above the critical depth down stream of the transition.

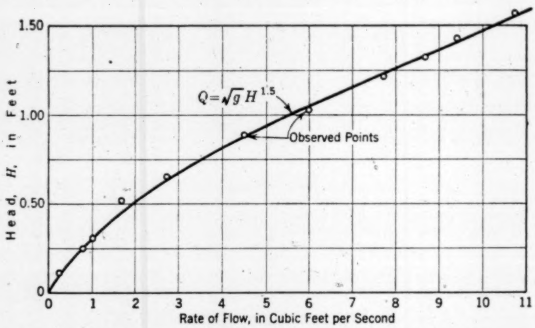

FIG. 11.—RATING CURVE FOR A 1-FOOT RECTANGULAR, CRITICAL-DEPTH FLUME WITH LEVEL FLOOR

As shown in Fig. 10, critical depths lay at points near the middle of the flume, where relatively parallel flow occurred. For the measurement of clear flows it might be feasible to use a flume similar to the San Dimas design, but with its floor set at a critical slope, so that parallel flow would be established at the critical depth and a rational formula might be applied. However, flow in such a flume would be very sensitive to small changes in floor friction or to the addition of silt or detritus, and any of these factors would result in unstable flow conditions.

Rectangular Cross-Section, 3% Flume Floor.—Table 2 shows observed and computed discharges for the 1, 2, and 3-ft rectangular flumes. With a small correction for changes in unit friction in different flume widths, these flumes gave the same general rating formula when water depths were measured at the same distance (3.0 ft) from the crest (down-stream end of the entrance transition). This piezometer location was chosen as the closest distance from the crest, which still remains down stream of the zone of critical depths at the highest water-stages measured in these flumes.

This formula follows the theoretical form,

$$Q = \sqrt{g}\, C B H^{\frac{3}{2}} \qquad (5)$$

in which C = an empirical constant to correct for the effects of floor slope and of energy losses in the flume. Based on present tentative ratings for flumes in

10	2.145	51.43	51.44	+0.01	+0.02

1-ft to 3-ft widths, the general formula is as follows:

$$Q = \frac{1.120\ B^{0.040}}{H^n}\ BH^{1.5} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which $n = 0.179\ B^{0.320}$. Supplying the value for B in 1, 2 and 3-ft flume widths, simplified expressions of Equation (5) are:

For the 1-ft flume:

$$Q = 6.35H^{1.321} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7a)$$

for the 2-ft flume:

$$Q = 13.05H^{1.277} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7b)$$

and, for the 3-ft flume:

$$Q = 19.90H^{1.245} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7c)$$

The corresponding rating curves are plotted in Fig. 12.

On the basis of computed deviations based on stilling-well readings, it is considered conservative to believe that this type of control flume should be at least as accurate for field measurements, especially of débris-laden flows, as any standard measuring device now in use. However, final conclusions as to its accuracy and the applicability of the general formula must be reserved, pending final rating of the flume in smaller and larger sizes.

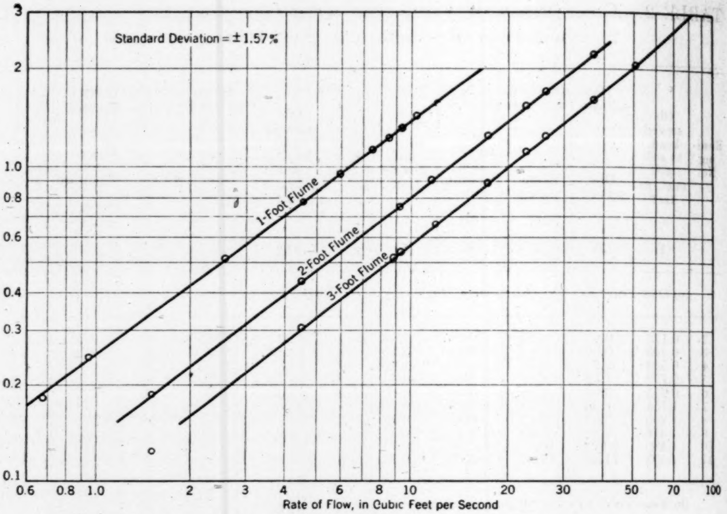

FIG. 12.—RATING CURVES FOR RECTANGULAR, CRITICAL-DEPTH FLUMES

Computed critical depths lie on the curved water surfaces (see Fig. 13) down stream of the transition. A line drawn through these depths is relatively straight, but lies at an angle of approximately 30° from the vertical. These results are similar to the findings of J. G. Woodburn,[9] Assoc. M. Am. Soc. C. E., when he tested broad-crested weirs with a crest slope of 2.6 per cent. In the San

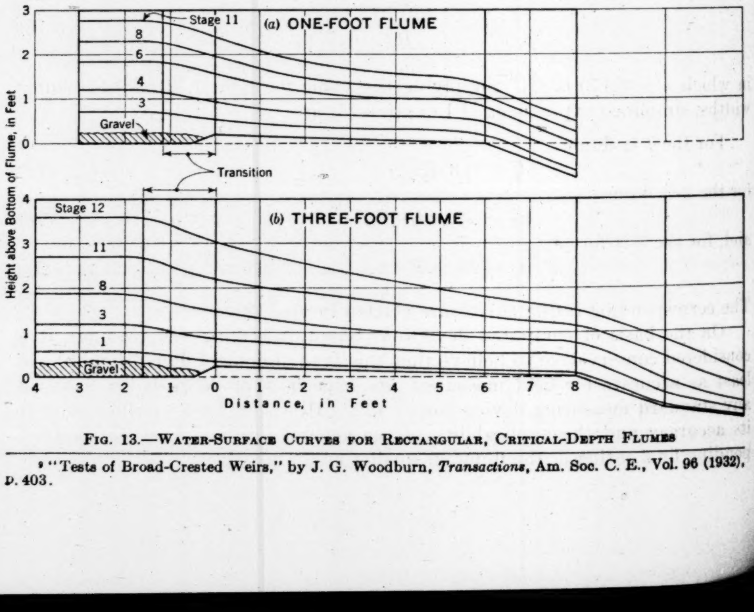

FIG. 13.—WATER-SURFACE CURVES FOR RECTANGULAR, CRITICAL-DEPTH FLUMES

---

[9] "Tests of Broad-Crested Weirs," by J. G. Woodburn, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 403.

Dimas flume, true critical depths, as indicated by the inversion of water-surface curvature (Fig. 13), actually lie closer than computed to a line vertically above the down-stream end of the entrance transition. These locations were roughly verified by computation of the true critical depths, attempting to correct approximately for centrifugal action in curved flow.

The remaining slope from the vertical of a line through true critical depths may be due to shortness of the intake transition. It is believed that critical depths would remain closer to the "crest" if the transition were more gradual. This belief is borne out by the locations of critical depths in the Parshall flume, and on broad-crested weirs with gently sloping ramp approaches, as tested by A. R. Webb, M. Am. Soc. C. E.[10]

The addition of as much débris as could be fed continuously to these flumes had very slight effect on their ratings (see Table 1). All grades of material from sand to angular stones as large as 10 in. in diameter passed through rapidly, with no deposition on the floor. A 4-ft San Dimas flume has been in operation during the rainy seasons of 1935–36 and 1936–37 in a stream in the Experimental Forest which carries bed-loads estimated at quantities up to 10% of the flow. This flume has remained clean of débris deposits and has shown uniform flow characteristics throughout this period. A 2-ft flume, similarly installed, has given excellent records for one season, in a stream carrying heavy loads of material eroded from road fills.

Flow in the experimental flumes was not affected by velocity of approach or by back-water causing a jump within the flume, as long as the jump remained down stream of the stilling-well inlet. In one test, the stream bed up stream of the flume was built up with gravel to a 25% grade. Although there were shooting velocities in this channel section, a jump occurred above the transition, a hydraulic drop within the cylindrical entrance, and measured heads in the flume were identical with those recorded under standard conditions. A hydraulic jump caused by obstacles held in the flume exit also had no effect on depths at the stilling-well inlet.

Trapezoidal Cross-Section, 3% Flume Floor.—These flumes, tested in bottom widths of 0.5, 1.0, and 2.0 ft, exhibited characteristics similar to those of the rectangular flume, in that flow within the flumes remained well below critical depths at all stages measured, and the addition of bed-load apparently had little or no effect upon their rating. However, unstable flow conditions, expressed in surface waves, persisted in this shape of flume at all stages and in all three flume widths. The result was undesirable variation of observed flow from computed flow values. In Table 3, the equations for the 6-in., 1-ft, and 2-ft flumes were:

For the 6-in. flume,

$$Q = 4.40H^{1.53} \qquad (8a)$$

for the 1-ft flume,

$$Q = 9.60H^{1.45} \qquad (8b)$$

and, for the 2-ft flume,

$$Q = 15.10H^{1.45} \qquad (8c)$$

---

[10] "Supplemental Tests—Weirs with Aprons Inclined Up Stream and Down Stream," by A. R. Webb, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), pp. 408–416.

These fluctuations may have been caused by over-abruptness of the conical entrance transition.

Critical depths deviated in this type of flume just as far from the vertical as in the rectangular flume.

SUMMARY OF CONCLUSIONS

Conclusions drawn from these experiments may be summarized briefly as follows:

(1) Construction modifications used in Parshall flumes on the San Dimas area have a negligible effect on their rating. The results indicate that the Parshall flume gives accurate measurements of clear water or flows containing loads of fine material, and is reasonably accurate for measuring large flows with bed-load.

(2) Presence of bed-load substantially influences the rating of Parshall flumes at low stages, although the resulting errors at high flows appear to be small.

(3) No alterations introduced into the Parshall flume succeeded in materially improving its accuracy in measuring small and intermediate flows containing bed-load.

(4) A new design of critical-depth flume was developed, which appears to give accurate measurements of discharge and to be unaffected by velocity of

approach or presence of bed-load. This flume functions as a broad-crested weir in which a cylinder-quadrant transition is used in place of the conventional contraction. Depth measurements are made down stream of the "critical" section, where rapid flow occurs. A tentative rating has been established for three widths and a general formula computed.

(5) Use of this type of flume in conjunction with the present San Dimas stations should make possible the measurement, with reasonable accuracy, of small and intermediate loaded flows which at present fail to be measured because of débris deposition in weir boxes and in the Parshall flumes.

DISCUSSION

R. L. Parshall,[11] Assoc. M. Am. Soc. C. E. (by letter).—The authors have developed an interesting measuring device for the special purpose of measuring flood flow in steep channels where the streams carry heavy bed-loads and high percentages of suspended material.

The name applied to this new measuring flume, perhaps, is somewhat misleading. The flow passes through the section of critical depth at a point approximating the up-stream ends of the parallel walls of the structure. The section, or point of critical depth, varies with the rate of discharge and, as stated by the authors, is not at a definite place. The gage section, as chosen, is considerably down stream from the point of critical depth, and, therefore, the observed values of the H_a head are always less than the critical. It is probable that a better index point for determining the head would be at a point slightly up stream from the upper end of the parallel section where greater depths would exist. For larger values of the head, thus observed, the error in depth measurement then would be less effective in the final computed discharge. This point no doubt has been investigated.

The authors have studied the accuracy of the Parshall measuring flume for their special purposes and report that if the floor of the converging section is made level and the length of this section of the structure is increased, little or no effect will appear in the discharge characteristic of the flume. However, when the floor is sloped to 5% in the direction of flow, the indicated discharge is less than the actual flow. This would be an obvious result because the control is moved up stream from the throat to a point at or near the upper end of the converging section. Moreover, the depth at the standard H_a point would be less because of the higher velocity of the water passing this section. This alteration materially changes the characteristics of flow, and the law of discharge for the standard setting is not applicable, particularly for the shallower depths of flow.

Sufficient data are not presented by the authors in their discussion of results of testing the Parshall measuring flume, under modified settings, to permit complete analysis of their conclusions, "as shown in Tables 1 to 3." The writer finds only one table dealing with the modified flume where the floor in the converging section has been sloped downward. The discharge formula, Equation (3), as stated for the flow through the 6-in. flume, is apparently not for a standard setting. At the hydraulic laboratory at Fort Collins, Colo., this particular size of flume was calibrated where the law of discharge was found to be:

$$Q = 2.06\, H_a^{1.58} \quad \ldots\ldots (9)$$

based on twenty-three observations for discharges ranging from 0.05 to 2.42 cu ft per sec. In this series there were two tests in which the deviation approached 6 per cent. In one case the H_a head was only 0.093 ft, and for this shallow depth it is believed the control at the throat was ineffective; however, the actual difference between the observed and computed discharges was only 0.003 cu ft per sec. For practical purposes this difference is not significant. For the other test in question, the H_a head was 0.217 ft, with a difference in the observed and computed discharges of 0.01 cu ft per sec. Another test in this series with the H_a head at 0.204 ft indicated a difference of only 0.001 cu ft per sec. These slight variations in discharge, for low heads, are thought to be due to the approaching limit of control at the throat for shallow depths. For the remaining twenty tests the mean deviation between the observed and computed discharges was 0.8 per cent.

---

[11] Senior Irrig. Engr., Bureau of Agricultural Eng., U. S. Dept. of Agriculture, Fort Collins, Colo.

An inspection of the data in Table 1 discloses that the 3% slope of the floor of the converging section, in the direction of flow, materially affects the indicated rate of discharge through the flume when based on a standard setting. For the very limited data presented concerning the four tests on the 1-ft Parshall measuring flume, having a sloping floor and carrying a débris-laden flow, the following relation has been found to exist: The gage point, H_a, is practically 3 ft up stream from the crest. At a 3% slope this point is 0.089 ft higher than the crest. When this increment of 0.089 is added to the observed H_a head the standard discharge for these corrected heads agrees reasonably well with the computed discharge shown in Table 1 as based on the San Dimas calibrations.

The development of a measuring device to meet extreme adverse conditions of heavy bed-load carried in the stream, has not yet been fully accomplished. The authors have intimated strongly that the Parshall measuring flume, when operated under the field conditions imposed on the experimental San Dimas Forest area, has failed to register the exact rate of flood-flow discharge. Experience in the field with weirs of various types, as well as the ordinary rating flume, has demonstrated that neither of these devices could be used successfully to measure flood flows such as were encountered in this experimental forest area. There were experimental data, both in the laboratory and in the field, in evidence prior to the recommendation of this type of measuring device for the San Dimas area, which indicated that the Parshall measuring flume did possess characteristics favorable in meeting such adverse conditions of measuring débris-laden stream flow. In the Fort Collins Laboratory numerous observations have been made to ascertain the effect of sand and gravel on the indicated rate of discharge where such débris was carried to, and passed through, the flume. No material effect was noted in the indicated rate of flow because of the fact that any bed-load brought by velocity of approach to the upper end of the structure was readily moved on through it, owing to the convergence of the flow and the increasing velocity through that part of the structure in which the control and measurement of the discharge was effected.

For a number of years, prior to 1937, at the east portal of the Laramie-Poudre Tunnel, 60 miles west of Fort Collins, a 6-ft Parshall flume was operated to measure the flow through this tunnel. The flume operated under adverse conditions as follows: First, the stream from the portal of this tunnel was abruptly turned 90° into a relatively short channel in which the measuring flume was placed; and, second, the excessive quantity of heavy material carried out of the tunnel was moved down and through the flume. Numerous current-meter check measurements had been made of the discharge by official hydrographers and others, which showed the rate of flow as indicated by the flume to be within reasonable approaches of accuracy. In Fig. 14 is shown the condition of flow through this 6-ft measuring flume on July 2, 1932. On July 10, a current meter gaging of the discharge was made of essentially the same flow and degree of gravel deposit, with the thread of the stream flowing along one side of the channel. For this gaging, the mean H_a gage height was found to be 1.18 ft, the computed discharge 31.25 cu ft per sec, and the metered discharge, 32.6 cu ft per sec, with a resulting deviation of about 4 per cent. Under such adverse conditions extreme accuracy cannot be expected.

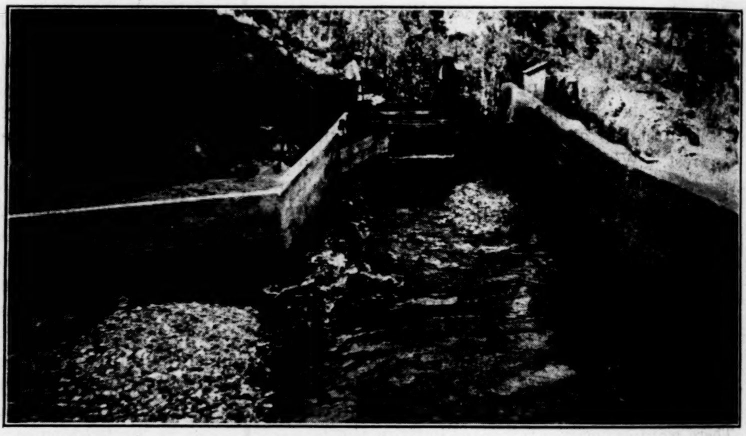

FIG. 14.—CONDITION OF FLOW THROUGH 6-FOOT PARSHALL MEASURING FLUME AT EAST PORTAL OF LARAMIE-POUDRE TUNNEL WHEN MEASURED AND COMPUTED DISCHARGES WERE IN REASONABLE AGREEMENT.

The Parshall measuring flume has been accepted throughout the irrigated Western States as a practical and reliable means of gaging the rate of flow of water diverted from streams and reservoirs under officially decreed rights. It is estimated that there are about 2 500 flumes in operation in Colorado at this time. This measuring flume is widespread in its use and is serving a useful purpose in this, and many foreign, countries for measuring both irrigation and power supplies, in sanitary engineering, and in industrial plants.

The first practical installation of this type of measuring device was a 10-ft framed structure built in the Las Animas Consolidated Ditch, near Las Animas, Colo., in 1926. The successful operation of this first flume resulted in the construction of other larger flumes in the Arkansas Valley in Colorado. These flumes were of reinforced concrete, and ranged in size from 15 to 40-ft throat widths. Prior to the construction of the 40-ft reinforced concrete flume in the Fort Lyon Canal, at La Junta, Colo., the discharge formula,

$$Q = 150\, H_a^{1.6} \qquad (10)$$

was set up for the purpose of designing this structure. After this flume was put into operation (November, 1928), current meter gagings of the discharge were made covering a period of several months. These gagings were made principally by the official State Hydrographer; however, some of the observations were made by the writer and others. This series of meter measurements, which consisted of twenty-three gagings, was found by comparison with the discharge, computed by Equation (10), to be as follows: Twelve indicated a plus deviation and eleven, a minus deviation; for nine of these comparisons, the difference was less than 1% and the maximum deviation for any one of the twenty-three observations was 2.5 per cent. For all flows measured, the submergence was well below the limit of interference. These check measurements of the discharge ranged from about 130 to 1 460 cu ft per sec. A very large number of current meter check measurements of the discharge through other Parshall measuring flumes of various sizes show close agreement between the observed and computed rate of flow.

The authors' report of tests on the newly developed critical-depth measuring flume, under laboratory settings, where the range of flow varied from less than 1 cu ft per sec to more than 50 cu ft per sec, shows marked consistency in the accurate measurement of flow. The practical operation of the flume in the field, for both large and small sizes, however, may indicate some shortcomings, especially where it is required to measure a flow of a few cubic feet per second through a structure having a capacity of more than 1 000 cu ft per sec. Experience with the Parshall measuring flume on the San Dimas Experimental Forest appears to indicate that better results would be obtained by having greater depths and less width of throat.

The writer is much interested in the development of a practical measuring device for the special purpose of gaging flood flows which carry an excessive quantity of bed-load. The authors' investigation of such a new device, to meet these requirements, is encouraging when viewed from the standpoint of laboratory results. There appears evidence, however, that from the standpoint of field experience this new critical-flow measuring flume has not been entirely successful.

MARTIN A. MASON,[12] JUN. AM. SOC. C. E. (by letter).—The accurate measurement of the discharge of streams carrying silt and solid materials has great interest for the hydraulic engineers of Europe, particularly those in Switzerland and the French Alps. Most of the streams in that section are of the nature of mountain torrents, transporting considerable solid material, and are usually characterized by very turbulent flow at high velocity. Because of the intensive power development of the streams the accurate measurement of their discharges is of more than ordinary importance. More or less satisfactory discharge determinations are generally made by the use of current meters at either a natural or an artificial control section; the use of weirs, Parshall flumes, Venturi flumes, and similar devices being precluded, except in unusual cases, on account of their lack of reliability when measuring silt-laden flows. The need for a simple, reliable, and accurate means which may replace current meter methods in the measurement of such flows is recognized; and it is to be hoped that the complete San Dimas investigations will represent, at least, a first step toward the development of such a method.

---

[12] Scientific Aid and Junior Mech. Engr., National Bureau of Standards, Washington, D. C.; Freeman Scholar, 1937, Grenoble, France.

A particularly difficult problem in silt-laden flow measurement was recently presented by the need of gaging the La Sésia torrent, a small mountain stream near Le Sautet Dam in the Préalpes of France. The normal flow of about 2 m^3 per sec (70.63 cu ft per sec), with velocities above the critical, carries solid materials, ranging in size from fine sand to boulders 30 cm or 35 cm (12 in. to 14 in.) in diameter, in quantities varying from 10% to 20%, by volume, of the discharge. In times of flood or melting snow this value may become as high as 50 per cent. If possible, it was desired to establish a gaging flume in the stream which would permit a reliable, accurate determination of the discharge under varying flow régimes.

The lack of information on the performance of such devices under these conditions led to co-operative studies being made at the hydraulic laboratories of the School for Hydraulic Engineers and of Ateliers Neyret-Beylier and Piccard-Pictet, at Grenoble, France, with the purpose of developing a Venturi or a Parshall flume which would function satisfactorily under the unfavorable conditions obtaining in the La Sésia.

These studies did not succeed in the development of a flume of either type which was entirely suitable. It was found at once that the Parshall flume was practically valueless due to the deposition of some of the transported solids, particularly the larger stones and boulders, wherever shooting velocities did not exist. It is interesting to note that exactly the same result was obtained at San Dimas in the tests of the altered Parshall flumes with débris-laden flow. A rectangular flume with converging side walls, designed on the principle that the super-critical velocities obtained would be sufficiently high to carry all the transported solids through the measuring section without deposition, was also unsatisfactory. It was found impossible to attain velocities high enough to keep the flume clean at all stages of flow.

The solution finally arrived at, although it is admittedly crude and susceptible of improvement, is nevertheless of interest for its ingenuity and entirely different approach to the problem from that adopted at San Dimas. A rectangular wooden flume about 13 m long, 3 m wide, and 1.5 m deep (42.7 ft by 9.8 ft by 4.9 ft), was substituted for the natural stream channel in a short section where the slope was relatively small (2 cm per m or 0.24 in. per ft). The stream was led into and away from the flume by rock-bundle transitions. A movable gate was installed at the down-stream end of the flume.

The technique used in making a gaging is as follows: With the flume gate normally open and the stream flowing freely through the flume a deposit of the larger solids carried is formed due to the reduction in velocity in the flume brought about by the reduced slope of the bed. When it is desired to make a measurement of normal flow (that is, no flood conditions) the flume gate is partly lowered, and the increased velocity under the gate scours out the deposited material. With the velocities existing in normal flow this operation requires about 10 min. When the flume is clean, as determined by sounding-rod observations, the gate is completely closed and the measurement begun.

Velocity measurements are taken with current meters at a number of points dependent upon the conditions of flow. No trouble is experienced with deposits forming in the flume during the short time required to make the meter measurements because, with the gate closed, there is a reduction of velocity in the flume causing, in turn, a jump to form some distance up stream. The solid material, with the exception of the finer sand, is thus deposited in the stream bed in the vicinity of the jump, only the now relatively clear water passing through the flume and over the gate. With the reduced velocity obtained and with the measuring section located about 10 m (32.8 ft) down stream of the flume entrance the flow conditions are very favorable to accurate velocity measurements. Upon completion of the gaging the gate is opened, and again free flow through the flume, at a velocity above the critical, takes place. The increased velocity in the stream bed above the flume entrance scours the deposit formed there by the hydraulic jump during the gaging, leaving only the largest of the boulders that have lodged there. These are removed manually from time to time as required.

In times of flood or of melting snow, when the solid content of the stream may become as high as 40 to 50%, by volume, the gaging is made with the flume gate open, correction being made for the deposit in the flume as determined by sounding-rod observations. The error in the measurement of the flow at such times is of the order of 10%, whereas for normal flow conditions the error does not exceed about 5 per cent.

EDWIN S. FULLER,[13] ESQ. (by letter).—Every one engaged in collecting flow data on streams in which the regimen varies with almost every change in rate of flow, should be grateful that an organization of the character of the California Forest and Range Experiment Station should have concerned itself with the task of attempting to develop a stable rating device for use on such streams. Those who have had much field experience in attempting to stabilize the conditions of flow in flood channels can appreciate the difficulties under which the authors of this paper have been, and are, laboring.

When the rating flume studies were inaugurated in 1935 at the San Dimas Experimental Forest, the writer was privileged to witness some of the earlier tests. His first impression upon seeing the various types of rating flumes that had been constructed, especially those in the testing laboratory down stream from San Dimas Dam, was that these structures would form excellent controlling sections for gages located a short distance up stream from the entrance to the rating flume, and that there might be a splendid chance to compare the ratings of gages so located with those within the rating flumes themselves.

Since readings on staff gages in the approach channels up stream from the rating flumes were included in the comprehensive data gathered during the tests, the publication of these data has been awaited with considerable interest, and great disappointment was felt when it was found that data covering water surface heights in the approach channels were not included. However, the determinations of water surface elevations in the approach channels were later furnished to the writer and will be used in this discussion.

---

[13] Hydr. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

It can be demonstrated that for a stable controlling section of rectangular shape, the rating curve for a gate situated a short distance up stream from the "control" section will have the form,

$$Q = K\,b\,H^u \qquad (11)$$

in which u is an exponent equal to 1.5; Q is the discharge, in cubic feet per second; b is the breadth of the rectangular "control" section, in feet; H is the height of the water surface, in feet, above the lip of the controlling section; and K is a constant depending only on longitudinal channel conditions. Such a rating curve, of course, can be defined from a single determination, at any stage of the discharge.

Applying the water surface elevations in the approach channel to the discharges listed in Table 2, rating curves for the 1-ft, 2-ft, and 3-ft rectangular, San Dimas type, rating flumes, were constructed on rectangular co-ordinates. The relation between the ordinates and the sub-tangents for these curves shows that in each case the points can be fitted by curves of the form of Equation (11), if $K = 2.80$ and $u = 1.5$, the deviation in all cases being well within the range of observational errors of the gage readings, which were made on gages marked on the walls of the approach channel, without any provision for stilling. This constant value of the coefficient and of the exponent offers much more promise of accurate extrapolation for the application to larger rating flumes than Equations (7), in which both the coefficients and the exponents vary with the size of the flume. Expressed in the same manner as Equation (11) formulas for a gage 3 ft down stream from the transition may be written from the following:

Width of flume, in feet	K	u
1	6.35	1.321
2	6.52	1.277
3	6.62	1.245

The extrapolation of these formulas up to widths of 50 ft or more, such as may readily be required, may easily introduce serious errors.

One of the causes for this observed variation in coefficient and exponent, of course, is that the stilling-well connections in the three sizes tested were at relatively different distances down stream from the flume entrance, this distance being 3 ft in each of the flumes tested. Had the stilling-well connection been made 3 ft below the entrance on the 1-ft flume, 6 ft on the 2-ft flume and 9 ft on the 3-ft flume, making each flume a model of the others, it is possible that the curve formulas might have shown better agreement for the three sizes.

In the three small rectangular flumes originally tested at the San Dimas Experimental Forest, the approach channel had a flat grade and was three times as wide as the rating flume itself. In all the runs reported by the authors the flow was at depths greater than critical in the approach channel and at depths less than critical in the lower end of the rating flume, passing through critical depth at some point between the transition section and the stilling-well connection section. Obviously, if the rating flumes were long enough normal flow at less than critical depth would eventually be established at some distance below the transition section, this distance depending on the rate of flow. For very low flows in the 1-ft flume, normal flow would be established in the rating flume at, or up stream from, the stilling-well connection. In such a case the ordinary formulas for uniform flow would apply. If the rating curve for a rectangular flume of uniform cross-section and slope is computed by the Manning formula, it will be found to be fitted closely by the formula,

$$Q = K_1 b H^{1.5} \dots\dots\dots\dots\dots\dots\dots\dots (12)$$

which, except for the coefficient, is the same as Equation (11) applying to gage heights observed in the approach channel. This coefficient will be found to depend only on the grade and roughness of the channel, wherever normal flow exists.

It seems, therefore, that the rating curve for a gage located 3 ft down stream from the lower end of the entrance transition section cannot be expressed as a simple parabolic function for the entire range of gage heights. It follows that the method of least squares, involving the assumption of expressions having constant exponents, cannot safely be used in computing the rating curve for a gage located in that part of a stream where the flow is accelerating. This point was illustrated recently in rating a 10-ft flume of the San Dimas type in actual use, when it was found that the discharges, when plotted against gage heights in the rating flume on logarithmic paper, could be fitted by a curved line. The extension of this curved line to higher stages than covered by the discharge measurements showed a wide departure from the straight line derived by the method of least squares applied to the discharge measurements.

The statement is made by the authors that the new design is "unaffected by velocity of approach" (Conclusion (4)), referring to the San Dimas type of rating flume. This statement must be incorrect, since the velocity of approach has a marked effect on the entrance losses and on the rate of acceleration in the rating flume at the stilling-well connection. If the approach velocity were zero, the velocity at the stilling-well connection would be in the zone of acceleration from zero velocity to normal velocity for a flume having a 3% grade. It should be expected, therefore, that a higher velocity of approach, such as would result from decreasing the width of the approach channel, would cause greater velocities at the stilling-well connection for a given rate of flow. This would mean smaller depths and larger discharge coefficients for the rating flume. That this is true has been demonstrated by recent experiments in which the width of the approach channel has been reduced.

Since the velocity of approach has a marked effect on the rating of the San Dimas type of rating flume, it follows that changes in the grade of the approach channel may cause changes in the flume rating. The experiments at the San Dimas Experimental Forest were made with an approach channel having a flat grade. Under these conditions the flow in the approach channel was at depths greater than critical during all the runs reported. In the ordinary flood channels in which some form of rating flume or artificial rating control is required if reasonably stable ratings are desired, the normal slope which has been established by the stream itself is commonly as great as 6% or 8%, the grade depending on some relation between the size of the stream and the nature of the débris being transported by the stream. In such a flood channel the velocities, even at low stages, are usually super-critical, and the depth of flow may be considerably less than critical.

If such a flood channel should be obstructed by a rating flume of the San Dimas type in which the width of the rating flume is one-third that of the approach channel, a hydraulic jump would probably occur at some point above the rating flume entrance, at all except low stages. Under these conditions, for clear-water flow, the rating of the flume might be expected to approximate that determined by the experiments reported by the authors, if the stilling-well connection is situated at a distance down stream from the transition bearing the same relation to 3 ft that the width of the flume bears to the width of the experimental flume whose rating curve is used.

However, with débris-laden stream flow, the conditions at the entrance to the rating flume should be expected to change radically after the construction of such an obstruction as this rating flume would constitute. In such a case any débris picked up by the stream in its upper reaches by the natural processes would be transported by the stream to the point of formation of the hydraulic jump. At this point a typical débris dune would be deposited, which would travel up stream or down stream in the manner typical of traveling débris dunes in flood channels. Eventually, as the supply of added débris became less than the transporting capacity of the stream, the dune would move down stream to the entrance of the rating flume, and would establish itself there with a down-stream face having the normal slope, depending on the relation between the rate of flow and the nature of the débris.

The establishment of such a débris dune at the entrance to the rating flume would tend to cause a change in entrance velocity similar to that caused by narrowing the approach channel, and a corresponding increase in rating-flume discharge coefficient should be expected.

In the experiments at the San Dimas Experimental Forest, débris was introduced by men with wheel-barrows, and at no time while the experiments were being observed by the writer did the dune fully establish itself at the entrance to the rating flume. Under the conditions of those experiments a small quantity of débris was cut away from the edges of the dune by the stream and carried through the flume, which kept itself clean. At no time, however, was the quantity of débris being transported through the rating flume more than a very small proportion of the débris-carrying capacity of the stream in the rating flume. Under these conditions it is not surprising that no serious change in flume rating was observed. To conclude from these experiments that, under natural conditions, débris would have no serious effect on flume rating is by no means safe.

In the case of the 10-ft San Dimas type of rating flume a small landslide occurred a short distance up stream some time after the flume was installed. Together with material dumped in the stream bed during the construction of the flume, this landslide formed a débris dune which was gradually moved down stream by the subsequent small flows of clear water. At the time a test was conducted for the purpose of determining a rating curve for the 10-ft flume the dune occupied a position about 25 ft up stream from the rating-flume entrance. The comparatively large flows used in the early part of this test moved the débris dune rather rapidly down stream until it occupied a position just above the rating-flume entrance. In this position it had rather a marked effect on the nature of the flow through the flume, as it caused the water to enter at an angle with the center line, resulting in cross-currents; and, at times, water "piled up" against the side of the flume opposite the stilling-well connection. Under these conditions it was not surprising to find variations of 10% or more in successive determinations of the stage-discharge relation. At the time the tests were concluded a small quantity of débris had begun to be discharged through the rating flume. At no time during the test was additional débris being added to the stream by further landslides above the rating flume; nor was the quantity of débris being carried through the flume, any appreciable percentage of the flow of clear water.

For the purpose of studying the probable behavior of this 10-ft flume under conditions of larger continuous landslides up stream from the rating flume, the writer constructed a small model and made qualitative studies of its behavior. In these studies the débris used was in the form of fine wind-blown beach sand taken from the back of a large sand dune about one-half mile back from the ocean shore. It consisted of irregularly shaped grains varying in size from about 0.001 in. to 0.020 in. and had a considerable degree of dimensional similitude with the actual débris in the prototype.

In the earlier part of his model tests the writer duplicated as closely as possible the conditions during the period leading up to, and including, the aforementioned rating tests. During this part of the model tests the appearances of conditions in the rating flume were about as previously observed in the prototype.

In the second part of the model tests a large volume of additional débris was introduced in the form of landslides some distance up stream from the rating flume. Under these conditions the approach channel gradually established itself at a uniform grade of about 8% leading down to the rating-flume entrance. This part of the test was concluded when the up-stream face of the débris dune reached the edge of the landslides. During the entire period of this part of the model tests some débris was rolling down the down-stream face of the dune and out through the rating flume, but at no time did the débris passing through the rating flume exceed 1% or 2% of the volume of clear-water flow, and the rating flume remained clean.

In the third part of the model tests a large volume of additional débris was introduced in the form of landslides occurring on top of the down-stream face of the large débris dune formed in the second part of the test, but still at a considerable distance up stream from the rating flume. Under these conditions the toe of the dune moved down into the rating flume to a point down stream from the stilling-well connection and the volume of débris passing through the rating flume increased to about 20% or 25% of the volume of clear-water flow. As the flow of water was decreased to zero, débris remained deposited in the rating flume, and the stilling-well was put out of commission. During this entire part of the model tests the rating flume obviously failed to function as a stable rating device.

These preliminary model tests indicated that the San Dimas type of rating flume is far from being the answer to the engineer's prayer for a stable rating device for shifting flood channels. Further quantitative tests are necessary to determine, first, how far this type of rating flume is from being the desired answer; and second, to find out, if possible, what type of rating device is best adapted to the conditions that must be met in the flood-control and flood-measurement fields. Experiments along this line should be based on the assumption that the best type of rating device will be that which least disturbs the balanced conditions that Mother Nature herself establishes in flood channels.

The most stable natural "controls" for a gage on a débris-laden stream are those in which, at all stages, there is a very slight increase in water-surface slope a short distance down stream from the gage. At such gaging stations there is a very definite relation between the exponent in the rating curve formula and the shape of the cross-section of the stream at the point where the change in slope of the water surface occurs.

The writer gratefully acknowledges the assistance he has received from members of the Los Angeles County Flood Control District, and from the authors themselves, in the preparation of this discussion. Unpublished water-surface elevations in the approach channels were made available through the courtesy of Professor Kotok.

HAROLD K. PALMER[14] AND FRED D. BOWLUS,[15] MEMBERS, AM. SOC. C. E. (by letter).—Débris-laden streams may be divided into three classes: (1) Muddy water in which the débris consists of fine silt, ordinarily considered as that passing a 200-mesh sieve, distributed uniformly throughout the entire cross-section; (2) water carrying a suspended load of coarser sandy material, the bulk of which is carried along in the lower part of the stream; and (3) water transporting rocks which roll and slip along the bed.

Any clear-water measuring device will give satisfactory measurement of the Class (1) stream. The authors state that with a level throat the addition of débris caused the critical point to move down stream, but that with a throat built on a 3% grade the critical point did not move when débris was added. In a throat with a level floor the acceleration of the water is caused by the difference in pressure due to the fall in the water surface. If there is a suspended bed-load which increases the specific gravity of the lower strata, but not of the surface, the force acting on the lower strata will be the same whether or not there is a bed-load. However, the weight of the débris-laden water being greater, this force must act for a greater distance to produce the same velocity. When the throat floor is on a grade, gravity accelerates the heavy water as much as the light water, but since the acceleration is caused by the slope of the bottom and the slope of the surface, the critical point may still be displaced somewhat by the addition of the débris.

---

[15] Res. Engr., Los Angeles County Sanitation Dists., Los Angeles, Calif.

All attempts in the past to make use of critical-depth measurements have failed because of the difficulty of locating the point of critical depth. Near critical velocity there is no appreciable change in energy for small changes in depth, therefore, the water surface is very unstable and the resulting waves interfere with the measurements. Placing the flume on a 3% slope, as the authors have done, causes it to avoid the resulting waves, since the water quickly attains a greater velocity, resulting in a concave water surface with a single point of critical depth. Since this is not at the same position in the throat for all flows, the stilling-well will show critical depth for only a small range of flow. Other flows will require an empirical formula which will apply only to one ratio of channel and throat width.

It is unfortunate that the authors had no way of measuring the quantity of débris added to the stream while making the experiments at San Dimas, because, neglecting other effects, it should at least add its volume to the flow. If the débris consisted of silt uniformly distributed throughout the stream, its only effect on measurements would be to indicate the combined volume of water and silt. If it carried a bed-load in the lower strata, its apparent roughness coefficient in a smooth channel might be slightly greater than for clear water, and it would accelerate more slowly in the throat. If, in addition to the débris carried in suspension, rocks were rolled on the bottom, there would be a further retarding of the flow, with increased uncertainty.

If the change in flow in the throat, due to the addition of débris, is materially different from the change in flow in a smooth channel, a correction for bed-load might be found from a second measurement in a smooth channel about 50 or 100 ft below, after the water surface indicated a stable flow. If the bed-load does not increase the apparent roughness coefficient this second measurement would be useless.

Whatever form the throat and transition may take, the method requires a point of critical velocity which, in turn, is dependent upon a change from mild to steep flow. The mild flow may be produced by means of a jump above the transition if the channel of approach is on a steep grade to prevent deposits of débris, but proximity to a jump is not conducive to accurate measurements. However, considering the past failure to make a successful meter which depended on critical depth measurements, it seems likely that even near a jump a measuring point above the throat would give better results than one near the point of critical depth. This might require a longer transition than the authors suggest, but the writers believe it would be worth trying.

The paper reveals two interesting and important results which have already been established: First, the exact shape of the transition to a Venturi flume is unimportant as long as it does not waste energy; and second, the Parshall flume can be used to greater depths than those covered by previous experiments. This will permit its use in many new places and increase the range for any one flume by using a deep and narrow throat instead of a wide shallow one.

The need for high velocities to prevent débris deposits would require a narrower approach channel than three times the width of the throat. If no measurements are made above the throat it would seem that the channel should be only wide enough to insure critical velocity in the throat at all flows. Probably 25% greater than the throat width would suffice.

As the authors state, they have made only a start and much experimenting will be needed to reach a final solution, and when that solution is found it is probable that the results will be only approximate. Even so, approximate results will be better than those now available, and the problem is well worth solving.

HARRY F. BLANEY,[16] M. AM. SOC. C. E. (by letter).—Results of experiments on the San Dimas flume are presented in an excellent manner in this paper. The complex problem of measuring intermittent débris-laden streams having wide variations in flow has interposed difficulties in mountain watershed studies in Southern California for many years.

Since the Parshall flume was included in the studies made by the authors, perhaps it would be well to call attention to the fact that this flume was not originally designed to measure débris-laden streams, such as exist in the mountain water-sheds, and that heretofore it has been used principally in the valley areas. For many years Parshall measuring flumes of various sizes have been used successfully in California under less extreme conditions than those in the San Dimas Experimental Forest.

The application of flumes to measurements in mountain canyons involves problems not ordinarily encountered in valley areas. The stream gradient is steep (often 10%, or more) and the water tends to cut a narrow channel, travel at a relatively high velocity, and carry a large bed-load as well as a considerable volume of suspended material.

A large flume, for example, placed directly in a stream channel where the grade is as steep as 10% may have a rating curve quite different from the standard calibration. It may pass much less water than that given for the lowest gage heights in the standard tables. The reason for this is that a small stream of water entering the center of a wide flume at high velocity tends to proceed through the center without changing its cross-section greatly, leaving dead water along each side of the wide flume. At high stages, the flume may pass more water than is indicated by the gage height in the standard tables, because of the high velocity of approach across the entire width of the flume. Large flumes, when used under such extreme conditions, should be rated in place.

In connection with some experimental studies in 1931, the writer was confronted with the necessity of measuring stream flows varying from 0.1 cu ft per sec to more than 20 cu ft per sec in mountain areas.[17] In order to measure large winter flows and also to obtain an accurate record of small summer flows, a combination flume such as that shown in Fig. 15 was found desirable. This combination consists of two Parshall measuring flumes, one 2 ft and one 3 in. wide, arranged so that both large and small flows pass through the converging section of the 2-ft flume. The small flows are by-passed from the dip in the large flume into a basin above the 3-in. flume and thence through this latter flume, while the greater part of the large flows continues on through the 2-ft flume. A record of the larger discharges is obtained by a recorder operated by a float in a stilling-well connected to the larger flume, and a record of the smaller discharges is obtained by a flow recorder operated by a float in a stilling-well connected to the smaller flume. Some overlap is provided, so there is a small range during which a record may be obtained from both flumes. Two separate recorders may be used, or one duplex recorder is sufficient if it is desired to record gage heights only. Several combination flumes of this type were installed in the mountain sections of Coldwater Canyon and Devil Canyon, near San Bernardino, Calif. These flumes gave satisfactory results for the few years they were operated.

FIG. 15.—COMBINATION PARSHALL FLUME FOR MEASUREMENT OF WATER AT BOTH HIGH AND LOW STAGES

There are denuded water-sheds in Southern California where no type of flume will measure the débris-laden stream flow accurately. This was demonstrated by the run-off that occurred in the La Crescenta-Montrose area on January 1, 1934.[18]

In 1928, the writer was one of several who suggested replacing a 30-in. rectangular weir with a 12-in. Parshall measuring flume, after the weir had proved to be very unsatisfactory in measuring the run-off from a 44-acre experimental denuded water-shed near San Bernardino. The flume operated satisfactorily under normal conditions but filled with débris when excessive run-off occurred. Some time later it was replaced with a 12-in. San Dimas flume. In February, 1936, this flume was also filled with débris after a heavy rain storm. A larger San Dimas flume has now (1938) been installed, and it is apparently operating satisfactorily under normal conditions. Whether the present installation will or will not solve the problem of measuring flows that carry excessive quantities of bed-load is a question that may be answered when it is put to the same test as its predecessors.

R. L. STOKER,[19] ESQ. (by letter).—Model tests of various modifications of the San Dimas Flume developed by the authors were begun at the University of California at Berkeley, Calif., in 1937, in co-operation with the California Forest and Range Experiment Station. As this type of flume presents an analytical problem that should be susceptible to solution by established methods,[20] it is interesting to make a comparison of the observed and computed water-surface profiles. The following comparison is for the case of clear-water flow through the flume.

The ordinary equations for non-uniform flow in open channels are derived on the assumptions that steady flow exists and that the flow lines possess negligible curvature and slope. These assumptions regarding the flow lines make it possible to express the pressure anywhere in the flow as being greater than atmospheric by an amount equal to the unit weight of the fluid, times the vertical distance beneath the free surface. However, in open channels where the section changes size or shape, or where the bed slope varies abruptly, it is evident that the flow lines are not in conformance with the foregoing assumptions. Nevertheless, in the following discussion, the computations are based on the simplifying assumptions of negligible curvature and slope of flow lines and have been made for a particular run of one of the models of the San Dimas Flume shown in Fig. 16, in spite of the observed conditions shown in Fig. 17.

The particular flume was coated with sand of uniform diameter of approximately 0.02 in. The value of n in Manning's equation was found to be 0.0148 from the formula,[21]

$$n = 0.043\, D^{1/6} \quad \text{(13)}$$

in which D is the mean sand grain diameter, in feet. Various experimenters have obtained approximately this value of n. For example:

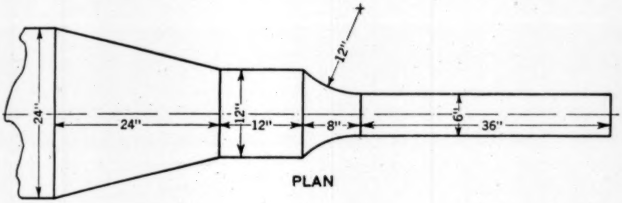
Authority	Manning's n
Strickler[22]	0.039 $D^{1/6}$
O'Brien[23]	0.049 $D^{1/6}$
Chang[21]	0.043 $D^{1/6}$

It is easily shown that the section at the beginning of the part of the flume that is 6 in. wide should act as the control section because the 3% bed slope is substantially greater than the critical slope for the given channel roughness and discharge. The discharge was 0.927 cu ft per sec for the particular run considered herein. Thus, in the computations the critical depth was assumed to occur at the beginning of the 6-in. width, and the back-water was computed up stream and down stream from this section by the specific energy method. The foregoing value of Manning's n was used in determining the energy loss. A comparison of the "observed," "computed," and "frictionless" water surface profiles is shown in Fig. 17.



PLAN

BED PROFILE

FIG. 16

It is interesting to note that although no contraction loss was assumed to occur in the flume transition, the frictionless and observed profiles are at very small variance in the up-stream section of the flume. In closed conduits the entrance loss due to a well-rounded transition is of the order of 2% of the increase in kinetic energy, which appears to be approximately the case in this open channel transition. According to much of the literature, a contraction loss of 10% of the kinetic energy increase is commonly assumed in designing transitions.

The observed and computed profiles are in fairly good agreement except in the immediate vicinity of the control. This would be expected, however, as it is here that the flow lines have their greatest slope, and this influence was neglected by the original assumptions. Some divergence is seen to occur at the free discharge end of the flume, but this is explainable in part because no allowance was made in the computed profile for the draw-down at discharge which is measurable 5 or 6 in. back from the brink.

[23] "The Vertical Distribution of Velocity in Wide Rivers," by M. P. O'Brien, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, 1937.

The good agreement between theory and experiment demonstrated by the example in this discussion indicates the value of applying the same method to all the data presented by the authors. Substantiation of the theoretical method in this manner makes interpolation possible in other designs, other locations of pressure taps, and variations in surface roughness.

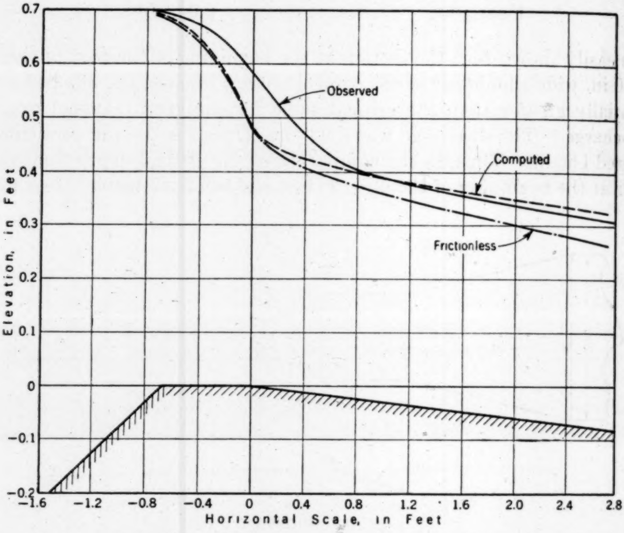

FIG. 17.—COMPARISON OF OBSERVED AND COMPUTED WATER SURFACE PROFILES; $Q = 0.927$ CUBIC FOOT PER SECOND

J. C. STEVENS,[24] M. AM. SOC. C. E. (by letter).—The authors of this paper offer a solution to a perplexing problem wherever the conditions permit the installations indicated. A prime requisite is an abundant drop at the structure. The profiles of Figs. 10 and 13 could not be maintained if the tail-water should cause a hydraulic jump on the bed of the flume and thus deposit much of the débris. A definite drop of substantial proportions below the end of the flume seems to be essential.

It would be interesting to determine some of the characteristics of the hydraulic jump when heavily ladened with débris. With coarse material this may be impossible but with finer sands some data might be secured.

It must be remembered that the Parshall flume was not designed for any such service as it has been subjected to here and it must not therefore be condemned as a measuring device. Its chief field of usefulness is in irrigation systems where, at most, sand or silt and not cobbles are encountered, and also where it is necessary to sacrifice a minimum amount of head. For such service the Parshall flume gives remarkably accurate and consistent results.

---

[24] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

Since the paper was written, the San Dimas Experimental Forest has experienced some floods that have doubtless given these devices a real test. It is to be hoped the authors will take the Engineering Profession into their confidence in discussing the effect of these floods on their measuring equipment.

H. G. WILM,[25] ESQ., JOHN S. COTTON,[26] ESQ., AND H. C. STOREY,[27] ESQ. (by letter).—The writers appreciate the interest taken by members of the Engineering Profession in the San Dimas flume, and are particularly grateful for the numerous constructive criticisms.

Two points regarding this measuring flume should be made clear, perhaps, as several discussions indicate some misconstruction of the writers' claims for it. In the first place, it has not been intended that this flume should supplant the well-known and widely used Parshall flume. The latter, as testified by its widespread adoption, is ideally adapted to use in measuring streams of relatively low gradient, in which conservation of available head is of prime importance and in which any transported material is fine enough to be moved by the low velocities characteristic of these streams and of the Parshall flume.

Stream velocities in mountain channels, on the other hand, are the result of relatively high gradients, and, ordinarily, are greater than critical. It is known that débris transportation is a function of some relatively high power of velocity. Therefore, in measurement of high-velocity streams it would seem scarcely logical to expect accurate results from any measuring device that is dependent upon the maintenance of sub-critical velocities in the measuring section.

The writers' experiments have been directed entirely toward the development of a flume characterized by super-critical velocities, but with a "critical" section close enough to the piezometer orifice to provide stability of rating. It is their belief that a flume of the San Dimas type satisfies these requirements. A long series of carefully controlled model studies, using a 6-in model of 1-ft, 2-ft, and 3-ft San Dimas flumes, as well as field observations since the original experiments, have demonstrated that the final design for this flume provides a remarkably consistent and accurate relation of pressure to discharge, very low transition losses, and an excellent degree of stability in rating even when it is subjected to variations in approach velocities or back-water conditions. For about 330 runs, computed discharges showed an average deviation of ± 1% from observed discharges.

As a second point, the writers have made no claim that a flume of the San Dimas type has unlimited capacity to measure flows containing unusually high débris contents. Flow velocities in this flume do not exceed 12 or 13 ft per sec even at high stages, and the load-transporting capacity, therefore, has this definite limit. Furthermore, it is doubtless possible that high concentrations of load affect hydraulic characteristics of flow. Under such conditions it would be too much to expect that any standard rating would continue to apply.

[25] Associate Silviculturist, California Forest and Range Experiment Station, U. S. Forest Service, Glendora, Calif.

[26] Engr., Federal Power Comm., San Francisco, Calif.

[27] Junior Geologist, California Forest and Range Experiment Station, U. S. Forest Service, Berkeley, Calif.

The writers' claim is simply this: That the San Dimas flume greatly extends the range of flow that can be measured with a reliable degree of accuracy in mountain streams.

Mr. Parshall and Messrs. Palmer and Bowlus suggest that a measuring point taken just up stream of the "critical" section would be better than that chosen by the writers. At the point suggested there is a considerable degree of flow curvature with its accompanying centrifugal forces, so that depth and pressure measurements deviate from each other, and the rating should be correspondingly undependable.

Mr. Parshall cites a good case of the Parshall flume having given accurate measurement of loaded flows. Accuracy of measurement depends largely upon movement of load at a velocity close to that of normal flow through the flume. Accordingly, the usability of any flume is determined by the relation between normal flow velocities in the flume and in the stream above, and by the concentration and "particle" size of the transported material.

Sixteen Parshall flumes installed by the U. S. Forest Service on the San Dimas Experimental Forest have been observed for four to five seasons and rated as well as can be expected under the difficult conditions imposed by loaded flows. As nearly as can be ascertained, all these flumes have produced discharges for any given depth considerably in excess of the standard rating. Although the over-rating percentage varies considerably with changing conditions of approach channel and bed deposits, it averages approximately 30 to 40 per cent. The reason for this fact is the deposition of bed-load within the flume proper to a gradient approximating that of the approach channel. Therefore, approach velocities continue through the entire flume, depths (even including the deposit) are lower than standard, and no critical section is present. Table 4 gives a comparison of standard discharge values and approximate actual discharges in a 30-ft and a 10-ft Parshall flume during the

(b) FACING UPSTREAM

FIG. 18.—THREE-FOOT SAN DIMAS TYPE OF FLUME, SAN DIMAS EXPERIMENTAL FOREST, MARCH 18, 1938

Mr. Blaney states that Parshall flumes in natural channels should be rated in place. This statement is certainly true, as demonstrated by the writers' experience, although it means that under such conditions the flume becomes no more than a rather costly control section. The writers, and doubtless other mountain hydrographers, would like to learn an accurate method of making such a rating. It should be remembered that many mountain streams are characterized by very flashy peak flows containing all kinds of débris, up to and including boulders, limbs, and even occasionally whole trees.

Mr. Parshall states that by the addition of 0.089 ft to the observed H_a-heads, "the standard discharge for these corrected heads agrees reasonably well with the computed discharge shown in Table 1 as based on the San Dimas calibrations." In Table 5, the writers have made the suggested change, and the resulting deviations still do not seem reasonable in magnitude. This correction would be valid if the values in question were measurements of total head (pressure + velocity head), and if friction and other losses were neglected; but the measurements involved are of pressure alone.

TABLE 5.—EFFECT OF DÉBRIS-LADEN FLOWS UPON MEASURING FLUMES
(Comparison of Observed and Computed Discharges in One-Foot Parshall Flume with Floor on 3% Grade)

1.456	1.545	9.76	7.08	−2.68	−27.5

Mr. Stevens asks that the writers describe the behavior of San Dimas Experimental Forest gaging stations during the storm ending March 3, 1938. That of Parshall flumes has already been described. San Dimas flumes, 3 ft wide, had been installed in six small gaging stations at the beginning of the 1937–1938 rainy season. These stations behaved perfectly up to the final peak flow of March 2, when four of the six were inundated and buried in a deposit of brush, boulders, and trees. The remaining two gave a complete record of the storm. For example, in the two views of Fig. 18, note the lack of deposited material either within the flume or in the approach channel, although in the storm of February 27 to March 3, 1938, about 400 cu yd of débris passed through this flume into the reservoir below.

San Dimas flumes, 2 ft and 3 ft wide, had also been installed in nine large gaging stations for the measurement of relatively low storm flows containing bed-load. These flumes were overtopped repeatedly, and most of them were finally put completely out of operation by boulders or trees too large to pass through.

During the major part of the storm, flow records were obtained from the adjoining large Parshall flumes by visual observation of velocities and recording of depths. Two of the 3-ft San Dimas flumes, over each of which about 2 000 to 2 200 cu ft per sec of peak flow had passed, cleaned themselves as the flow dropped and automatically went into operation at the end of the storm (see

Fig. 19). These two flumes, although badly battered, simply happened not to have been clogged by boulders or trees.

Mr. Mason describes an original, and apparently effective, technique for the gaging of very heavily loaded stream flow. Such a method would doubtless be the only possible method of measuring flows loaded beyond the range of a flume of the San Dimas type. Incidentally, Mr. Mason's observations verify the writers' conclusions as to the inadequacy of Parshall flumes in the measurement of high-velocity, heavily loaded stream flow.

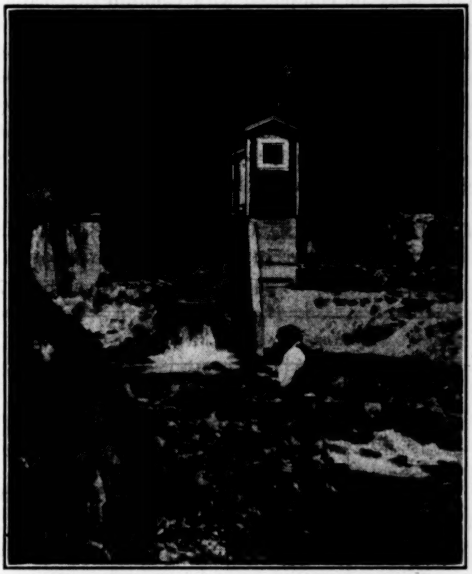

FIG. 19.—THREE-FOOT SAN DIMAS FLUME IN THE DOWN-STREAM END OF 15-FOOT PARSHALL FLUME; VIEW FACING UP STREAM, TWO WEEKS AFTER STORM OF FEBRUARY 27 TO MARCH 3, 1938

Mr. Fuller outlines a useful and valuable method for gaging streams when a stable section is available and cost requirements prevent the use of a critical-depth flume. His method can be nicely demonstrated as valid for stable sections. However, the measurement of depths up stream of such sections is believed by the writers to be subject to inaccuracies, due to changing bed deposits with changes in stream velocity at various stages. The San Dimas type of flume, on the other hand, provides a stable measuring section, characterized by high flow velocities and controlled by a "critical" section up stream and a free over-fall below the point of measurement.

Attention is drawn by Mr. Fuller to the variation of coefficients and exponents in the San Dimas flume with variations in flume width. He fails to note that this variation is an exact function of width, caused doubtless by variations in energy losses due to width variation. Under frictionless conditions discharge would be expected to show an exact relation to flume width.

Incidentally, the San Dimas flume might be considered simply as a broad-crested weir, in which depths are measured directly on the crest instead of up stream. In this case, it is easily seen that successively greater widths of weir do not have to be considered geometric models of each other as to total length and point of pressure measurement, in order to produce the same discharge per unit width.

According to Mr. Fuller, rating points for a 10-ft San Dimas flume installed by the Los Angeles County Flood Control District, formed a curved line on a log-log paper. Therefore, a least-squares formula could not be fitted to these data. Table 6 contains rating data kindly supplied by the Los Angeles County Flood Control District for this flume, based on several accepted hydrographic methods. These methods show some variation among themselves, due to the difficult conditions of measurement and the volume of transported material. They may be compared with Column (5), Table 6, however, showing values computed by extrapolation of data from the San Dimas model flume. The computed flows agree excellently with observed values obtained by Pitot-tube traverses which, of the various methods used, should provide the most reliable data. The observed values by Pitot tube can be fitted just as well by a straight line as by one which is slightly curved, and there would appear to be no more reason for charging the apparent slight curvature to the flume's characteristics than to errors of measurement.

TABLE 6.—PACOIMA CREEK BELOW PACOIMA DAM; SUMMARY OF RESULTS, TEST OF SAN DIMAS TYPE OF RATING FLUME

(Date of Test, November 17, 1937)

RATE OF FLOW, Q, IN CUBIC FEET PER SECOND					Mean gage heights, in feet †
By Pitot Tube			By current meter at 0.6 of depth	By formula, $Q = 84\,h^{1.16}$

* Pitot-tube measurements, each with thirteen vertical velocity curves, not computed.

† By tape in well; stilling-well connection, 4.5 ft down stream from transition.

Mr. Fuller states that "velocity of approach has a marked effect on the rating of the San Dimas type of rating flume." Theoretically, velocity of approach should have no effect, although deviation of practice from theory makes it also true that marked changes in approach velocity may have, not "marked," but some, effect on the flume rating. This phenomenon is logically caused by displacement of the location of critical depths, as a result of varying approach velocities.

In the San Dimas flume, however, depths (and pressures) at the measuring point are controlled not only by the location of the critical depth, but also by the over-fall down stream and by the floor slope of the flume. Accordingly, they are affected much less by horizontal displacement of the critical depth, resulting from increased approach velocities, than are depths up stream of the critical section. This fact is well illustrated by Mr. Stoker's analysis, showing a comparison of theoretical and actual water surfaces. It will be noted that, although the critical depth actually lies considerably down stream of its theoretical location (neglecting centrifugal effects), computed and actual water surfaces agree very closely at the piezometer location (1.5 ft in Fig. 16).

Mr. Fuller states that the San Dimas experiments were made "with an approach channel having a flat grade." On the contrary, floor gradients as steep as 4% were used for the approach channel, and, in one run, the channel was built up with heavy gravel to a 25% grade. These alterations had no measurable effect on pressures measured at the piezometer point. As another test of the effect of approach conditions, in the 6-in. model a standard obstruction was introduced into the approach channel during each experimental run. This obstruction consisted of a metal plate, about two-thirds of the channel width, placed at one side perpendicular to the direction of flow. It caused a violently changed flow direction and increased the approach velocities. The resulting effect on discharge, based on the average of right and left piezometer readings, did not exceed 4% of the true volumes.

It is true that, in these model studies, flumes having an approach channel narrower than in the original design showed higher discharge coefficients. It is probable, however, that this result was caused more by an improved and longer entrance transition than by increased velocities in the approach channel.

Mr. Fuller concludes his discussion with a description of qualitative studies made with a small model of the 10-ft San Dimas flume. The model (0.1 ft wide) had a geometric scale ratio of 1 : 100 in dimensions, and 1 : 100 000 in discharge. The relative friction was probably unknown. The writers' feel that too much credence should not be placed in results from such a small-scale model, especially in studies of débris movement, the hydraulic characteristics of which are little known. In any case, as stated previously, the writers recognize that any measuring device has limitations and do not claim the San Dimas flume to be capable of measuring landslides.

Messrs. Palmer and Bowlus present a neat analysis of flow phenomena in a critical depth flume. As indicated in their discussion, variations in approach velocity or bed-load content should be expected to cause some horizontal displacement of the location of critical depths. Such displacement has been demonstrated (see Mr. Stoker's discussion and the writers' comments on it) to have little effect upon pressure measurements at the standard piezometer location.

Messrs. Palmer and Bowlus comment on the advisability of a narrower approach channel than three times the flume width. As a result of the writers' model studies in co-operation with the University of California, a final design has been adopted in which the approach channel is twice the width of the flume proper, rather than three times. The entrance transition has been kept cylindrical in form, but with a radius twice the flume width instead of equal to it. This flume has very satisfactory flow characteristics, with little turbulence and entrance losses computed at less than 2 per cent. A sketch of the present design is presented by Mr. Stoker in Fig. 17.

The writers are personally acquainted with the tandem Parshall flume installation described by Mr. Blaney. In the stream in question, very little bed-load is transported except by unusually high peak flows. In the senior writer's experience, the installation functioned quite adequately—except in measurement of such high flows—as long as the approach channel was kept shoveled out to provide reduced velocities of approach.

The 3-ft San Dimas flume mentioned by Mr. Blaney functioned perfectly throughout the great storm of March, 1938. Although a heavy load of sand and gravel was carried through this flume into a small reservoir below, at no time were deposits formed in the flume, and it was perfectly clean at the end of the storm.

The question has been frequently raised as to actual contents of transported material in flows measured through San Dimas flumes. These contents are necessarily unknown as the writers are acquainted with no means of determining them accurately; they have been estimated, however, at values as great as 15 to 20% of solids.

THE VALUE OF WATER TRANSPORTATION

By Rufus W. Putnam,[1] M. Am. Soc. C. E.

Synopsis

The completion, within the past decade, of the slack-water improvement of the Ohio River, the connecting of the Great Lakes to the Mississippi River *via* the Illinois Waterway, and the near completion of the Lower Missouri and Upper Mississippi projects give rise to a series of questions for which approximate answers might be found. When this 3 500-mile system of trunk inland waterways is completed what will have been the cost to the public of these facilities for commerce and what will be a fair approximation of the annual fixed charges and of maintenance and operation costs? To what extent and in what manner has this business of water transportation developed? How much traffic will have to be developed in order to reimburse the public treasury for the expenditures made?

These and other questions of like application the writer endeavors to answer in an effort to satisfy his own mind as to whether there is any value to water transportation.

Historical

The regional plan of the Mississippi Valley, as it is known to-day, is the direct result of the necessity of using its rivers to transport persons and goods during the early period of exploration and development. Access to the great domains which the early explorer claimed in the name of his sovereign, was had by way of the national water routes then existing; while the development of that rich territory was almost entirely dependent upon the use of these routes by the traders. Thus, water transportation had an early and continuing influence upon the political and economic growth of a large portion of the area lying between the Allegheny and the Rocky Mountains.

Before the introduction of the steam engine as a means of propelling vessels, the rivers of the Middle West were navigated first by canoe, and, later, by keel boats, flat boats, and a few sailing vessels. The commerce of these early days was largely a down-stream movement because, with the keel boats and the flat boats, down-stream movements were made with the current and up-stream journeys by man power. Cargoes were shipped from Pittsburgh, Pa., for instance, to New Orleans, La., and there the boats were taken apart and sold for what they would bring as lumber. Sailing vessels never were a success for river navigation in those early days because the channels were not buoyed or otherwise marked, and groundings and more serious disasters were too frequent to warrant any extended use of this type of vessel.

A few years after the introduction of steam as a means of propulsion (about 1810) the boats in use soon reached a degree of efficiency and reliability that permitted their being operated economically for up-stream as well as for down-stream traffic. The river settlements then began to increase in number and size; trade between various parts of the Mississippi Valley and the Gulf thrived; and New Orleans became the focal point of most of the domestic and foreign trade of the Middle West. By 1860, for example, there were about 3 600 arrivals and departures of river "packets" each year at that port, with more than 750 vessels of that type in commission on the Mississippi and Ohio Rivers.

---

[1] Pres., Maritime Eng. Corporation, Chicago, Ill.

While water transportation was thus in its prime and had already determined the plan of development of the Mississippi Valley, rail transportation was still in its infancy. This new method of transportation found the framework of the economic structure of the country fairly well outlined when it became strong enough to become effective; it is only natural, therefore, to find that the first railroads were initially feeders to river ports as well as to seaports. As a result, the river communities received a further impetus in their development which was reflected in increased commerce on the rivers and also in greater stability of the regional plan for the interior, based on the rivers themselves.

When the rail lines between the Middle West and the Atlantic seaboard were completed traffic which formerly was routed by river to New Orleans and thence by vessel to export trade and to Eastern ports was diverted from the river routes to the direct rail routes to the East, and what began as a battle between two groups of ports resulted in serious injury to water transportation in the interior. Shortly thereafter came the completion of rail lines located parallel to the river lines; the latter were faced with a competition that they could not meet; and their general demise was then only a matter of time.

During the greater part of this period of thriving river traffic, the physical improvements to the inland water routes of the Valley were limited to projects for canal construction, undertaken by some of the States, with some Federal assistance, and some canals built by private undertaking. The main arteries of commerce, the rivers, were left as Nature made them. Many sections of the rivers, therefore, were impassable during low water; channels were unmarked; and snags were a constant menace. Apparently, it was not until after rail transportation had gained the upper hand in the struggle for carrying the commerce of the Mississippi Valley that a sincere effort to avoid the inevitable was made on the part of interests which had considerable investment at stake. It is somewhat significant that the first comprehensive undertakings for the improvement of the major inland water routes were not begun until the decade of 1870 to 1880, when projects for the betterment of navigation conditions on the Mississippi, Missouri, and Ohio Rivers were adopted by the Congress of the United States.

Even had they been promptly and effectively carried to completion, these improvement programs were begun too late to save the "packet" system of river transportation. Outmoded and obsolete, it had no place in the modern system of moving goods and passengers, and was due for death regardless of what might have been done to prolong its life. Nevertheless, although this particular method of transportation became practically extinct, there must have been something of the nature of John Brown in it for "its soul went marching on." Generations of men had made their living on the rivers, or were in some other ways directly dependent upon them; and they not only preserved the faith but they were determined that, somehow or other, river transportation would be returned to them if only the program of extensive improvement of navigation conditions could be completed. In this manner the river projects, launched well after the decline in the "packet" business had begun, were intermittently promoted until a new impetus came along and provided enough additional energy to bring them to their present state of near completion.

Navigation interests desirous of securing improvements on the Mississippi and Missouri Rivers were aided greatly in their efforts to obtain Federal appropriations for river works by two influences only partly related to water transportation. The great damages resulting from floods focused national attention on the general improvement of these streams from an entirely different angle, and, in addition, there was a desire to stabilize the banks which were quite subject to erosion during even intermediate and low-water stages. The alliance of the three interests involved in the control of these rivers has proved sufficient in recent years to insure the prompt execution and early completion of a program designed to serve them all.

The betterment to navigation conditions which has resulted from these programs of improvement to the rivers in the Mississippi Valley has permitted an efficient development of methods of water transportation which are entirely different from those of the packet-boat days. Passenger traffic (except for the excursion variety) has disappeared entirely. Freight traffic, which is now greater in volume and value than it was during the days when water transportation was the chief reliance of the commercial interests of the Mississippi Valley, is handled almost exclusively in large tows consisting of a number of barges adapted to carry the particular commodities which they are engaged in transporting, and pushed by towboats of ample power to handle up-stream as well as down-stream traffic. Naval architecture and marine engineering have made great progress with respect to the design of equipment suited to the various requirements of the water-transportation service. It is quite evident, therefore, that in treating the subject of present-day inland-water transportation in the Mississippi Valley one is dealing with facilities and equipment wholly different from those in use when the basis for the commercial and industrial framework of the interior was laid during the first half of the Nineteenth Century.

EXISTING WATER-TRANSPORTATION FACILITIES

Routes.—Of the 15 000 miles of rivers in the Mississippi Valley, said to be susceptible of improvement, only the main north and south and east and west arteries are under consideration in this paper. These arteries include the Mississippi River below Minneapolis, Minn., the Illinois Waterway from Chicago, Ill., to the Mississippi; the Ohio River; and the Missouri River below Kansas City. These comprise about 3 500 miles of completed or projected 9-ft channels. It is believed that all the more important factors involved in the problems affecting inland water transportation will be developed by thus limiting the scope of discussion. Improvements and operations on the tributaries are not sufficiently different from those on the main routes to justify their inclusion. A notable exception is to be found in the case of the improvement of the Tennessee River System by the Tennessee Valley Authority, but the basis of that project, as it is now (1937) being undertaken, is so fundamentally different that it is in an entirely separate category from that into which the projects herein described naturally fall.

The total expenditures chargeable to capital improvements for navigation on these main routes amounts roughly to about $550 000 000 to date (1937); and it appears that approximately $100 000 000 will be required to pay for the works necessary to complete these projects. The cost of maintenance and operation has been estimated to amount to $10 000 000 per yr.

Terminals.—With the exception of the Great Lakes cities of Milwaukee, Wis., Detroit, Mich., Toledo, Ohio, Cleveland, Ohio, Buffalo, N. Y., and the inland City of Indianapolis, Ind., all the great cities of the Middle West are situated on this trunk system of inland waterways. As a result extensive facilities have been provided at many places of importance for the transfer and storage of freight handled over these navigation routes. Pittsburgh has extensive equipment for unloading coal from the Monongahela River; its steel mills have ample arrangements for loading steel on to barges destined for points on the Lower Ohio and Mississippi Rivers. Coal-loading points have been established at Colona, Pa., Huntington, W. Va., and Ashland, Ky., on the Ohio River, and terminals for the receipt of water-borne coal have been provided at Cincinnati, Ohio, Louisville, Ky., and Evansville, Ind. Facilities for handling steel, pipe, petroleum products, building materials, and miscellaneous cargo are available at some of the aforementioned points, as well as at Paducah, Ky., and at Cairo, Ill.

On the Lower Mississippi River, equipment is available at all the river cities of importance for the handling of water-borne commerce of all kinds including, in addition to those mentioned, cotton, sugar, sisal, bauxite, bulk cement, molasses, and grain. On the Illinois Waterway System, only recently completed, facilities are available for the loading of grain at many points, of miscellaneous cargo at Peoria, Ill., and at Chicago, Ill., and of coal at Havana, Ill. On the Upper Mississippi River municipal terminals have been provided at Davenport, Iowa, Rock Island, Ill., Dubuque, Iowa, and St. Paul and Minneapolis, Minn.; and Kansas City has recently provided itself with terminal equipment to serve the barges navigating the Lower Missouri River.

Substantial investments have been made at all these terminal points and at many others. The writer has no knowledge of any cumulative estimate of the cost of all these facilities; the mere recital of them should be sufficient, however, to give an indication of the comparative magnitude of some of the elements of the subject under consideration.

Transport Equipment.—A study of the latest published Government report on the subject shows that the commercial fleet in active operation during 1935, on the main inland water routes under consideration in this paper, consisted of about 540 towboats and 2 340 barges. The aggregate installed horsepower in the towboats approximated 176 000; the carrying capacity of the barges totaled about 1 600 000 tons. Details as to size and type of towboats appear in Table 1. The replacement cost of this fleet (allowing $200 per 1 hp for towboats and $20 per ton for barges) approximates $67 000 000. More than 1 700 of the barges are built of steel.

In 1935, there were twelve operators, each having in active service one or more towboats with a total of at least 2 000 hp and barge fleets of 10 000 tons or greater carrying capacity. These operators had 87 towboats with an aggregate installed horse-power of about 85 000 and 937 barges with a total carrying capacity of 911 000 tons. About one-half the total equipment in active service was thus operated by twelve major transportation companies. The towboats in use by these companies had propulsion equipment averaging almost 1 000 hp and the barges in use averaged nearly 1 000 tons in carrying capacity. It is appropriate, therefore, to assume the use of units of these sizes, or greater, in a study of modern inland waterway transportation costs.

As with other methods of transportation the cargo carriers are adapted to the kinds of commodities carried. Barges for carrying coal have been largely standardized, and are built to dimensions best suited for easy passage through the locks on the waterways they are required to traverse. These are open top barges and are suitable for the transportation of any other type of dry bulk cargo which does not have to be protected from the elements. Sand, gravel, and crushed stone are usually carried on deck barges, to permit draining if wet, and also because the greater weight per unit of volume of this class of material results in the requirement of less cargo space to obtain project draft. Special tankers have been developed for the transportation of liquids of different kinds, although in some cases liquid cargo is carried in side and bottom tanks built into barges primarily designed for carrying miscellaneous cargo.

One of the barge lines which transports more miscellaneous cargo on inland rivers than any other operator has been prominent in the development of the modern type of barge for the transportation of freight of that character. These barges have been standardized in two sizes. For operations on the Lower

Mississippi River, where a full 9-ft channel is available, barges designed to carry 2 000 tons are used extensively. (Each barge carries 2 000 tons of freight with a draft of 8 ft. The average running time for a tow, including all stops, is 8 days from St. Louis to New Orleans, and 15 days on the return trip.) The hull of the barge may be used for grain or for miscellaneous cargo; the cargo house which is built on top of the hull is also used for package freight of various kinds. Hatches and side doors have been standardized as to dimensions and as to spacing, and correspond closely with the door spacing at the terminals. Barges in this trade on the Upper Mississippi River and into Chicago (where vertical clearances are controlling) are similar in design, but built on a smaller scale.

Self-propelled barges are somewhat rare on the Mississippi System of waterways; quite contrary to practice on the canals and other waterways in the East. One barge line had three in service as express boats for several years, operating between St. Louis and New Orleans. They were self-contained units carrying about 1 600 tons of high-class freight on a draft of 7 ft. Although they made fast time in navigating, too much time was lost at the terminals, with the result that they were taken out of service in 1935.

Traffic.—Without going into details it should be sufficient for the purposes of this paper to state that the traffic carried on each component of this main system of inland waterways has been much greater in recent years than during the period when water transportation was the only means of transporting large quantities of freight over long distances. Furthermore, there has been substantial growth of traffic since the projects for the improvement of these routes have been nearing completion. Excluding the traffic on the tributaries, the total water-borne commerce on this system in 1915 approximated 15 000 000 tons; it now (1937) totals about 30 000 000 tons per yr. A large proportion of this movement is over a comparatively short haul and is composed of coal and building material on the Ohio River. The average haul has been gradually increasing, but whether this will continue is problematical, as an important factor in this tendency has been the rapid development of long-distance traffic, during the past 10 to 15 yr, over the Mississippi River routes.

WATER-TRANSPORTATION COSTS

There has been sufficient experience with reference to the cost of constructing and operating water-transportation equipment since about 1920 to make it possible to reduce this experience to useful data for those interested in the subject.

Equipment Costs.—Although there appears to be a wide variety in costs of towboats this is due largely to differences in size or class of operating machinery. The more modern type of steam towboats will be found to vary in cost, roughly, as follows:

Range of indicated horse power	Cost, in dollars per indicated horse power
500 to 1 000	250
1 000 to 1 500	225
1 500 to 2 000	200

Towboats using Diesel engines are usually slightly higher in cost. The foregoing data apply to installations with direct drive; if electrical drive is provided, the costs are higher. There is also a wide range in the costs of barges, but they may be grouped, roughly, as follows:

Type of barge	Cost, in dollars per ton of cargo capacity
Hopper type	15 to 20
Deck barges	18 to 25
Package freighters	30 to 40

Fixed Charges.—An approximate idea of the fixed charges which are usually applied to barge operations may be gained by reference to Table 2.

TABLE 2.—FIXED CHARGES IN BARGE OPERATION, AS PERCENTAGES OF THE TOTAL COST

Description	Towboats	Barges	
		Bulkers	Package freighters
Interest	6	6	6
Depreciation	5	6	4
Insurance	3	2	2
Taxes	2	2	2
Annual overhaul	2	2	2
Total fixed charge*	18	18	16

* Percentages of total cost.

Operating Costs.—Such costs include the items of wages, food, fuel, lubrication, repairs to towboats, repairs to barges, superintendence, and miscellaneous.

The wage item depends upon the size of the crew employed and also the locality in which the operations are conducted. One barge line pays an average of about $3 per man per day. Its operations extend throughout the entire stretch of the Mississippi River below St. Paul, and the crews on the towboats vary in number between 20 and 30 men. In the Pittsburgh District wages have averaged as high as $6 per man per day. The operators in that vicinity, however, have been able to use fewer men in the crews (normally, about twenty men on a towboat with a capacity of 1 500 ihp). Rates on the Upper Illinois River vary between $4 and $5 per man per day, and the crews more nearly correspond in number with those in the Pittsburgh District.

Subsistence costs vary between $0.55 per man per day for the barge line mentioned to as high as $1.10 per man per day in the Chicago District. Pittsburgh rates are in the vicinity of $0.75 per man per day. These rates depend upon the number of men employed and upon the availability of good markets.

Fuel costs vary in different parts of the country. In the Pittsburgh District coal is generally cheaper than fuel oil, whereas on the Mississippi and Illinois Rivers fuel oil has the advantage. Fuel oil requirements are best expressed in ton-miles of cargo transported per barrel of fuel. For steam towboats this factor averages about 2 600 ton-miles per bbl of fuel for oil-burning steamers and about 4 800 ton-miles per bbl of fuel for Diesel engines.

These performance data apply to operations in still water where ample depths are available.

Lubricating costs for steam towboats average approximately 3 mills per ihp for each full day of service. For towboats equipped with Diesel engines the cost of lubrication is about 8 mills per ihp per day for a two-cycle engine and about 4 mills per ihp per day for a four-cycle engine. These values are based on the use of a centrifuge for cleaning the oil and a price of $0.60 per gal.

Part of the total cost of repairs to towboats is included as a fixed charge under the caption, "Annual Overhaul." In addition, repairs throughout the season for steam towboats cost on an average of $0.03 per ihp per day and, in the case of Diesel engine installation, this cost is about $0.04 per ihp per day.

The cost of repairs to barges depends largely upon the service for which they are used. If used for handling bulk cargo, which is unloaded by heavy machinery, the total annual costs are comparatively higher than in the case of package-freight barges on which lighter materials are unloaded by hand. These two services represent the extremes, and repair costs will be found to vary, therefore, between 1% and 5% of the first cost of the barges.

Costs of superintendence vary with the character of service and the territory covered. A check of the various operations indicates that this item will amount annually to from 1% to 2% of the cost of the fleet. Miscellaneous charges include deck supplies, laundry, waste, and other small items and are found equal to $0.01 per ihp per day of service.

Performance.—A study of performance statistics of a large number of steam towboat operations on the Mississippi River gives the ton-miles per horsepower-hour, up stream, as 10; and down stream, 17. These values will be found to vary with the project depth and with the quantity of free water under the barges. If the barges are "hugging" the bottom, there is considerable drag, which is reflected in decreased speed for the same fuel consumption. For instance, in still water, performance factors would vary with the depth of water under the barges, as follows:

Depth of water under the barges, in feet	Performance, in ton-miles per horse-power-hour
5	15
2	12

Transportation Costs Consolidated.—Table 3 contains the estimate of costs for the several items involved in connection with the operation of a typical tow of 5 000 tons propelled at the average rate of $5\frac{1}{2}$ miles per hr in still water. Costs are estimated for different load factors applying to the propelling units and also for several load factors applying to conditions under which barges might be utilized. Table 4 gives the cost of transportation for self-propelled barges of three different sizes and under varying conditions as to load factor. The costs for the 1 600-ton unit were compiled from records of actual operations; those for the 2 400 and 3 200-ton units were computed for purposes of comparison.

Representative values have been used for unit costs of fuel and lubricating oil, and for wages and subsistence, and a suitable allowance has been made wherever necessary to correct for partial use of equipment. Referring to

* 300 days in commission. † 2% to 4% of Column (3). ‡ 1% to 3% of Column (3). § 90% of the corresponding values in Table 3(*a*). ‖ 70% of the corresponding values in Table 3(*a*). ¶ 50% of the corresponding values in Table 3(*a*).

Table 3(*a*), Column (3), the first cost includes: Towboats @ $300 000; bulk cargo barges @ $20 000; and package-freight barges @ $30 000. In Column (4), the annual fixed charge includes: Towboats and bulk cargo barges @ 18%, and package-freight barges @ 16 per cent. Towboat wages (Column (6), Table 3(*a*)), are based on an average rate of $1 350 per yr per man; and, bargemen's wages (one man for each two barges) on a rate of $900 per yr. The assumed food allowance for the towboat crew (Column (6)) is $250 per yr per man. Fuel and lubrication costs (Column (8), Table 3(*a*)) amount to $36 per yr per ihp, with the cost of maintenance and repair at $11 per yr per ihp. The costs in Column (9), Table 3(*a*), are based on an assumption of $20 to $30 per day for bulk carriers and $30 to $40 per day for package freighters. Table 3(*a*) is of no final use in itself but may be used in the process of computing water transportation costs if the necessary load factors are known. Unit costs are shown in Fig. 1.

Load Factors.—A load factor in water transportation might be said to be the ratio between the total number of ton-miles resulting from one season's operation of a unit and the theoretically possible total movement. Therefore, to determine a load factor for a towboat it is first necessary to determine the total number of hours during which the towboat will be in commission. Multiply this by the number of tons in a capacity tow and by the still-water speed, in miles per hour; the result gives the theoretical total tonnage possible for the number of hours during the year in which the towboat is in commission. The actual performance will be measured by the number of hours the towboat is in line service, deductions having been made for terminal and mechanical delays and also for channel delays, such as groundings, time lost through passing through bridges or locks, etc. Another item that must be used to reduce the load factor for a towboat is the average loading of carriers as compared with the theoretical capacity load. The final item for consideration is the character of the cargo movement, itself; if it is a balanced movement no further adjustment in load factor is required; if the movement predominates in one direction correction must be made accordingly.

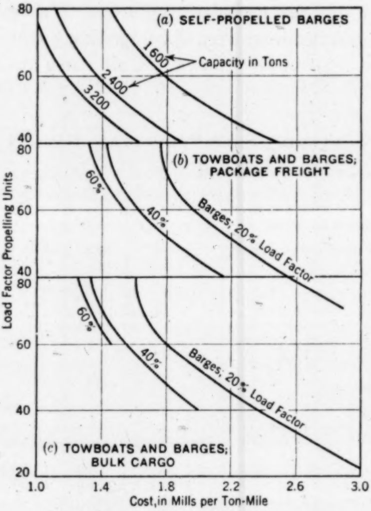

Fig. 1.—Unit Costs of Water Transportation

In the case of barges a similar procedure should be followed in determining the load factor for the operation under consideration. It will be seen that a very thorough knowledge of operating conditions must be available before these load factors may be determined intelligently.

In Justification

Preliminary.—Many notable papers have been published in an attempt to prove economic justification for many of the waterway projects that have been undertaken in the United States. Possibly as many contributions have been made on behalf of rail transportation. The waterway papers have been discussed and criticized by railroad advocates, while the railway point of view has been argued against by those favoring the waterways. One would think that all points for both sides of the controversy had been covered time and time again; that there was nothing more to be said, and that nothing could be gained by prolonging the argument; and yet the strife appears to continue; waterways are accused of "robbing" the taxpayer and of taking traffic away from their competitors, whereas the railroads are alleged to be engaged in the nefarious practice of reducing rates wherever water competition exists and making up the loss at the expense of their customers located where the advantages of water competition are not available. Of course, this attitude is understandable when it is realized that each side is attempting to protect its own interests; but the results are not necessarily along the lines of better understanding or of constructive accomplishments for the public at large.

Tangible Economic Values.—The main water transportation routes in the Mississippi Valley will have cost the United States at the rate of about $186 000 per mile of length when completed. Maintenance, including the operation of the locks and movable dams, will cost at the annual rate of approximately $3 000 per mile. The capacity of these water highways for carrying freight will vary. The open rivers will be able to carry practically an unlimited tonnage, but the canalized sections will be limited by the rapidity with which the carriers may pass through the locks of highest lift in those sections. For instance, the traffic from the Lower Mississippi River and the Missouri River to and from the Upper Mississippi and the Illinois Waterway System will be limited by the capacity of the lock on the Mississippi River at Alton, Ill.; through traffic between Chicago and the Valley may not exceed the capacity of the lock at Lockport, Ill., at the lower end of the Chicago Drainage Canal; and the capacity of the Upper Ohio River will be determined by that of the locks at the dams below Pittsburgh. With single locks at these three critical locations, as built or as proposed, the limits will approximate between 20 000 000 and 30 000 000 tons per yr, respectively. The construction of twin locks at these places would result in more than doubling the capacity of those sections of the waterways at a cost which would be comparatively small.

By way of comparison, it is understood that modern railroad construction costs in the Mississippi Valley vary between $50 000 and $70 000 per mile of single track, and that maintenance of way and structures cost on the average of from $2 000 to $3 000 per mile annually under heavy traffic. Furthermore, it is the understanding that the annual traffic capacity of a single-line railroad varies between 20 000 000 and 30 000 000 tons, depending on the class of freight which predominates. It is thus apparent that inland-waterway construction is much less flexible than is the case with railroad construction and, without regard to capacity, it costs more to build and to maintain. Furthermore, railroad distances between given points are generally shorter than those by water, which is an additional credit to railroad transportation when construction and maintenance costs are under consideration.

Conditions vary so much as to terminal operations that it is difficult to draw any general conclusions. Usually, rail terminals are located on more expensive property than water terminals so that total fixed charges are comparatively high; but since they are likely to have a higher use factor there is probably little difference between unit fixed charges. With operating costs conditions should favor the railroads because such transfer operations are generally conducted at one elevation, whereas at the river terminals there is a wide fluctuation between low and high-water stages which requires a considerable vertical movement of cargoes. Where joint rail and water transport operations are involved additional transfer operations are required, and as regards the waterway traffic in the Middle West, these transfers are always at the cost of the waterway carrier. This condition is somewhat different from the methods in vogue at several seaboard rail terminals where such costs are absorbed by the rail carriers.

As to comparative costs of the two methods of transportation, there should be no further cause for misunderstanding. Modern methods of inland water transport have been successfully in operation for a sufficient length of time, and enough data have been assembled on the subject so that fairly definite conclusions may be reached. First costs and fixed and maintenance charges for equipment for both types of transportation facilities on comparable operations are readily ascertainable, and actual operating costs for a variety of traffic conditions are known. Why argument continues along these lines is a question.

A study of various authorities on the subject indicates that for railroad operation in the Middle West the cost of maintaining equipment plus fuel, supplies, and wages, averages very close to 4 mills per ton-mile. Interest on investment in equipment and its depreciation (which are dependent upon the load factor when unit costs are under consideration) vary from about $0.0006 per ton-mile for a load factor of 100% to as much as $0.0015 per ton-mile when the load factor is 40 per cent. Total unit costs for this range of load factors, therefore, lie between $0.0045 and $0.0055 per ton-mile. Comparable costs for water transportation, as demonstrated previously, are from $0.00125 to $0.003 per ton-mile. The latter should be corrected for circuity as the water distances are generally longer than those by rail. Between points on the Ohio River this factor averages about 1.4; between Chicago and St. Louis, it is about 1.2; on the Lower Mississippi River, it approximates 1.5; and up stream from St. Louis the factor is 1.1.

Comparison of Costs.—It is now possible to make a rough comparison to determine the net tangible cost to the country at large of supporting traffic on the main inland waterways of the Mississippi Valley. If it is assumed that all the existing waterway traffic was carried by railroads serving the same points and allowing a cost of $50 000 per mile for the roadway, a capital investment of about $175 000 000 would be involved compared with the present cost of the water highways of $550 000 000. The annual traffic to be handled is about 5 500 000 000 ton-miles *via* water routes, the equivalent of about 4 000 000 000 ton-miles by rail. Comparative costs would then be as shown in Table 5(*a*). It is apparent, therefore, that the country at large is paying more for its transportation in the amount of about $22 000 000 per yr on account of the present use of the main inland waterway routes in the Mississippi Valley.

TABLE 5.—COMPARISON OF COSTS, IN MILLIONS OF DOLLARS

Description	(*a*) WATER TRAFFIC CARRIED BY RAILROADS SERVING THE SAME POINTS		(*b*) COMPARISON ON THE BASIS OF PRESENT WATERWAY IMPROVEMENTS		(*c*) COMPARISON IF WATERWAY TRAFFIC EQUALS THE CAPACITY OF A SINGLE-TRACK RAILROAD	
(1)	Rail (2)	Water (3)	Rail (4)	Water (5)	Rail (6)	Water (7)
Interest	17.5	44.0	35	52	17.5	52.0
Maintenance of way and structures	4.0	8.0	36	15	25.0	12.5
Operating charges	22.0	13.75	162	100	112.5	78.8
Total	43.5	65.75	233	167	155.0	143.3

When improvements under way are completed these water transportation routes could easily accommodate an annual traffic of at least 50 000 000 000 ton-miles and with the addition of duplicate locks at critical locations, this capacity could be doubled. If a comparison is made on the basis of the capacity of the present waterway improvement projects (in which case the first cost of railroad roadway to carry it would be twice the sum given previously) costs involved would approximate those in Table 5(*b*). In this case the comparison favors water transportation. If the water traffic totaled 35 000 000 000 ton-miles the corresponding railroad tonnage would be about 25 000 000 000, approximately the capacity of a single-line road. Under such conditions the comparison in Table 5(*c*) would apply. The future tangible economic justification of this large expenditure for waterway development, therefore, lies in the ability of industry and commerce in the Middle West to develop and support water traffic approximating 35 000 000 ton-miles per yr.

It is to be noted that these comparisons take no account of rates charged for either rail or water transportation. Rates are notoriously artificial as far as the railroads are concerned and where they are in competition with water they bear little relation to the cost of services performed. Water rates, on the other hand, are generally as close below the corresponding rail rates as the traffic will bear. In any event it is the costs that determine the net direct effect on the national wealth, and it is only when rates become so low as to be destructive of healthy competition or so high as to prevent industrial development that they affect a drain on national resources.

The foregoing comparisons of costs of transportation were intended to be made in a way that would avoid controversial questions. The results show the tax on the nation's pocket-book of the existing uncompleted system of waterways as reflected in transportation costs. Questions of subsidy to water carriers are thus eliminated; nor is consideration given to the subsidy enjoyed by rail lines paralleling the water routes paid for by shippers located where they cannot use them.

In one respect only are the comparisons incorrect; that is, with regard to the costs of the transportation routes themselves. For the water routes, the total costs result from a study of the records of actual expenditures by the Federal Government since the inception of the projects. These costs, therefore, are not replacement costs, but the accumulation of expenditures from sporadic appropriations made over a long period of years, a substantial proportion of which has been undoubtedly wasted by reason of the uncompleted nature of the construction works. For the rail routes replacement costs are used and, therefore, they make no allowance for wasteful expenditures of the past which are the experience of many great enterprises. There is no accurate method of arriving at a replacement cost of the waterway system; nor is there any way of telling how much has been spent to bring any given part of the railroad system of the country to its present efficiency and condition. In this respect, when the conclusion is drawn that inland water transportation over these particular routes costs the nation approximately $22 000 000 per yr, the rail carriers are given a substantial advantage.

Intangible Values.—In a discussion of the intangible effects of a major program of public improvements as involved in the development of water-transportation routes in the Mississippi Valley, it is necessary at the beginning to take as broad a point of view as possible. The investigator is concerned neither with the immediate effect on small communities nor with individual enterprises. Water carriers as well as rail carriers are only a means to an end, and that end is best expressed by the statement that the people still are engaged in building a nation.

Another point to be kept in mind is that most of the construction operations in connection with the improvement of these routes have been completed and the expenditures already made. The sum of $550 000 000 has been expended, 2 500 miles of channel finished, and about $100 000 000 will be required to complete the remaining 1 000 miles of channel to project dimensions. Arguments as to the wisdom of works already completed are somewhat academic as the money expended cannot be recovered without putting these projects to work. It would seem more to the point for all concerned to join efforts to insure as large a return on the previous investment as possible, whether it was good or bad.

There is little question but that the old "packet" boat was a controlling influence in the formation and growth of the "plan" for the Middle West. As a result, this "plan" was based on the great rivers, and as many as have been the changes in industrial development and in the forms of transportation which serve both commerce and industry, the fundamental elements of that "plan" still persist. The present problem, therefore, is simply to determine whether that "plan" has sufficient merit to justify its perpetuation as against any other that might be advanced.

All the great nations of the world have been developed on the premise that the sea is the base of the system of transportation. The world ports achieved their pre-eminence because they served as focal points for the lines of transportation to the interior and as gateways for commerce over the free routes of the high seas to domestic as well as foreign destinations. The controlling elements in this situation are: (1) That ocean transport was, and still is, cheaper than land carriage; and (2)—which is possibly of greater importance—that the water highways are free and dedicated to the unrestricted use of all.

By close analogy the interior of a great country may be developed to best advantage by preserving for the use of the general public the free water highways of its great rivers even at some expense, if necessary. The principle involved is identical. In the writer's opinion the price of about $22 000 000 per yr is a small one for this country to pay if, in making this investment, it accomplishes the multiple purpose of salvaging large expenditures made in previous years, of preventing a violent readjustment in the distribution of industries and population, and of preserving a group of minor "sea bases" located on a secondary coast line 7 000 miles in length.

There is another important set of intangible values involved in this question which can be emphasized to best advantage by quoting a short part of a statement[2] by the late C. E. Grunsky, Past-President, Am. Soc. C. E.:

"In his opening paragraph the author [the late William Murray Black, M. Am. Soc. C. E.] presents the conclusion that a new waterway line of transportation should not be established unless the need for it can be shown and unless 'if established, it will produce an annual saving in the cost of transportation greater than the interest on construction plus maintenance and operating costs.' There is another element which should sometimes be considered when the advisability of such a line of transportation is being studied, and by virtue of which many a project may be found advisable, despite the fact that it cannot, perhaps, for many years in the future, produce revenue to meet in full the interest charges against it. This element is the project's contribution to general prosperity as measured in terms of population, of business, and of property values. It becomes a factor because the expenditure of funds in its construction, and the utilization of the facilities which it provides when it is completed, bring increase of population; and to the extent that the growth in population of the zone coming under the influence of the improvement is thus accelerated, to the same extent will land values increase and wealth be created, which may fairly be weighed against the cost of the improvement when the advisability thereof is under consideration. Society, in other words, may reap material advantage from many an enterprise that would be condemned by the stockholder who weighs only the cost of the service against the prospective revenue."

---

[2] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 553.

The application of the principle stressed in this quotation to the advisability of completing and utilizing the main water-transportation routes of the Mississippi Valley should not encounter serious opposition.

THE HIGH COST OF INLAND WATER TRANSPORTATION

By S. L. Wonson,[3] M. Am. Soc. C. E.

Synopsis

Due to its historical background, water transportation in the Mississippi Basin, in earlier years, impressed itself strongly into the national consciousness. After the decline of river traffic, following the fixation of traffic routes and the development of railways, having certain elements of inherent superiority in satisfying traffic needs, this early impression resulted in a public demand for the continuing development of river transportation at public expense.

This demand was largely based upon the supposed necessity of waterways to supplement inadequate facilities of the railways and to act as regulators of their rates and practices. Under present and foreseeable future conditions, these reasons have lost such validity as they may have had, and the justification of waterway development in the Mississippi Valley at the expense of the taxpayers now rests upon the test of relative economy of water and rail transportation, taking into account all elements of cost.

The rivers of the Valley are not of the class of waterways freely navigable in a state of Nature; they require large expenditures for channel improvement. The major elements in the cost to the public of transportation on these rivers are: The annual charges pertaining to Federal expenditures for improvement, and the service charges of the river carriers. Certain other elements of cost, such as those pertaining to bridges and river terminals, are not now known in total.

When the two major elements are reduced to a ton-mile basis, for comparison with the total cost to the public of rail transportation, which is closely known, it is found that they generally exceed the latter, in many cases to a marked degree, and that any impression as to superior economy of river transportation in the Valley is based upon a misapprehension.

Introduction

The question of waterway improvement for transportation purposes, particularly in the great interior basins of the United States, has been long and actively discussed, before this Society and elsewhere, and it would appear that every pertinent viewpoint has been adequately covered. The continued activity of the question, however, would seem to indicate that a realistic appraisal, from the viewpoint of the public interest, has not yet acquired general accept-

---

[3] Asst. Chf. Engr., Mo. Pac. R. R., St. Louis, Mo.

ance, and that river improvement for transportation purposes has been and is being over-emphasized, to the detriment of the primary function of these streams, namely, that of drainage channels.

VIEWPOINTS

The rivers of the Mississippi Basin exercised an essential function in the national life from the time of the first explorers in the Sixteenth Century, through the years of the pioneers and settlers, and well into the period of settled trade and commerce that opened with the Nineteenth Century. As long as the muscles of men and animals were the only motive power available, river transportation held an inherent superiority in efficiency over any form of land transportation.

Consequently, there were impressed into the national consciousness certain feelings as to the superiority and virtue of river transportation as such, and as to the necessity of its continuance, in the future as in the past, as an essential part of the national life. It is a characteristic of such general impressions, upon other subjects as well as this, to persist for some time after their factual basis has passed, and to be evidenced, in discussion of the particular subject, by emphasis upon the emotional, rather than the realistic, viewpoint. The Mississippi Valley Committee of the Federal Public Works Administration, for example, writes of the waterways in the Valley, "they have a romantic and traditional interest which cannot be disregarded."[4]

DECLINE OF THE RIVERS

The function of the railroads as freight carriers did not develop immediately upon their first construction. Like the first river steamboats, the first railroads were primarily passenger carriers. An examination of the railroad map of 1840 will disclose the complementary relation of the early railroads to the waterways. West of the Alleghenies the first railroads were mostly short lines running to the Great Lakes and to various rivers. The same situation is marked on the railroad map of 1850. The map of 1860 shows a different picture. The shift of traffic from river to rail had begun, following the great change in direction of traffic initiated by the opening of the Erie Canal. The growth of the country was such, however, that neither of these causes produced an immediate decline in Mississippi River commerce; the year 1860, for example, exceeded all previous records in number of steamboat arrivals and value of goods received by river at New Orleans, La.

Professor Frank H. Dixon cites[5] two causes, independent of rail competition, for the rapid decline in Mississippi traffic after 1860: (*a*) The Civil War, which closed the lower river to commerce for several years; and (*b*) conditions at the mouth of the river which, after the introduction of steam navigation, seriously obstructed the access of ocean carriers to the Port of New Orleans, and which were not remedied until the completion of the Eads jetties in 1877.

[5] "A Traffic History of the Mississippi River System," by Frank Haigh Dixon, *Document No. 11*, U. S. National Waterways Commission, 1909, Govt. Printing Office, Washington, D. C

NATURAL DISADVANTAGES

In comparison with the service which the rail carriers were in a position to offer, some of the natural disadvantages of the rivers of the Valley as transportation routes may be mentioned as:

(1) Rigidity of location, preventing a universal and flexible service, requiring use of land transportation to serve interior points and involving additional time and expense for transshipment;

(2) In many cases the river courses lie across, rather than along, the major currents of traffic movement;

(3) Circuity, or greater distance between given points;

(4) Channel conditions, imposing limitations upon speed of movement and upon use of economical types of craft, and only to be partly remedied by large expenditures;

(5) Large variations in river level, requiring additional elements of dock and wharf facilities for handling goods between river bank and river craft; and,

(6) Closure of northern waterways during the winter season.

The rail carriers, in turn, held an inherent superiority over the rivers in transportation efficiency. This situation seems not to have been as clear prior to 1870 as it is in retrospect. Professor Dixon makes the interesting statement that:

> "* * * one of the causes assigned for the building of cars by shippers was the fear of the railways that the restoration of river business after the war would have such a serious effect upon their business that it would be unwise for them to make the necessary outlay themselves."

RIVERS NEEDED TO SUPPLEMENT RAILROADS

The shift of traffic from river to rail, and the rapid growth of the country and of its transportation needs after the Civil War, caused the railroad plant to be overtaxed at times and the situation of the waterways from the viewpoint of the public interest became the concern of various official committees and commissions, as well as of many private organizations and individuals. All these bodies based the need for inland waterway transportation upon the periodic inadequacy of the railroad plant as then functioning, and the national necessity for supplementary and additional transportation facilities.

The sudden and large increase in the nation's commerce and transportation needs during the World War again taxed the railroad plant to its limit, and, together with the taking over, by the United States, of transportation on certain waterways in 1918, apparently contributed to the feeling that land transportation could not be considered adequate for the nation's needs; that it must be supplemented by inland waterway development.

As the march of events and the passing of an era came to discount the correctness of this conclusion, emphasis seems to have shifted to a superior economy claimed for inland waterway transportation.

ECONOMY OF RIVER TRANSPORTATION

From the viewpoint of economy, waterways fall at once into two distinct classes: First, the oceans, the wide and deep estuaries of great rivers, and certain great lakes (including, in some cases, relatively short connecting channels); and second, rivers, such as the rivers of the Mississippi Basin, which have the natural disadvantages previously mentioned and which require large expenditures to permit navigation by a restricted type of craft. Waterways of the first class present no great limitation upon efficient type, size, and operation of the cargo carrier, and constitute transportation routes superior in economy to any present form of land transportation.

From the viewpoint of transportation economy no analogy can follow from one class of waterway to the other, unless there be considered and included the cost of creating and preserving such conditions of the rivers as navigation upon them may require.

Of the total costs of river improvement only a part is recorded so as to be available, namely, that part representing the direct expenditures of the United States and, in some cases, of political subdivisions. Substantial additional costs, such as those involved in the construction and reconstruction of highway and railroad bridges, combine to make up the true but unknown total. A finding as to the various elements of true total cost pertaining to public improvement work, including river improvement, was adopted by the American Railway Engineering Association in 1935[6] and is also stated in the 1935 report of the Committee of the Engineering-Economics and Finance Division on Principles to Control Governmental Expenditures for Public Works.[7]

Rivers as Regulators of the Railroads

Accompanying the thought that waterway development is necessary to provide additional transportation facilities, has been the viewpoint that improved waterways are natural competitors of the railroads and effective regulators of their rates. This theory was advanced as early as 1874 by the Windom Select Committee on Transportation Routes to the Seaboard of the United States Senate. The more clear-sighted commentators, however, have recognized the fallacy of this view.

In 1909, Professor Dixon stated that "if the purpose is to reduce railway rates, there are more direct and less costly methods of accomplishing this result." In its first report of 1910, the National Waterways Commission pointed out that expenditures on waterway improvement for the purpose of regulating railroads or reducing rates were not justified by either reason or experience.

The scope of railroad regulation has been so extended and strengthened in recent years as to justify the conclusion of these two authorities. The subject is treated by the National Transportation Committee, which, in its report of 1933 to the President, states, in part:

> "The development of regulation and of new methods of transport make it unnecessary for Government further to create and foster competition with or among railroads as a defense against monopoly. That is an expensive and ineffective attempt to do indirectly what Government has shown its ability to do directly. Regulation is sufficient."

Regulation of the railroads "has been practiced long enough and sufficiently extended to prove that it dominates competition or any other influence as the governing law of railroad practice. To the extent, that the monopoly inherent in the railroad franchise was a menace, it is of the utmost importance to recognize that current railroad regulation safely controls it."

[7] *Proceedings*, Am. Soc. C. E., February, 1936, p. 219.

* * * * * * * *

"In so far as government policies have been designed, by Federal intervention, to create and maintain competition with or among railroads as a defense against monopoly, they should be abandoned as wasteful and unnecessary. Regulation is sufficient."

The Public Necessity

In view of the foregoing, an attempt to appraise the fundamentals of the situation may be in order. The public necessity requires a satisfactory transportation service. A satisfactory service is one that is, to the highest practicable degree, adequate, efficient, and economical. Although these characteristics are more or less interdependent, they may be commented upon separately.

There seems to be general agreement that the railroad plant is adequate for the transportation needs it is called upon to meet and that it will continue to be so for some time to come. The total revenue freight transported by Class I rail carriers of the United States in 1929 and 1935, is shown in Table 6, Columns (2) and (3). The transportation performance of the major rivers of the Mississippi Basin—the Ohio, Missouri, and Mississippi—covering river traffic between Pittsburgh, Pa., Minneapolis, Minn., Sioux City, Iowa, and New Orleans, in 1935 was as shown for comparison in Column (4), Table 6; the figures for waterways include materials used in river improvement work as well as materials rafted.

TABLE 6.—Comparison of Revenue Freight Transported

Revenue freight transported:	1929	1935	
	Railways	Railways	Waterways
(1)	(2)	(3)	(4)
Millions of tons	2 452	1 427	41
Millions of ton-miles	447 322	282 037	5 487

In a broad sense, the railroads serving the Valley have a reserve capacity at least proportionately equal to that of the railroads of the United States. Considering that the railroad plant was not overtaxed in 1929, and that its productive efficiency has been increasing and will continue to increase, it would appear that the construction, maintenance, and operation of waterways in the Valley is no longer justified upon the broad ground that other agencies of transportation are, or will be, inadequate in capacity to serve the public need.

From the viewpoint of efficiency, the rail carriers have certain inherent or natural advantages, such as a superior universality and flexibility of service, and the power to render continuous transportation without delay or expense for transfer at intermediate points. Under an equality of conditions the relative efficiency of two or more types of transportation service will be clearly revealed by the test of public use. These conditions are such as would cause each type to offer a service reflecting its own natural advantages or disadvantages, as well as any superior or inferior degree of management, and are more or less as follows: (1) Substantial equality in respect of beneficial, restrictive, or punitive legislation and regulation; and (2) a system of service charges covering the total cost of the service.

Under such conditions there is little doubt as to the direction in which the verdict of public use would point. It is well known, however, that such equality of conditions does not now exist. The rail carriers are subject to a great mass of restrictive legislation and regulation, originally purporting to be in the public interest and now considered by many to extend far into the field of management. On the other hand, the river carriers are largely free to pursue such policies and practices as may seem to them appropriate, and are further enabled, by acts of Government, to offer their service for a charge which does not cover its total cost by a substantial margin; in other words, the users of the service are paying a part of the cost and the taxpayers are paying the remainder.

Even under the present inequality of conditions, the superior efficiency of rail transportation, based both upon its natural advantages and also upon alert and progressive management within the limits imposed by regulation, is generally conceded. Definite expression of this judgment may be found in voluminous shipper testimony before the Interstate Commerce Commission in one of its current general proceedings.[8]

Relative Costs

The third major requisite of transportation is that it be economical. Economy is necessarily relative, and certain approximately known elements of cost of river and rail transportation may properly be compared.

Broadly, the total cost of rail transportation to the public may be measured by the charge for the service, the freight revenue. In 1935 the average charge, or revenue, per ton-mile of revenue freight transported by the Class I rail carriers of the United States was 9.9 mills, of which 0.7 mill was directly refunded to the public in the form of taxes, thus reducing the average total charge to 9.2 mills per ton-mile. Substantially these figures apply to the railroads serving the Valley. For convenience, the rounded unit of 1% per ton-mile may be kept in mind as the outside total cost to the public of rail transportation.

The rivers of the Valley are of that class of waterways requiring large expenditures for navigation, and these expenditures do not appear in the accounts of the river carriers. Neither the costs of these carriers nor their charges for service are a measure of the total cost to the public of transportation on these rivers. This total cost includes at least the following elements: (1) Expenditures upon river improvement for purposes of navigation (*a*) by the United States; (*b*) by States and political subdivisions; and (*c*) incidental costs to public and private interests; (2) public expenditure on river terminals; and (3) service charges or costs of river carriers.

Expenditures by the Federal Government

The portion of river transportation cost paid by the Federal taxpayers, when reduced to the ton-mile unit, differs widely as between the rivers of the

---

[8] I. C. C. Docket No. 26 712, Rail and Barge Joint Rates.

Mississippi Basin. In the following paragraphs these values are given for the major rivers, the Ohio, the Upper Mississippi, the Missouri, and the Lower Mississippi, and for a few of the tributaries. The data are derived from the Annual Reports of the Chief of Engineers, U. S. Army, and are for the year 1935, which is the latest for which ton-mile data are available. Interest at $3\frac{1}{2}\%$ and current maintenance costs are used, and no allowance is made for amortization. To produce unit costs comparable with those of rail carriage, a circuity factor is used, representing the excess of river distance over rail distance.

In order that the discussion may include every possible factor favorable to river transportation, a number of findings are quoted from the report of the Mississippi Valley Committee of the Public Works Administration, which seems to be the latest comprehensive and independent study of the subject. This Committee, stated by the Administration to be "a group of the nation's leading scientists and technicians," devoted a year to the preparation of a report upon the use and control of water in the Mississippi Basin, which was made public in December, 1934. The membership of the Committee included the Chief of Engineers, U. S. Army, and its attitude was one wholly sympathetic with river values. In considering the following data it should be remembered that transportation on these rivers is no new or untried experiment; it is older than rail transportation—as old as commerce in the Valley.

Ohio River.—During the period of the Revolution considerable trade developed between Ohio River settlements and New Orleans and *via* New Orleans to the Atlantic seaboard. A regular packet service of keel-boats was established on the river in 1794. The course of the river is largely parallel to the main currents of traffic; it flows through a section highly industrialized for many years and in which bulk commodities are found in great quantities. Tonnage on the Ohio exceeds that on the Mississippi from Minneapolis to New Orleans.

Notwithstanding these favorable factors, Federal expenditures on the Ohio River amount to 5.5 mills per ton-mile of river traffic. To make the total cost as low as the total for rail transportation would require that all the other costs of river transportation previously mentioned aggregate not more than 3.7 mills per ton-mile. It seems improbable that such is the case.

The Monongahela River should be mentioned as a case exceptionally favorable to low-cost river carriage. Its tonnage, but not its ton-mileage, has been larger than that of the Ohio; in 1935 it was about 86% of the latter. Disregarding circuity, which is slight, the Federal contribution to cost of transportation on this river is 1.3 mills per ton-mile; 85% of the tonnage is coal, moved down stream from mines along the river.

If it be asked, what interests have benefited from the expenditure of about $185 000 000 of Federal money on the Ohio alone, the Mississippi Valley Committee of the U. S. Public Works Administration answers:

> "Private carriers—largely coal and steel companies—now transport more than 95% of the total commerce on the Ohio River."
>
> * * * * * * * *
>
> "Practically all of this traffic is handled by private carriers who pay no tolls. In other words, under present policy, the construction costs and the operation and maintenance costs of navigation projects are at Federal expense, and no

part of either of these costs is directly returned to the Government. The Committee believes that this policy should be modified."

Mississippi River Above the Ohio.—The first steamboat is said to have ascended to Fort Snelling, near St. Paul. Minn., in 1813. During the era of active settlement in the Northwest, beginning about 1845, the river carried a considerable commerce. Following the extension of railroads into the Trans-Mississippi region, traffic left the river rapidly because of its natural disabilities, such as the condition of the channel, its closure during the winter, and chiefly its location across the direction of traffic.

The contribution of the Federal taxpayers to the cost of river transportation on the main stem between Minneapolis and the mouth of the Ohio is 2 cts per ton-mile and maintenance alone amounts to 0.6 ct per ton-mile. One-quarter of the total tonnage is material for river improvement.

The Committee finds that as of June, 1934, expenditures on the Upper Mississippi System, plus expenditures required to complete the present project, exceed $217 000 000, exclusive of $40 000 000 for maintenance and operation; the Committee remarks:

"It is not possible by any calculations of business accounting to discover an economic justification for the vast expenditures on the projected improvement of these waterways; especially from the prevailing viewpoint of self-liquidation, but also even from the viewpoint of complete coverage of cost of maintenance and operation."

Missouri River.—Although the first steamboat ascended the Missouri River in 1819, its commerce has always been relatively insignificant. Its natural channel conditions are particularly unfavorable for navigation and its location up stream from Kansas City is equally unfavorable for the needs of traffic.

Disregarding circuity and any expenditure on the Fort Peck project, the cost to the Federal taxpayers of river transportation between Sioux City and the mouth is 22 cts per ton-mile of total tonnage and the maintenance cost alone is 4 cts per ton-mile. In 1929, more than 99% of the total tonnage was material for river improvement work. In later years, the percentage is simply stated as "large"; however, in 1935, rafted piling, stone, and sand made up 84% of the total tonnage.

The Committee finds that the total construction cost of improvements under way will be about $250 000 000 and characterizes this expenditure as having "very doubtful justification." Considering that $3\frac{1}{2}$% interest alone would require a ton-mileage of about forty-three times the present (in itself largely composed of Government materials), in order to reduce this interest cost to 1 ct per ton-mile, the characterization may be pronounced conservative.

As to the possibility that Missouri River traffic will ever be such as to justify this expenditure, or any substantial part of it, the Committee comments:

"Assuming that the more optimistic estimates of future traffic on the river will be realized, the savings to shippers which would result from free operation of the waterway would exceed by only a small margin the annual charge to be borne by the public for maintenance and interest on the investment. *** Most current estimates of prospective tonnage are exceedingly liberal, and if the present traffic on the section below Kansas City may be accepted as in any degree indicative of future prospects, the probability of those estimates ever being realized, even on a free waterway, is very slight."

To complete the picture, it should be mentioned that the construction period of the project has produced considerable business for the constructors, the producers of materials, and the transportation agencies, including the rail carriers.

As to the tributaries of the Missouri, the Committee finds that for the 5-yr period, 1928–1932, excluding non-recurring tonnage for construction of the Bagnell Dam, river traffic on the Osage cost the Government $3.50 per ton-mile for maintenance alone.

Mississippi River, Cairo, Ill., to New Orleans, La.—On the Mississippi below its three great branches one would expect to find, if at all, the great national waterway, carrying a large volume of traffic at a cost less than the possible range of any transportation cost by land. What are the facts?

Up to June 30, 1935, the total cost of construction and maintenance work done by the Mississippi River Commission above the Head of Passes was about $417 000 000, of which a relatively small amount pertains to the river above Cairo, Ill. The 1935 maintenance was $5 177 000. In recent years these figures include expenditures for flood control which are not segregated from expenditures for navigation. However, the Committee finds that the cost of improving this section of the river (Cairo to New Orleans) for navigation, including the amount appropriated for this purpose under the Flood Control Act of 1928, may be estimated conservatively as $190 000 000 and that the average annual maintenance is at least $2 700 000.

The Committee also finds that the average annual traffic for the 5-yr period, 1928–1932, exclusive of material used in Government work and of the coastwise and foreign traffic below Baton Rouge, La., was about 1 681 000 000 ton-miles and that, after allowing for circuity, the total Government subsidy provided to shippers by river would be about 9 mills per ton-mile.

Disregarding any expenditures subsequent to those considered by the Committee, a similar calculation for the ton-mileage of 1935 shows a subsidy of 7.2 mills per ton-mile.

The addition of costs pertaining to river terminals and the costs or service charges of river carriers will obviously produce a total ton-mile cost on this section of the river greater than that of rail haul.

The Committee comments that "the matter seems to merit more thorough and comprehensive consideration than it previously has received."

Tributaries of the Lower Mississippi.—These tributaries present a picture unfavorable to the economy of river transportation. Table 7 shows, for 1935, on the more important tributaries, the dominant tonnage, the total Federal subsidy per ton-mile, and that part of the subsidy represented by the year's maintenance cost. Circuity is disregarded.

Major Rivers Consolidated.—More broadly comparable with the substantially uniform unit cost of rail transportation, is the consolidated Federal subsidy to transportation on the aforementioned four major rivers. For the year 1935, the annual charge pertaining to Government expenditures on these rivers is

TABLE 7.—DOMINANT TONNAGE AND FEDERAL SUBSIDIES, ON TRIBUTARIES OF THE LOWER MISSISSIPPI RIVER

River	Character of tonnage	Total subsidy, in cents per ton-mile	Required for maintenance only, in cents per ton-mile
St. Francis	96% logs and piling rafted	1.7	1.3
White	98% sand, gravel, and logs	2.3	1.8
Arkansas	99% sand, gravel, and logs	9.6	4.7
Red	60% logs	45.7	7.6
Ouachita and Black	36% logs, gravel, and riprap	2.8	1.7
Yazoo and Big Sunflower	45% sand, gravel, and logs	13.3	3.4

$29 000 000 or, allowing for circuity, 10.1 mills per ton-mile of commercial river traffic.

OTHER EXPENDITURES

From time to time States and agencies of the States have made considerable expenditures on improvement of waterways in the Valley. In the case of highway and railroad bridges over these waterways, the additional expenditures necessary to provide the type of structure and the horizontal and vertical clearances imposed in the interest of navigation have been considerable, and there is a continuing element of cost in lifting traffic to the elevation of many fixed bridges. A number of cities in the Mississippi Valley have provided terminals, at their own cost, for the use of river carriers, and the results of these expenditures have not been satisfactory to the municipal taxpayers in all cases.

At present, there appears to be no comprehensive and authoritative compilation of these other expenditures on any of the major waterways of the Valley. Although the total would doubtless increase, perceptibly, the unit cost of river transportation derived from the cost of channel improvement, it is probably small in comparison with Federal expenditures.

REVENUE OF WATER CARRIERS

The Inland Waterways Corporation, owned and controlled by the United States, is the dominant common carrier by water in the Valley. Operating the Federal Barge Lines with modern and efficient equipment, its freight revenue is presumably an approximate measure of that part of the cost of river transportation represented by the necessary charge for carrier service. In 1935, this freight revenue was 3.85 mills per ton-mile.

It appears, therefore, that 3.5 or perhaps 4 mills per ton-mile should be added to the costs previously mentioned as representing the necessary revenue of the common carrier by river. The costs of private and contract carriers are doubtless less, although the cost of private terminals should be included; but, under present conditions, the provision at public expense of a free waterway to these carriers seems open to serious question.

Again, the circuity factor should be applied to the ton-mile cost or revenue of the river carrier, in order to make it comparable with the cost of rail transportation. On the Lower Mississippi, for example, the two factors—Federal expenditures and common carrier revenue—produce a ton-mile cost to the public of 12 or 13 mills as against a total cost of 9 or 10 mills for rail carriage.

Any consideration of the feasibility of common-carrier traffic on the river by the use of private capital should include the experience of barge lines operating between St. Louis, Mo., and New Orleans, from 1875 and 1903, as given by Professor Dixon.

The equipment appears to have been up to date for the time. The barges had a capacity of from 50 000 to 60 000 bushels of grain and the lines carried general merchandise as well. Fuel was carried for the round trip and prompt and reliable schedules were planned. One shipment in 1880 included: 6 757 bbl of flour, meal, and grits; 6 710 sacks of corn, oats, and bran; 1 500 packages of meat and lard; 150 bales of hay; and 24 992 bushels of bulk corn. In 1887, four lines were operating 16 towboats and 120 barges and were later consolidated into one company.

For the seventeen years, 1887 to 1903, inclusive, the published rates on grain from St. Louis to Liverpool, England, by river *via* New Orleans, were from 5 to 9 cts per bushel lower than those *via* rail to New York, N. Y., and, in the latter year, were 6 cts lower. Notwithstanding this differential, the movement of bulk grain by river showed a general decline after 1890, and by 1903, the barge lines seem to have passed out of the picture as an unprofitable investment.

At present, grain is not an important part of river tonnage. In 1935, after eliminating the tonnage in foreign and coastwise commerce on the lower river, wheat, corn, rice, and all other grains form the following percentages of the total tonnage: Ohio, 0.05; Upper Mississippi, 4; Missouri, 0.8; and Lower Mississippi, 1.6.

INTANGIBLES

The suggestion is sometimes made, and at first glance appears pertinent, that consideration of expenditures that have already been made on the waterways is "academic," apparently using the term in a somewhat disparaging sense. In effect, however, this suggestion is the same as stating that present and future action should ignore the experience of the past.

It is also suggested, at first with apparent force, that although the existing investment in waterways may not have been wholly wise, this investment should be preserved or "salvaged" by providing for its continued use. It is generally admitted that the United States has a very great surplus of transportation facilities. In so far as transportation efficiency is in the public interest, the use of, and the addition to, the less efficient agency is a drain upon the nation's resources and a check upon its total productivity. The real present question is not as to the salvage of an investment; it is as to the preference for the smaller and less efficiently functioning investment over the larger and more efficient.

No agency of transportation, rail, water, or any other, regardless of investment, should be preserved and fostered simply because of its past performance. If and when it becomes relatively inefficient, outmoded, and obsolete, the public interest requires that it be retired from use as rapidly as may be practicable. From the viewpoint of past performance, however, whatever it may be considered to be worth, there is something to be said for the rail carriers. In the words of the Mississippi Valley Committee:

> "A nation with our territorial extent, population, culture, and vital dependence of one section upon another, is unique. It has been made possible only by an elaborate and adequately supported railroad system. Therefore, any move, however desirable it may be in itself, which unduly infringes upon the serviceability of railroads, is to be deprecated."

SUMMARY

Considerations of "romance and tradition," the emotional viewpoint, although based upon an essential part in the national life formerly played by the waterways of the Mississippi Valley, is no longer a sound basis for expenditures upon the improvement and maintenance of these waterways for transportation purposes. The justification of these expenditures in the public interest has been based upon the supposed necessity of transportation facilities additional and supplementary to an inadequate capacity of the rail carriers, and also upon the assumed necessity of improved rivers as competitors of the railroads and regulators of their rates. These considerations may or may not have been valid in the past. To-day, they are no longer relevant; the public interest is based upon the relative economy of such available agencies of transportation as are capable of rendering a satisfactory service.

The total unit cost of river transportation in the Valley, including that part of the cost paid by the taxpayers, is, in general, greater than the total unit cost of rail transportation. Due to the fixity of river location, any benefits of river improvement paid for from the National Treasury tend to accrue, not to the nation as a whole, but to special or localized industries and localities.

The nation's credit is of the highest and is expected to remain so. Consequently, public expenditures will have to be repaid, with interest, by taxation. Expenditures which are an exercise of a power of Government, rather than an exercise of one of its basic and essential functions, should rest upon a basis of economic justification. Otherwise, they constitute a levy upon the nation's total consumption of goods and services.

CONCLUSIONS

The application of the foregoing to the matter of waterway improvement in the Valley would appear to prompt some such suggestions as the following:

(1) Projects upon which the cost of Federal maintenance exceeds the cost of using other transportation facilities, should, if such other facilities are available and adequate, be retired forthwith, or be turned over to such local interests as may be able to operate and maintain them on an economic basis.

(2) Projects upon which the cost of Federal maintenance is less than the cost of using other available facilities should, in justice to the taxpayers who provided and now support them, carry such service charges to the users as may be equitable in each individual case.

(3) Additional expenditures should not be made except upon a basis of economic justification; a definite showing, after consideration of all costs

involved and a realistic appraisal of traffic to be expected, that a satisfactory transportation service will be produced at a total cost less than that of existing agencies.

In the words of the Mississippi Valley Committee:

"It is believed that this phase of the subject has in some instances in the past been too lightly considered—if considered at all. Economic justification should be definitely established early in the study of any proposed river or canal improvement."

DISCUSSION

George Hartley,[9] Esq. (by letter).—An important factor mentioned in the introduction of the paper (see "Historical") was excluded from the remainder of the text.

Major Putnam calls attention to the fact that, in the past, those who have wished to secure improvements for navigation on the Mississippi and Missouri Rivers have been aided greatly in securing Federal appropriations for river works: (*a*) Because great flood damage focused national attention on river improvement from an entirely different viewpoint; and (*b*) because "there was a desire to stabilize the banks which were quite subject to erosion * * *." No further references to either flood control or erosion are made in the paper, and, in a later statement, when evaluating the cost of capital improvements, no specific mention is made as to what proportion of the capital improvements may be assigned to flood control and erosion. For example, under the heading, "Existing Water Transportation Facilities: Routes," the author states: "The total expenditures chargeable to capital improvements for navigation on these main routes amounts roughly to about $550 000 000 to date (1937)." The specific reference to navigation at once infers, by reference to Major Putnam's previous statement, that some allowance may have been made in an attempt to proportion specific charges between navigation and the two factors, flood control and erosion. In the event that the total cost, as given, includes the expenditure for flood control and erosion, the capital cost utilized as a comparative economic study later in the paper could very well be reduced by an amount equal to the cost of these improvements, and the resulting costs would place the waterway at once in a much more favorable position when viewed from an economic standpoint relative to railroad transportation.

No attempt has been made to evaluate the capital charge as well as the operation charges on bridges erected over these rivers to correct for increased cost of construction due to navigation requirements. Mr. Wonson makes the following statement (see "Other Expenditures") with respect to this feature:

> "In the case of highway and railroad bridges over these waterways, the additional expenditures necessary to provide the type of structure and the horizontal and vertical clearances imposed in the interest of navigation have been considerable, and there is a continuing element of cost in lifting traffic to the elevation of many fixed bridges."

The charges referred to by Mr. Wonson are directly chargeable in a comparative analysis to the capital cost of the waterway. In most instances, were it not for the navigation requirement, all the bridges constructed over the part of the rivers considered in the Symposium could be reduced a distance of approximately 50 ft and still provide more than sufficient elevation to clear the highest high water. This reduction in height might result in a saving of approximately 50% of the capital cost of construction. Furthermore, the reduction, if allowed, would result in a program of new bridge construction over these rivers, and to consider, economically, the advantages potentially released thereby, would be incalculable.

---

[9] With Robinson & Steinman, Cons. Engrs., New York, N. Y.

Bridges have always been at a disadvantage when navigation requirements were the controlling economic factors. No attempt is ever made by the U. S. War Department to determine, economically, the relative value of the proposed bridge with respect to the vessels requiring increased clearance. These decisions are always in favor of water-borne traffic, and the War Department has always upheld any reasonable objection to reduction in clearance requirements. A bridge costing millions of dollars may never be constructed if some yachtsman using the waterway should require a clearance that would increase the cost of the structure to such an extent that the project would have to be abandoned.

W. D. FAUCETTE,[10] AND J. E. WILLOUGHBY,[11] MEMBERS, AM. SOC. C. E. (by letter).—The region included in Mr. Wonson's paper is a land area encompassing the Mississippi River and its tributaries. The truth, as disclosed by Mr. Wonson, is sound for general application to all inland river and canal transportation in the United States. That truth applies whether the relative land area to length of river and canal is great (as for the great interior land area drained by the Mississippi), or of less extent, as for the peninsula of Florida. This peninsula has a form such that no producing area is more than 75 miles from the coast. The annual rainfall is large, and there are many rivers from the interior to the sea. The rivers are drainage channels now flowing in submerged valleys, the filling of which was the result of the recent subsidence of the peninsula. Florida has a long shore line with many harbor indentations, and much Federal money has been spent on recommendation of the Chief of Engineers, U. S. Army, to develop a river traffic for Florida products to the cities along the Atlantic and Gulf Coasts, the river to be used to the seashore, and then the Atlantic Ocean or the Gulf of Mexico. This peculiar condition makes for minimum river haul and maximum ocean haul, as compared with the area discussed by Mr. Wonson. The inland waterways in Florida that have been created into a system at Federal cost aggregate: Thirty projects, including 1 869 miles, and with a 1935 traffic of 57 233 000 ton-miles. Federal expenditure, including cost of construction equipment, to June 30, 1936, has been $31 836 000. The average annual maintenance for the 5-yr period ending in 1936 was $425 000. Service at 3½% on the total expenditure of $31 836 000 is $1 111 250 per yr. The total annual maintenance and service charges are $1 536 250. The cost to the Federal Government in 1936 was 27 mills per ton-mile, not including the cost of vessel operation, or service on capital invested in vessels, wharves, etc. This ton-mile cost of 27 mills will be increased as compared with railway and highway transportation, due to the circuity of the water route. The four principal railways in the peninsula of Florida in 1935 handled a freight traffic of 4 337 243 000 ton-miles at a cost of 10 mills per ton-mile, which includes the total cost to the user—service on capital, maintenance of railroad and equipment, and cost of transportation.

The high cost of inland water transportation in the Florida Peninsula is demonstrated as follows:

---

[10] Chf. Engr., Seabord A. L. Ry. System, Norfolk, Va.

[11] Chf. Engr., A. C. L. R. R., Wilmington, N. C.

Description	Cost, in mills per ton-mile
Inland Water Transportation:	
Service on total of permanent-way expenditures to 1936	20
Maintenance of permanent way (5-yr average, ending 1936)	7
Total paid by taxpayers	27
Estimated cost of transportation, paid by user	4
Aggregate cost for inland transportation	31
as compared with inland rail transportation:	
Service on total expenditures for permanent way and equipment, cost of maintenance of permanent way and equipment in 1936, and cost of transportation	10

It is of interest to note that the service charge on the cost of permanent way of a water carrier for freight service is 20 mills per ton-mile. The service charge on the cost of permanent way for rail transportation, when allocated as between freight and passenger traffic, develops only 2 mills per ton-mile for the Florida Peninsula.

In addition to the low cost per ton-mile of rail transportation as indicated in the foregoing list the four principal railways in Peninsular Florida paid taxes for the year, 1936, to the State, and other civic units in Florida, equal to $2 698 401, which is equal to 0.6 mill per ton-mile on freight traffic carried, leaving a net cost of inland rail transportation, as compared with inland water transportation, of 9.4 mills for rail against 31 mills for water.

Mr. Wonson touches upon the question of waterways having rigidity of location, which prevents universal and flexible service; and, in his "Summary," he shows that improvement when made, tends to accrue not to the nation as a whole, but to special and localized industries and localities.

This prompts the suggestion that, when it is being considered, inland water transportation should also comprehend consideration of the service features in connection with water-borne traffic. In the final analysis the question of service of transportation to the nation, is inextricably interwoven with considerations of economics. Probably at no time during the past 10 or 20 yr has the matter of transportation service entered so largely into problems pertaining to commerce and industry. This transportation, of course, means moving one's goods from where they are to where they are to be sold; and delivering them, with reasonable and suitable promptness, in a condition such that they can be sold. In order to serve the greatest number and maximum requirements for all classes of commerce and industry, of course, the complete transportation instrumentality should not be limited and rigid in its location and should not be circumscribed by being adaptable to only certain classes of industrial products, which narrows the field of usefulness. On the contrary, railroad facilities as they stand, offer and are able, in substance, to carry all classes and character of goods and commercial products with speed, safety, protection, and responsibility, and (when all factors of cost are properly considered and taken into account) economically, as compared to water transportation. The railroads permeate and serve the entire nation. They are not rigidly held to any one geographical location. They are performing transportation to a nation, highly developed and still developing. Therefore, in the public interest and in the expenditure of public funds, consideration must be given to the fact that rigid location for water transportation narrows it to certain commodities and is not a broad instrumentality that finds itself easily justified. The facts are that when goods and commerce are to be moved, it is service and quality and expedition of that service that is sought—a fact which cannot be ignored.

C. D. **Bordelon**,[12] Esq. (by letter).—The authors of the papers comprising the Symposium—otherwise of generally divergent views—agree that inland waterway transportation was essential to the very life of the Middle West and the Ohio Valley at least until about the 1860's. Before that time there was virtually no other means of mass transportation of goods and people.

Even at the middle of the Nineteenth Century there were no railroads west of the Mississippi River; St. Louis, Mo., Cairo, Ill., Chicago, Ill., and New Orleans, La., had no lines of railroad whatever until about 1852, and the important cities of New Orleans, St. Louis, Chicago, Cincinnati, Ohio, Pittsburgh, Pa., and the "Twin Cities" (Minneapolis and St. Paul, Minn.) were connected only by watercourses. It is small wonder then, that the inland waterways were regarded at that time as of such great value to the life and development of the nation.

The authors are also in agreement that the subsequent extension of rail lines to include all the vast territory tributary to these main rivers brought about the general demise of river transportation. These rivers were no longer indispensable to economic existence.

The essential differences between Major Putnam and Mr. Wonson may fairly be said to be whether there is at this time any economic justification for the further expenditure of public funds to create and maintain inland waterways whose use is free to private purposes as well as to operations for profit; and whether inland waterway costs should include interest on funds spent in creating and maintaining the channels. An appraisal of these differing points of view, as well as of governmental policy in respect to the inland waterways, may be aided by a review of certain facts probably, in the main, forgotten.

Beginning this brief discussion with the period in which the railways had virtually supplanted inland water carriers, and at which time also the capacity of the rail lines was occasionally over-taxed, it is found that the organized movement for a revival of inland water transportation began in the early 1890's and crystallized in 1895. During that year the International Waterways Convention was held in Cleveland, Ohio, followed five or six years later by the First National Rivers and Harbors Congress, in Baltimore, Md. The assembling of these two conventions, joined with the work of various commercial associations, stimulated new interest in waterway transportation. In 1902, Congress passed a Rivers and Harbors Act providing for the establishment of a

---

[12] Asst. Freight Traffic Mgr., Mo. Pac. Lines, St. Louis, Mo.

Board of Army Engineers to review, from an engineering standpoint, all recommendations for waterway projects. In 1903, the people of New York voted $101 000 000 for the improvement of the Erie Canal.

Many conventions and congresses were held in 1907, and in that year, acting in part on the belief he had voiced in his Memphis, Tenn., speech and as a part of his general conservation program, President Theodore Roosevelt appointed the Inland Waterways Commission with the then Senator Theodore E. Burton, of Ohio, as Chairman. In the preliminary report of that Committee, in 1908, it was stated:

"While the railways of mainland United States have been notably efficient in extending and promoting the production and commerce of the country, it is clear that at seasons recurring with increasing frequency they are unable to keep pace with production or to meet the requirements of transportation."

The Commission further declared that, although navigation of the inland waterways had declined with an increase in rail transportation during the latter decades of the Nineteenth Century, it was clear that the time had arrived for restoring and developing such inland navigation and water transportation as upon expert examination appeared to confer a benefit commensurate with the cost, to be utilized as a necessary adjunct to rail transportation.

"While trustworthy estimates cannot be made without further data," said the Committee, "it is reasonable to anticipate that congestion of interstate commerce can be obviated in a large measure by judicious improvement of waterways adapted to barge and boat traffic, at a figure much less than estimated by competent authorities for so increasing railway facilities as to meet present needs."

The Commission recommended that the President, with the advice and consent of the Senate, appoint a National Waterways Commission to bring into co-ordination the Corps of Engineers of the Army, the Bureau of Soils, the Forest Service, and other branches of public service in so far as their work related to inland waterways, for the purpose of making further investigation of various kinds.

The National Waterways Commission, composed of twelve members of the Senate and House of Representatives, came into being as the result of an Act of Congress, dated March 3, 1909. The duty imposed upon this Commission by statute was to investigate questions pertaining to water transportation and the improvement of waterways, and to make recommendation to Congress.

In its preliminary report in 1910 this Commission declared that although there had been a tendency to improve waterways for the purpose of lowering railway rates, it could not endorse this as a desirable policy to adopt; that such a policy rested, in the first instance, upon the transparent fallacy that the railways constitute an intrenched and uncontrollable monopoly which could not be reached by legislation or other orderly legal methods; and that the only way in which to compel them to lower rates is by the expenditure of large sums of money.

It recommended that a definite policy be adopted regarding the relations between railways and waterways. Such a policy, the Commission stated, should be based on the idea that the purpose of improving waterways was to secure additional means of transportation, and not to reduce rates or regulate the railways. Experience had demonstrated, according to the Commission's report, that waterways could not be relied upon as the great cheapeners and regulators of railway rates, which they once were supposed to be. The report also contains the statement that no European country used its waterways to control railway rates, that function being accomplished by the proper administrative bureau of the Government, and that the waterways were improved with the idea of securing additional means of transportation.

In its final report, in 1912, it was said that some of the economic factors theretofore unfavorable to the development of water transportation were gradually changing. Population was increasing rapidly. The average increase for the decade preceding 1912 had been more than 1 590 000 per year. Industrial development of the country was also making rapid strides, according to the report, and the value of agricultural products had doubled in the preceding ten years.

The Commission found that the movement of traffic had increased entirely out of proportion to the increase in transportation facilities. During the period, 1900 to 1910, according to the report, the railway mileage increased about 36%; the number of locomotives increased 56%; the number of freight cars, 56%; while the ton-miles of service performed increased 80 per cent. Previous to that time, the development of transportation facilities had increased more rapidly than the demand for them, and the railways made special efforts to secure traffic of any kind for their idle equipment, even on very low rates. With the rapid expansion which took place between 1904 and 1907, however, all the surplus capacity of the railways was soon exhausted, and a traffic congestion ensued.

The car shortages of 1906–1907 caused widespread complaint and dissatisfaction, and increased the belief that the railroads were inadequate to meet the needs of the country's commerce. Herbert Quick,[13] one of the most ardent advocates of inland waterway development, declared that the railroads could not handle the nation's traffic. He referred to the car shortage in 1906 and 1907 as establishing this fact, and stated:

> "The best railway description of the situation is that we have been trying to force a three-inch stream of commerce through a two-inch pipe of railways; that we need over 75,000 to 120,000 miles of new track, and so many new cars and engines that on the whole there is not enough iron in the country to meet their needs, not labor enough to make and install the new equipment and track, and not enough money to pay for the transactions."

This thought persisted during the years prior to the World War.

In the "Census of Transportation by Water," a special report of the Census Bureau for 1916, it is stated that, although the development of inland waterways had not continued in the preceding decade to the extent desirable, further development was necessary to meet the demands of existing commerce, to prevent the recurrence of congestion at the ports and to permit water-borne commerce among the States.

---

[13] "American Inland Waterways," by Herbert Quick (1909), p. 75.

The World War brought the situation to a head. The movement of traffic which it caused undoubtedly over-taxed the then existing railroad plant. Water transportation was partly taken over by the Government as a means of transport supply and to supplement existing transportation services in sections where abnormal production prevailed.

It is of more than passing interest to observe that the entry of the Federal Government into the water-transportation business was due to the exigencies of war. In the Annual Report of the Hon. William G. McAdoo, Director General of Railroads, to the President in 1918, the former stated that he had appointed a committee to make a prompt investigation and to suggest a definite plan for the additional use of internal waterways so as to relieve or supplement the railways under the conditions caused by war.

The Annual Report of the Chief of Inland Coastwise Waterways Service to the Secretary of War for the fiscal year 1920 stated that the particular purpose of the Committee on Inland Water Transportation, and that to which its efforts were mainly addressed, was the study of the feasibility of utilizing the waterways for the relief of war-time freight congestion of the railroads, which was then beginning to be keenly felt; and, that the necessities of the circumstances required the adoption of a plan that would give immediate relief to shippers and the public by moving a fixed quantity of water-borne freight to the relief of other facilities. He stated further that as rail-transportation facilities became yearly less able to handle, alone, the entire traffic business of the Mississippi Valley, and as annual periods of rolling-stock shortage brought increasing losses to the mercantile communities of the Central West, active interest began to be directed to the interior river system.

Corroborating this thought, Maj. Gen. T. Q. Ashburn, in his testimony in March, 1935, before the Joint Committee of the Senate and House considering the bill[14] to regulate water carriers, stated in part: "Please remember that the rehabilitation of our interior waterway commerce began with the crying need of our interior communicative system for more and better means of supplying the needs of our troops at home and overseas."

The experience of the war led to the deep-seated belief in many quarters that the railroads would never be adequate for the transportation needs of the country and that they would have to be supplemented by some other agency, which later was considered to be the waterways. This belief was repeatedly expressed by those who investigated inland waterway development or who championed the inland waterway movement. For example, James E. Smith, President of the Mississippi Valley Waterways Association, stated in 1919:[15]

> "The time has come when the people of our whole country are insisting upon the Government adopting a broad, comprehensive plan for the improvement and use of all of our important navigable rivers as transportation highways.
>
> " * * * The people of our country know that our railroads have not kept pace with the growth of our commerce, and that its further growth and expansion and the full development of our country's resources are absolutely dependent upon the use of our navigable waterways * * *."

---

[15] *National Waterways Magazine*, March, 1919.

At the same time Jackson Johnson, President of the St. Louis Chamber of Commerce, made the following statement:

"Heretofore the Mississippi Valley has not had sufficient outlet to encourage intensive production. Agricultural, industrial, commercial and mining resources of the Valley are so varied and so unlimited, that it was not surprising that commerce, growing out of these resources, was expanding beyond the capacity of the railroads to handle, even before the war added to their burdens; and now with the return to peace conditions, the transportation outlet by rail is not encouraging. It cannot be for several decades to come, even at inestimable expense. There has been no railroad development at all in the last two years. In fact, there is less trackage now than there was two years ago, and yet there is an industrial condition that demands a greater outlet. We must find a market for the overplus of manufacture and agriculture, which was developed by the intensified war production."

The statement by A. W. Mackie, Manager of the Mississippi Section, Mississippi-Warrior Waterways, follows:

"Wonderful as has been the development of railroad transportation in the United States, commercial development employing that transportation has been equally marvellous, and we now face a situation more serious to business progress than is generally recognized. That situation is one of continued rapid development of industry and production without adequate expansion and development of rail facilities. Proof of this statement is offered every time there is a heavy crop movement on, as in the recent war emergency, a heavy demand upon transportation. The railroads alone cannot provide the necessary transportation facilities and service. We must, then, employ the proven capacity of our improved inland waters."

During the consideration by the House of Representatives of the original Inland Waterways Act, Mr. E. E. Denison, who was on the Committee, and more or less in charge of the bill, emphasized the supposed inability of the railroads to carry the nation's commerce.[16] To the same effect are the following conclusions in the 1922 report of the International Joint Commission on the St. Lawrence Waterway:

(1) The then existing means of transportation between the tributary area in the United States and the seaboard were altogether inadequate, and the railroads had not kept pace with the needs of the country.

(2) Although war conditions had something to do with the dislocation of railway traffic in the United States and, although various other factors should be taken into account, such as the congestion of traffic at certain critical points between the West and the Atlantic Seaboard, and the abnormal demand for cars at certain times of the year, the fundamental difficulty lay rather in the phenomenal growth of the population and industry throughout the Middle Western and Western States, a growth with which the railroads had failed to keep pace.

(3) The solution of the problem called for the utilization of every practicable means of communication, and particularly of the natural waterway extending from the Atlantic into the very heart of the continent.

That the belief of the Department of Commerce that the further and continued improvement of inland waterways was justified was based at least in part on inadequate rail transportation facilities, and this is clearly demonstrated in the statement of the Director of the Bureau of Foreign and Domestic Commerce in submitting, in June, 1923, to the then Secretary of Commerce, a survey of inland water transportation in the United States. The Director stated that, although interest in the development of internal water routes had never been entirely lacking in recent years, particularly those during and immediately following the World War, there had been a definite focusing of attention on rivers and canals as a means of supplementing the periodically inadequate transport system. He said that it was the opinion in many quarters that the railroads would be unable in the future to increase their capacity to the extent demanded by a rapidly expanding commerce, and that it would be necessary to rely to a greater extent than formerly on water routes for the carriage of both bulk and package freight.

---

[16] *Congressional Record*, Vol. 65, Pt. 9, p. 8720.

Even after the inauguration of the program for the rehabilitation and expansion of the national railroad system, the notion of the permanent inadequacy of the railroads continued. Expressions of this so-called inadequacy are found in the hearings before the Committee on Interstate and Foreign Commerce, House of Representatives.[17] The so-called Denison Act, which resulted, gave rise to the Court proceedings relating to the Commission's power to prescribe, without a hearing, through routes and joint rates between the railways and inland water carriers.

Later, and in 1930, Mr. Theodore Brent, in an address before the Thirty-Sixth Annual Convention of the Ohio Valley Improvement Association, said that during the last 75 or 80 yr, the American public had given its attention almost exclusively to the development of railroads as a means of transportation. "Since the beginning of the Twentieth Century, however, there had been rude awakenings," said Mr. Brent. Furthermore, one need but read the elaborate and emergency provisions of the Interstate Commerce Law, dealing with congestions and break-downs of service, and remember the conditions that caused their enactment, to realize that the railroads had marked limitations, and that these reflections had brought studious people to renew their pleas for the development of the inland water resources as auxiliary means of transportation.

Senator Joseph E. Ransdell, in an address at the same Convention, stated that shortly after the National Rivers and Harbors Congress was formed in 1906, he traveled throughout the United States, everywhere talking waterways, but that his voice was like one in the wilderness; that no interest was taken in waterways, but that gradually, as the result of educational work of the Rivers and Harbors Congress, of the annual conventions which were being held, and of the many speeches made in the United States by the field directors and agents, some public sentiment was developed.

The divergence of views of these two waterways spokesmen is remarkable. Mr. Brent referred to the pleas for inland waterway development as an auxiliary means of transportation, and Senator Ransdell deplored the lack of public sentiment which manifested itself, in some degree, only after many years of intensive educational work. It may be said that the need for new and additional transportation facilities lent great strength to public demand and served largely to secure the appropriations of generous sums of money for the development of the inland waterways of the United States.

---

[17] H. R. Doc. No. 10710 as amended by H. R. Doc. No. 13512, 70th Cong., 2d Session.

It is proper to conclude, therefore, that the periods of greatest interest in inland waterway transportation can be traced generally to those of railway congestion. The great majority of the people, apparently, have been indifferent to the question, except on those occasions in the past when railroad facilities and service have proved inadequate.

No one will deny that the existing railway plant is capable of handling much more tonnage than is available, or in reasonable prospect. The peak traffic of 1929, amounting to more than 447 billion revenue ton-miles, was handled with no car shortage. This compares with the traffic volume of 410 billion revenue ton-miles in 1920 during which year there was a reported maximum shortage of 147 309 cars.

The potential capacity of the railways is only the result of a plan of expansion adopted shortly after the end of Federal control. Early in 1923, railway executives agreed upon this program, looking toward the rehabilitation of facilities, and to an increase in efficiency and economy in operation. The entire program rested upon the basis of investment of large sums of new money in the industry. During the succeeding eight years, until the end of 1930, the program of heavy annual expenditures for additions and betterments to plants was consistently advanced. During that 8-yr period nearly 6.75 billions of dollars were so expended. The program had a twofold purpose: First, to supply the country with adequate rail transportation; and, second, to assure the public that the transportation would be efficiently and economically rendered, from the standpoint both of the user and the producer of the service. The program still continues.

In the report of Federal Co-Ordinator of Transportation, Joseph B. Eastman,[18] of March 10, 1934, the statement is made that from 1920 to 1932 the net total expenditures for new transportation facilities amounted to $19 110 000 000, or substantially the same as the railways' investment in 1920. Included in that sum is an investment of $423 613 000 in pipe lines for the transportation of petroleum products; $12 500 000 000 for highways and streets; and $604 000 000 of Federal money for the improvement of rivers and harbors.

With this great increase in transportation facilities and the fact that the physical expansion of the nation is largely accomplished, it is apparent that there is little if any justification for the continued spending of millions of dollars yearly on the inland waterways as supplements to land transportation facilities.

Despite the conviction that water transportation was necessary to supplement the railways, it has generally been considered by responsible authorities that the cost necessary for the creation and maintenance of waterways is a factor to be given consideration. The report of the Windom-Select Committee on Transportation Routes to the Seaboard, in 1874, stated that, after a most careful consideration of the merits of various proposed improvements, taking into account the cost and other factors, the Committee came to the conclusion that certain water routes would be feasible and advantageous. The following is quoted from the report: "The Committee believes that the water route suggested should constitute free highways of commerce, subject only to such tolls as may be necessary for maintenance and repairs." To quote further from the report: "If, however, Congress shall deem it expedient to require them to provide interest on the cost of construction and the means for ultimate redemption of the principal, the whole improvement will involve only a loan of Government credit."

---

[18] Senate Doc. No. 152, 73d Cong., 2d Session.

The preliminary report of the Inland Waterways Commission, in 1908, contains the statement that inland waterway transportation should be restored wherever, upon expert examination, it appeared that a benefit commensurate with the cost would result; and, that the practicability of any waterway project depended not only on local and general demands of commerce, but upon various factors, including physical and economic considerations, entering into or tending to counterbalance the cost.

"The cost of facilities for carrying freight," quoting from the Commission's report, "whether borne by the Federal Government or by private capital is a burden upon the resources of the country. While the tendency of water improvements to lower freight rates is an important element to be considered, the fundamental criterion should be whether a railway or a waterway, whether constructed or improved, will be a profitable investment of capital." In its final report, submitted in 1912, the National Waterways Commission reached the conclusion that if inland waterways cannot afford cheaper transportation than railroads, the sums spent for navigation could be more profitably utilized for increasing railway mileage and efficiency, and that in determining the cost of transportation by water each ton should be charged with its proportion of the cost of improvement even if, in actual practice, this expense is borne by the Government.

The Commission found that a frequent method of demonstrating that water transportation is cheaper than rail is by comparing the average cost per ton-mile on some waterway with that for all the railways in the United States but that no such exact comparisons as these can be made for the reason that the rates compared do not include the same elements of cost. It made the definite statement that any comparison of transportation cost by rail and by water would be of value only when the two rates include similar elements of expense. The Commission held that whether water traffic should be charged with all the expenses incurred for aiding navigation, or whether these should be met, in whole or in part, by taxation, is a question of public policy.

As to differentials in favor of the water carriers, the National Waterways Commission declared that the main problem is whether the cost of transportation by a water route is sufficiently cheaper than that by rail to warrant the granting of a certain differential in its favor.

The Department of Commerce takes the position that, although the Government has authorized the expenditure of many millions of dollars to provide the most improved type of equipment for the experiment it has undertaken, and the benefits of its experience will be available to private capital, it may be that the experiment will not prove remunerative if all factors of cost are taken into consideration, including interest on the sums spent in constructing the channels; and, furthermore, that for services on channels already made navigable, or on canals already built, the returns need cover only current operating expenses and necessary maintenance of channel, terminals, and floating equipment. The Department further stated that, although the expenses for these waterways are borne by the Government, they are a drain on the economic resources of the country.

Recognition that the "savings" in transportation costs accruing to the users of barge service are made up by the taxes paid by the general public, is found in the Annual Report of the Chief of Inland and Coastwise Waterways Service, for 1923, wherein it is stated that there should be a free interchange of freight with the railroads, on the ground that otherwise it would be unfair discrimination "to tax the public at large" for the benefit of a small section of the country.

In an address at Louisville, Ky., on October 23, 1929, President Herbert Hoover, Hon. M. Am. Soc. C. E., stated that "as a general and broad policy, I favor modernizing of every part of our waterways which will show economic justification."

The Board of Engineers for Rivers and Harbors, of the U. S. War Department, in co-operation with the United States Shipping Board, deals with the subject in these words:[19]

> "The primary measure of the economic value of any waterway system is the savings in transportation costs which it affords. Usually, this saving is shown by comparing the water transportation cost with the rates for moving the same goods between the same points by rail. Included in this cost of water transportation should be the charges for interest on capital investment in waterway improvements plus annual cost of operation and maintenance."

In an address before the Thirty-Sixth Annual Convention of the Ohio Valley Improvement Association, in 1930, C. O. Sherrill, M. Am. Soc. C. E., in discussing certain data relating to Ohio River operations, stated that they were based on the real cost of transportation by water, including the interest charges on the costs of the improvement, as well as operation and maintenance costs.

The United States Chamber of Commerce submitted to the so-called Shannon Committee, investigating Government competition with private enterprise, a number of principles, among which is found No. IV, reading as follows:

> "Grants of public money, whether as gifts or as loans and regardless of the conditions attached, to particular forms of business enterprise, or for the special advantage of particular forms of business enterprise in their competition with other lawful forms, cause unfair damages to private citizens in their lawful pursuits and this damage cannot be offset either by pretended or realized benefits to other citizens or classes of citizens."

The report of the Shannon Committee,[20] states, among other things, that one of the facts which has been demonstrated in the investigation is that transportation by barges of the Inland Waterways Corporation is not cheap transportation. To quote the words of the Committee: "When a shipper ships by railroad, the rate which is charged by the railroad is the total charge for the transportation of material." The report further stated that the Barge Line pays nothing for taxes, makes no attempt to earn a return on its investment, and pays nothing for the use of the stream or to reimburse the Government for its expenditures for construction and maintenance. It also declared that part of the transportation cost represented by the maintenance of roadway, interest on investment, and taxes, which is paid by the shipper when he ships by rail, is borne by the taxpayer when the materials move by the Federal Barge Line, and that this burden which is borne by the taxpayer is much greater than the difference between the railroad freight rate and the Barge Line freight rate.

---

[19] "Transportation on the Ohio River System" (Interim Report), Library of Congress Card 27-26771.

[20] H. R. Doc. No. 1985, 72d Cong., 2d Session.

The National Transportation Committee, in its report of February 13, 1933, reached the conclusion that Government assumption of all or part of the costs of inefficient competing transport as a defense against monopoly is no longer warranted and should be abandoned, and that, as a general principle, inland waterways should bear all costs of amortization, interest, maintenance, and operation of the facilities for their navigation. The report concluded that the studies of the Committee showed no economic benefits to the country commensurate with the money spent on inland waterways; that these costs bore heavily on the taxpayer as a direct burden. The Committee found it difficult to justify the wasteful outpouring of hundreds of millions of dollars for results so barren of economic returns.

It will be recalled that the National Transportation Committee was composed of the Hon. Calvin Coolidge, the Hon. Alfred E. Smith, and Messrs. Bernard M. Baruch, Clark Howell, and Alexander Legge.

In an address before the National Rivers and Harbors Congress, at Washington, D. C., on April 30, 1934, Joseph B. Eastman, Federal Co-Ordinator of Transportation, stated:

"The point is that the cost of construction of the new waterway and the annual cost of its maintenance are as much a part of the real cost to the public of the new transportation facilities as are the cost of construction and the cost of maintenance of the steamship or barges which operate over the waterway. The water carriers do not bear the expense of constructing or maintaining the waterway under our present practice; nevertheless, it is there—it cannot be escaped and, in one way or another, it is a burden upon the people of the country."

Similar views were expressed by Mr. Eastman in an address before the American Life Convention, at Chicago, on October 10, 1934, and before the Convention of the Mississippi Valley Association, at St. Louis, on November 26, 1934.

The report of the Mississippi Valley Committee of the Public Works Administration, which Committee was composed, according to the Department of the Interior, of a group of the nation's leading scientists and technicians, had the following to say on this point:

"A system of accounting is also required through which the capital investment, as well as maintenance and operating costs, on any given going navigation project can be currently determined * * *. The nation undoubtedly needs more definite and disinterested data to show the relative costs, taking in all factors, of transporting commodities by inland waterways in comparison with other media of transportation. Factual data are needed on this subject to establish justification or non-justification for either the building or continuation of any waterways program whether it be extensive or limited."

To summarize: (*a*) As recently as ten years ago justification for inland waterway development at public expense rested almost entirely on the supposed inadequacy of the railways; (*b*) the railway plant is now, and has been for many years, capable of handling much more tonnage than is reasonably in sight—much more than was moved in the peak year of 1929, and without car shortage or delay; (*c*) overwhelming expert opinion holds that the cost of providing and maintaining these waterways is a drain on the resources of the country; and (*d*), there has been a tremendous expansion in the transportation facilities of all kinds since 1920, so that to-day there are far more ways to move goods than there are goods to be moved.

In presenting this discussion, the writer does not have in mind so much a rebuttal of the conclusions or theories presented in the Symposium as the need for emphasizing, in this connection, the background and history of waterway development in the United States. In the earlier days, there was an absolute necessity for waterways and in the consideration of new projects it was the very definite view of various authorities, including governmental bodies, that costs incurred in creating and maintaining inland waterways were a fixed burden upon the people—one that must be borne by them through taxation.

If the writer has interpreted Major Putnam's theory correctly (especially as given in the text following Table 5) he has not given much weight to this fact. In common with all advocates of further inland waterway developments he ignores entirely the undisputed fact that land transportation (that is, rail, motor, or pipe line) is now fully capable of handling all the commerce of this country. This is a condition, of course, that did not exist even as late as 75 yr ago. In other words, the reasons that prompted and justified the creation of waterways at public expense, to move the Nation's goods, have disappeared completely.

J. E. GOODRICH,[21] ESQ. (by letter).—Much information of interest is contained in the papers of this Symposium. Fully realizing his incapacity to present any meritorious critical discussion of the opinions of experts in the matter, the writer requests that his comments be considered in the nature of inquiry.

Major Putnam has defined one important characteristic of the movement of commerce on an inland waterway—that is, the load factor of the floating equipment engaged therein. It is to be hoped that, in his closing discussion, he will present data as to actual existing load factors based on his definition. It may be found that they are quite low. For instance, he indicates that the commercial fleet in active operation in 1935 on the waters under consideration in his paper, included towboats with an approximate horse-power of 176 000 and barges with a carrying capacity of 1 600 000 tons and, furthermore, under his comparison of costs, that the annual traffic to be handled is about 5 500 million ton-miles. Using these data, it appears that the actual average load factor of the towboats is about 24% and of the barges about 8.7 per cent. It is possible that the foregoing is an improper derivation, or that after the waterways have been fully developed, the average operating load factor may be somewhat improved. At any rate, before a reliable comparison between water and rail costs can be made, a reasonable determination of the probable load factor is essential.

---

[21] Senior Engr., with U. S. Div. Engr., St. Louis, Mo. Elected an Assoc. M. Am. Soc. C. E., on June 13, 1938.

It appears that the main purpose of comparisons between the costs of transportation by land and inland waterways is to determine whether additional waterway improvements should be undertaken. Obviously, an investigation for that purpose should take into account the extent to which existing transportation facilities are adequate. Reduced to a simple case in which a waterway under consideration for improvement is to serve an area now adequately served by rail, should not the comparison be based on the total cost of transportation in the area served by the two systems before and after the waterway is improved and placed in service? Before the waterway is put into service the costs include the fixed and operating charges of the railroad alone. When the waterway is in service the total cost includes the fixed and operating charges of the waterway and the carriers thereon plus the same fixed charges on the railroad as existed previously, as well as operating charges on such freight as is left to the railroad. The only way the railroads could avoid these fixed charges (which persumably the public must pay) would be to abandon the service. Even if this were permissible, it would entail a destruction of capital which, "in the long run," would be paid for by the public. If this view is entitled to consideration, it would appear necessary to include in the balance sheet of water *versus* rail transportation an evaluation of the public loss due to rendering the existing rail facilities less economically efficient.

It may be contended that by reducing the cost of certain commercial movements, water facilities would stimulate industry so that the traffic diverted from the rail line would be restored from other sources. Industry, however, is affected by taxes as well as by direct transportation costs. If the waterway improvement increases the tax bill to a greater extent than it reduces the direct transportation bill, it is difficult to foresee a resulting general stimulation of industry so as to bring about increased commerce in the country as a whole. On the other hand, a waterway which results in a substantial reduction in combined transportation and tax costs may be an actual benefit to the railroads as well as to other interests. In investigating the merits of a waterway to serve an area already adequately served, it should not be assumed that benefits of this character will arise until it has been shown from other considerations that the waterway is warranted and will actually reduce total costs. It should be shown that the horse exists before it is assumed that the cart will be drawn. Thereafter, these factors, too, should be taken into account and thoroughly analyzed in determining the extent to which the waterway improvements are worth while.

A knowledge of relative cost without consideration of the relative value of the service obtained is not sufficient to indicate the worth of an investment.

It is generally recognized that waterway and rail transportation are not equally expeditious, flexible, and dependable, and these inequalities should enter into the economic study. Perhaps the best indications available at this time of shippers' views as to these inequalities are the differentials between rail and barge line rates necessary to place the two types of service on a competitive basis where common carriers are involved. It is possible that shippers' views in this respect may be modified as the waterways become more adequately improved and their services better established.

Economic comparisons of rail and waterway transportation costs are frequently made in which the interest on the cost of the waterway is computed at a lower rate than that applicable to railroads. Such methods seem improper if the purpose is to show the inherent superiority of waterways aside from the advantage that they possess due to low-cost Federal financing, but proper if the purpose of the comparison is confined to determining the most economical medium under actual present methods of securing capital.

If economic comparisons were limited to reductions in the cost of freight movements, and the foregoing ideas were given application, some proposed inland waterway improvements might not be found so meritorious as to warrant the degree of enthusiasm often afforded them. However, waterways may be beneficial to a substantial volume of pleasure-boat navigation. In some degree waterway improvements, through increase in low stream flows, or the concentration of head, may facilitate the production of power. They may result in flood-control benefits by the storage of flood water, stabilization of banks, improvement of the hydraulic characteristics of streams at flood stages, and the supply of vessels for rescue work, although these benefits may be offset somewhat by the stimulation of objectionable and inadequately controlled concentration of industry in the flood-plains of streams. The availability, in operating condition, of ordinarily excess transportation facilities to meet unanticipated emergencies, is apparently of some benefit. Under certain conditions the undertaking of waterway improvements which approach the border line of economic feasibility may be warranted because it will afford productive employment of labor which, otherwise, would receive non-productive relief funds. Without involving sentimentalism, these items may properly be given consideration in an economic comparison of rail and waterway transportation.

H. R. FAISON,[22] M. AM. SOC. C. E. (by letter).—Opportunity to take part in the discussion of water transportation costs in an impartial technical publication is welcomed by the writer. After all, finding the value of improvements for navigation is a technical problem. Most of the publicity accorded this important topic in the commercial press is too partisan in viewpoint to serve the man who is seeking facts. The "picture" is too likely to be colored, perhaps unconsciously, by the interest of some particular section, industry, or type of carrier; or distorted by an array of selected statistics which illuminate only one side. As a consequence some theories as to the cost of water transportation, not strictly in accord with sound economics, have apparently gained wide popular acceptance even among engineers. In spite of Mr. Wonson's obvious sincerity, some of these theories leading to unsound conclusions seem to have crept into his otherwise able and fair treatment of the subject. With his basic principles the writer is in complete accord.

---

[22] Senior Engr., U. S. War Dept., Washington, D. C.

The writer does not advocate providing or maintaining, by artificial stimulants, any route or means of transportation that proves uneconomical. There would be no point in trying to hold traffic on the rivers to keep water service alive if no general public benefit resulted. He would make an even broader application of this principle to cover outmoded and uneconomical transportation routes and service of all kinds in which the public has a stake. Differences with Mr. Wonson arise, not as to principles, but as to methods of appraisal and bases of comparison between the several types of transportation. It seems incumbent upon engineers confronted with waterway problems for solution in the interest of the people as a whole to exercise particular care in adopting the proper "yardstick." Because there are well known inherent draw-backs to barge transportation, it cannot soundly be assumed that all inland waterways are bad investments. Averages obtained by grouping good and bad projects together are obviously valueless. It is frequently found in the case of individual improvements that favorable factors, fully recognized and evaluated, outweigh all natural disadvantages.

Circuity.—Prominent among such disadvantages stressed by Mr. Wonson is the fact that river routes are generally longer than competing rail routes. Like most of the other elements of comparison, circuity in the case of individual waterways can usually be measured and given a definite value. Mr. Wonson attempts to do just that, but he derives his circuity factors from a comparison of river mileage with the shortest rail distance, ignoring competing rail routes. He uses these factors to raise the actual unit cost of freight movement by water to a higher sum for comparison with rail cost. This procedure gives no consideration to the fact that the great preponderance of rail freight also travels by circuitous routes. The Federal Coordinator of Transportation finds that the average rail carload moves 11% farther than would be necessary by a direct line in common use.[23] As a result of their analysis of freight movements by rail between river ports, the barge lines have petitioned the Interstate Commerce Commission to recognize officially the rail circuity factor of 20% in excess of short line mileage in the Mississippi and Ohio Valleys.[24] In cases of competition with water routes involving relief from the long-and-short-haul requirements of the Transportation Act, it is not uncommon to authorize rail routes as much as 50% longer than the short line. It should be remembered that the circuity of some of the principal inland water routes is less than that. The canalized Monongahela River is actually shorter, as a matter of fact, than competing rail lines, but the fact is dismissed in Mr. Wonson's analysis as negligible. Obviously, the circuity factors in the paper under discussion must be reduced to conform to the facts, if the reader is to arrive at the correct answer.

Amortized Expenditures.—It was not found possible to reconcile Mr. Wonson's distribution of costs among the several interests affected with published statistics. Apparently he charges such items as bank protection, and, in fact, all the money ever spent on inland streams except flood control allotments, to existing navigation facilities. According to his theory these charges must be borne by existing water lines on their present tonnage or improvements should be abandoned. In this situation the engineer must face the fact, squarely, that the millions spent for purposes other than navigation, and for navigation improvements which have been outmoded and abandoned or superseded by modern projects, are not involved in any conceivable way with his problem.

---

[23] Freight Traffic Rept., Paragraph 71.

[24] Interstate Commerce Commission, Docket No. 26712.

Only a small part of the open channel work done on the Ohio and Warrior Rivers, for example, contributed in any manner to the present efficiency of these waterways, but it served its purpose for many years and its cost was amortized by contemporary river commerce. At most, only the cost of useful work necessary for present navigation has any practical bearing. On the Warrior River, canalization was begun in the Nineties and completed just prior to the serious congestion of the Nation's transportation system incident to the World War. Justification of expenditures providing this alternative freight route between an essential producing area and tidewater would scarcely have been seriously questioned at that time. Such waterways cannot be duplicated over-night, and naturally it is impossible to expand and contract permanent investment already made, to synchronize with fluctuating traffic volume and business cycles. In this connection it is far from clear just what end would be served with respect to all these past expenditures if the waterways were to be abandoned now as recommended in Mr. Wonson's paper.

Interchange of Traffic.—Mr. Wonson's analysis indicates that benefits due to the improvement of inland rivers are restricted to communities along their banks. The evident intent of all legislation having to do with water transportation is to secure the widest possible distribution of benefits paid for by the general public. The clause of the act establishing rail-water differential routes and rates is obviously designed to extend to "dry land" territory the same scale of savings enjoyed by ports along the waterways. Barge lines have in fact instituted a broad system of traffic interchange with railroads and motor truck lines extending far into the riverless regions of the country. The effect would doubtless be felt more generally were it not for the openly avowed unwillingness of the railroads to co-operate. As a group, their opposition has ranged from challenging the validity of the legislation in the Courts and opposing each proposed extension of the system, to the current proceeding before the Interstate Commerce Commission aimed at cancellation of all routes and differentials through which localities inaccessible by water already enjoy the benefits of barge service.[24] It is desired to emphasize at this point that the writer does not mean to imply that there is anything fundamentally wrong with this perfectly natural attitude of rail and water competitors toward each other, their interests being involved primarily in the profitable operation of their individual properties. The engineer must recognize, however, that these interests cannot be expected to coincide with each other nor with the interest of the country at large.

Distribution of Benefits.—For reasons obscure to the writer, Mr. Wonson seems to hold that savings resulting from common carrier water service may be counted as public benefits, whereas savings from contract or private water carriage are not public benefits. Congress does not attempt to assess the benefits resulting from the various types of river improvement to any particular region or group of beneficiaries, except where the effects are local in character. The waterways are made open to all, and because of the competitive element it is impracticable for the producer, carrier, or distributor of goods to monopolize the benefits. The writer has long recognized the futility of trying to trace savings from river improvement to their ultimate recipients, or to devise any system of charges that would distribute the burden more equitably than the present one in which the public pays for its waterway and the shipper pays for transportation on it. He agrees with Mr. Wonson that improvement for navigation is not warranted if the potential aggregate of such costs is greater than by other available means of transport. He differs from him in the method of measuring these costs, and the significance of the results. The engineer's problem is not to identify the beneficiaries, but to determine whether there is, in fact, a net economic saving to be distributed.

Tonnage Estimates.—Mr. Wonson attaches great significance to the relative public use of rail and water facilities. On the other hand, his estimates of the volume of water commerce that can reasonably be expected are based on the comparatively small tonnage which the boat lines thus far have been able to develop and hold in the face of competitive rail rate depression. It is necessary to bear in mind that inland river improvements comprise a system that is still under construction and far from complete. Records show[25] that the growth of water commerce is in the direction of longer and longer hauls as the individual waterways are progressively extended and connected into a system. The period for building up permanent water traffic involving the gradual development of storage warehouses, grain elevators, cotton compresses, industrial plants, and auxiliary services at the water side without sacrificing existing facilities, is a period of evolution reasonably expected to extend over a considerable number of years. It is believed that the greatest impetus toward building up a representative volume of tonnage on waterways will result from the eventual adjustment of freight rates to conform more closely than they now do to the cost of the transportation service. That this trend is officially favored is evidenced by numerous decisions of official regulatory agencies; for example, a concurring opinion of a member of the Interstate Commerce Commission in the Petroleum Products case,[26] reads in part as follows:

> "I am much inclined to believe that a system of rates for all agencies based on cost plus a reasonable profit under normal traffic conditions would allow them all to perform their appropriate functions, and in the end be better for all concerned, including the country and its industries, than any system of competitive rates."

Mr. Wonson's insistence that freight charges measure the cost of the service, and his attack on waterways as tending to favor regions adjacent to rivers at the expense of more inaccessible territory would lead the reader to infer that rail freight charges are commensurate with cost, and that rail carriers do not tax riverless regions with high rates in order to support low rates along the waterways. The writer agrees that when rates are made proportionate to cost of operation, it is reasonable to expect an appropriate distribution of traffic among the several forms of transportation, to each falling the share best adapted to its particular kind of service. Direct comparisons of tonnage would then be significant, and total relative ton-mile costs would offer conclusive evidence of the degree of justification of river improvements. That ideal condition is more remote from the rail rate structure, however, than from the scales prevailing on water.

[26] 194—ICC—31.

In its profound effect on relative public use, it is necessary to recognize the practically universal railroad policy of depressing rates to profitless levels when confronted with competition from water lines. Such rates not only fail to cover fixed charges but usually cover only a part of operating and maintenance expense.[27] The expectation of this result on the part of shippers undoubtedly gives rise to much of the organized agitation for improvement of inland streams, and introduces the most troublesome single factor into the problem. The writer joins Mr. Wonson in earnestly deploring this use of waterways to regulate rail rates, but the depression of rates to meet water competition, of course, is a wholly voluntary act on the part of the railroads. It is clear that freight recaptured by this means from economical routes and diverted to uneconomical routes, causes the public to forego the real savings made available by water. When thus deprived of profitable tonnage the barge lines sustain material loss which is totally uncompensated by profit to the rail carrier or real benefit to the shipper.

The Added Traffic Theory.—For the most part the competitive depression of rail rates is confined to traffic between ports served by waterways, the rates between intermediate and interior points being held up on the "dry land" level. In addition to this non-competitive traffic between intermediate points, the railroads normally handle between ports many commodities not adapted to barge movement. Under these circumstances the depression of rail rates to competitive levels on commodity movements adapted to water theoretically, at least, leaves the bulk of rail traffic to carry the expense burden. Obviously, the total revenue collected by either type of carrier must exceed its total expenses "in the long run" if it is to prosper. Thus, the water carriers would be completely at the mercy of rail competition were it not for the fact that under normal conditions barge lines can handle adapted commodities at much less cost than rail carriers.

The "added traffic" theory invoked by the railroads to meet this situation is based on the premise that once a carrier is provided with adequate equipment and terminals, and is in operation, with supervisory staffs employed, and a sufficient volume of traffic moving at normal rates to pay the overhead, the out-of-pocket cost of handling any additional freight that may be secured is but a small part of the full cost of maintenance and operation. For the creation of new traffic there is nothing fundamentally unsound in this theory, provided always that rates are so fixed that the extra tonnage brings in as much money as is spent to move it. It is when carriers begin to view each other's business as potential added traffic, and to prey upon each other's basic tonnage by means of out-of-pocket rates, that the theory breaks down and the public eventually has to make good an uncompensated loss. The raided competitors certainly cannot afford to submit cheerfully to "subtracted" traffic, nor subscribe to the theory that their revenues and expenses are not affected thereby. When carried to the extreme now characterizing the aggressive campaign against water transportation, almost all traffic is rapidly taking on the status of added traffic, and revenue with which to pay full operating, maintenance, and fixed charges, not to mention dividends, is becoming progressively scarcer among the railways adopting this policy.[28]

---

[27] ICC Stats., 3 352—1933.

Practical Illustration.—The most typical case brought to the notice of the writer was decided July 23, 1937,[29] and involves the shipment of about 100 000 tons of molasses annually from the New Orleans area to Peoria, Ill., on the Illinois River. When this movement began the rail rate was $6.00 per ton, which over the short rail line of 840 miles would yield 7.1 mills per ton-mile. The industry purchased a towboat and tank barge equipment and found that it could transport its own raw material for $2.60 per ton, or at 2.0 mills per ton-mile for a water distance of 1 270 miles. The initial floating plant being found inadequate, the shipper was negotiating for the purchase of an additional fleet when the railroads depressed their rate to $3.50 per ton. This reduction was sufficient to hold a substantial part of the business for the railroads and to bring about the cancellation of orders for new barge equipment. The reduced rate yields 4.2 mills per ton-mile gross. This rate compared with the 9.9 mills average rail rate used by Mr. Wonson would indicate that the molasses business to Peoria is not "pulling its weight" on the railroad but that the river loses tonnage it could carry profitably. The rates on molasses to intermediate dry-land points, of course, are held up to the old high level and, together with other noncompetitive traffic, are doubtless carrying the added burden. This typical case is used to emphasize the fact that each departure from the long-and-short haul regulations of which there are hundreds, tends to divert a substantial block of tonnage from the waterways where it could be handled economically, and where it would serve to decrease the average unit costs of water movement.

Effect of Rate Cutting.—No single type of carrier holds a vested right in any particular traffic. As already stated there would be no point in trying to hold traffic on the rivers to keep water transportation alive if no net benefit resulted. However, water transportation is clearly entitled to a chance to justify itself, before the public can pass judgment intelligently. There is no logic in recapturing tonnage from water by means of profitless rail rates, and then pointing to the lack of water-borne tonnage as significant. Out-of-pocket rail rates hold the volume of barge tonnage far below that which would normally seek that form of carriage, and which river carriers have justifiably equipped themselves to handle. Naturally unit costs of water line operation rise in response to such depletion, and the cost per ton to the Federal Government of waterway construction is unduly inflated. It will be readily understood that, in use of the term, "inflated," and all other expressions of difference of opinion with Mr.

[28] See testimony of the rail representatives in Ex Parte 123, ICC, December, 1937.

[29] 223—ICC—221.

Wonson throughout this discussion, there is no thought of imputing any conscious or deliberate bias. The writer believes that the angles stressed herein have been overlooked, and that their full consideration will reverse some of Mr. Wonson's conclusions. He is not concerned with regulation of the practices of the carriers, but with due recognition of their effect on cost factors.

Summary.—Long-range analysis of the future of river commerce must contemplate, in all reason, a closer approach to the cost basis of fixing transportation charges than now prevails. The present system is leading toward bankruptcy for the carriers and a collapse of the transportation structure. Doubtless there is a present surplus of transportation capacity in certain areas and the least efficient and economical carriers, whether rail or water, must inevitably perish, to the advantage of the general situation. It seems scarcely reasonable to the writer, however, to hold that the internal waterway system is a liability rather than an asset to the country. Eliminating the cost of improvements for other purposes such as prevention of soil erosion and the cost of outmoded and superseded improvements, placing the remaining costs on a factual basis, and using the low operating costs of going barge lines, completely changes the picture in comparison between rail and water carriage.

It is firmly believed that traffic, if permitted freely to seek the best adapted routes, will flow in greatly increased volume to the important links in the waterway system, resulting in total ton-mile costs so reduced as to compare favorably with the most economical competitive service. Lest it appear that the points discussed herein are trivial in their bearing, the reader is asked to make a hasty computation of the results of applying Mr. Wonson's method of appraisal. A 50% drop in water-borne tonnage as a result of rate cutting, means a 100% inflation of the cost of Federal improvement, computed on the ton-mile basis, in addition to the rise in unit costs of the boat lines. Adding extraneous costs, and those for superseded improvements, using cost ratios of projects still under construction and not yet ready for traffic, employing excessive circuity factors, all err in the same direction, combining to depress still further the water-borne tonnage figures and inflate unit costs. If taken at their face value, these factors would nullify every real economy the most worthy waterway project is capable of effecting; and yet it is this depleted tonnage and these inflated costs that are cited as proof of the failure of river improvement to justify itself as a national policy.

RUFUS W. PUTNAM,[30] M. AM. SOC. C. E. (by letter).—In preparing one of the two basic papers for this Symposium, it was hoped that the main points at issue in this question of rail *versus* water transportation would be set up in such a manner that in the subsequent discussions there would be avoided rehearsals of the many minor subjects which in the past have been responsible for the apparent confusion of thought obscuring the few facts and principles involved. The almost complete absence of direct discussion or criticism of the paper itself leads the writer to the conclusion that it failed in its purpose and that he inadvertently so expressed himself as to stir up a "hornet's nest" of indirect comment.

---

[30] Pres., Maritime Eng. Corporation, Chicago, Ill.

It has been held that the public necessity requires a satisfactory transportation service—one which is adequate, efficient, and economical. A general statement, such as this, necessarily becomes relative only when applied to specific cases. It would not do to condemn river transportation because of the closure of northern waterways during the winter season, or on account of circuity, or because of rigidity, any more than it would be correct to condemn transportation on the Great Lakes for the same reasons. From the point of view of the user these considerations affect only his over-all transportation costs, which include the cost of storage of requirements during the closed winter season.

No general plea for the necessity of waterway improvement should be entertained these days on account of the inadequacy of rail service. Even in times of national emergency, although the waterways themselves might have excess capacity available for use, the floating and terminal equipment might not have; therefore the value of this means of transportation, as a reserve against inadequacy of other forms, is not great.

On the tangible side, the entire question is one of economics; but, unfortunately, this seems to be a very difficult question when it comes to obtaining any degree of agreement as to the factors involved. In the first place whatever method of comparison is used it would be best to apply similar, if not identical, tests to rail as well as to water transportation. It is believed that the use of the method of comparing freight rates is generally recognized as incorrect. Rates of water carriers do not carry the investment, maintenance, and operating costs of the projects; those of rail carriers in some cases are no more than, if as great as, out-of-pocket costs, whereas, average rail rates are known to be insufficient to carry fixed charges on the entire railroad investment of the country. Rail rates should not be compared with water costs, even if the latter include fixed charges on the waterway improvement plus maintenance costs (see heading "In Justification: Comparison of Costs," in the writer's paper). The only solution apparent to the writer seems to be to attempt to compare rail costs with water costs, and, at best, such a procedure can result only in an approximation.

As to out-of-pocket operating costs of the carriers there appear to be no particular difficulties except the reluctance of water carriers to reveal their confidential data. Maintenance-of-way costs for the railroads and maintenance costs for waterways are readily available. The principal obstacle seems to be in reaching even a reasonable approximation of what should be the capital cost in each case.

If it is assumed that capital cost is to be measured in terms of expenditures to produce these transportation agencies, difficulties are encountered in either case. For the waterways, it is possible to go back and sum up the expenditures for "New Work" for any project. Where flood control and bank protection are not involved this is comparatively simple, but where they do form a part of the improvement, segregation is not so easy. An approximation is necessary and this the writer made in his paper in arriving at a 1937 cost of $550 000 000 for the system under discussion (refer also to Mr. Hartley's discussion). This estimate did not take into consideration the invisible costs of bridges which, in a more accurate determination, should be included. Merely for purposes of illustration, the writer has roughly estimated that the extra bridge costs involved on the 850 miles of the Mississippi River above Cairo, on account of greater clearances, and the provision and operation of draw-spans (capitalized), would approximate $16 500 000. The item is substantial but not large in comparison with the totals involved.

The writer's estimate made no deductions for the cost of early river improvements, long since superseded, and which had very little value as parts of the more modern projects now under way or recently completed (see Mr. Faison's discussion). A more accurate determination of costs would make allowance for these substantial items of expense.

To measure the cost of any part of the railroad system of the United States in a similar manner is next to impossible. Calculation of the actual sum of money expended on capital construction would not give the answer as there are costs of very substantial proportions which the investing public have paid during the lifetime of the railroads for which there are no visible, tangible returns. Several of the railroads in the Mississippi Valley have gone through the experience of alternate periods of prosperity, receivership, sale, and reorganization. Securities have been scaled down and in some instances "wiped out"; the cost of any such losses should be included as they represent expenditures by the public made for the purpose of providing transportation.

The use of the cost-of-reproduction method as a basis of comparison is not believed to be correctly applicable in this case. To do so would be to supplant fact with theory, and theoretical returns on theoretical investments cannot be used for the payment of taxes, interest, or dividends. As far as waterways are concerned, it would be necessary to calculate the cost of reproduction on the basis of an assumed rate of construction which is next to impossible to predict with irregular Congressional appropriations. Assumptions or theories would have to be applied to determine rights-of-way costs, which are substantial factors in railroad costs.

The writer made use of this method in his computation of railroad transportation costs merely because he was unable to determine the capital cost of the railroad system in the Mississippi Valley on the basis of past expenditures. His results, therefore, are only an approximation and should be so considered.

It is noted that Mr. Goodrich is of the opinion that the load factor of the floating equipment on the inland waterway system is an important factor, and he expresses the hope that the writer would present data as to actual existing load factors in the closing discussion. Such data are quite confidential so that only generalities may be given. One large operator has a towboat load factor of about 21% with a barge load factor of only 6.4%; this case represents about the minimum. Large coal operations on the Ohio River and the Monongahela River are conducted with towboat load factors of about 40% and barge load factors of 25 per cent. Only where an operator has a fairly well balanced two-way movement of bulk commodities do the load factors exceed these values.

Much of the confusion with which these questions are attempted to be solved, and most of the difficulties that exist without confusion, are borne of the effort to make a scientific comparison of two activities which cannot be reduced to terms with a common denominator. An approach to a satisfactory determination might be made by a committee of engineers skilled in this subject, but accord through published papers and discussions seems to be hopeless.

S. L. WONSON,[31] M. AM. SOC. C. E. (by letter).—The writer desires to express appreciation of the discussions of his paper and of the various considerations of interest and value that have been presented, both pro and con.

To the extent that the discussions present a viewpoint opposed to that of the paper, it would appear that a rebuttal would involve substantially a repetition of facts and conclusions already expressed.

There is one collateral consideration that seems worthy of mention, namely, that the natural and primary function of a river is that of a drainage channel, and that works for the improvement of navigation, or for other purposes, should not be allowed to impair the drainage function, or to impede any necessary improvement of it.

Of the force of this consideration, the disaster of 1937 along the Ohio River is a grim reminder. Along another major stream of the Mississippi Basin, upon which extensive works for the improvement of navigation are being constructed, there are communities in apprehension of the effects of a major flood following even the present stage of those improvements.

PRE-STRESSED REINFORCED CONCRETE AND ITS POSSIBILITIES FOR BRIDGE CONSTRUCTION

By Ivan A. Rosov,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Charles S. Whitney, Karl W. Lemcke, Dean F. Peterson, Jr., M. Hirschthal, A. Floris, A. A. Eremin, and Ivan A. Rosov

Synopsis

This paper contains a brief citation of uses made of pre-stressed steel reinforcement in the past and the development of formulas for the solution of special cases. The symbols are defined where they first occur and are summarized for reference in the Appendix.

Introduction

It is customary to consider that the complex, non-homogeneous nature of reinforced concrete is its greatest disadvantage. It is impossible to utilize the strength of steel and of concrete, in the same structural member, with the same degree of economy. In parts of a structure where compression predominates the steel is always understressed, and when tension predominates the designer nearly always assumes that the steel resists all of it. The tensile stress in concrete often exceeds the ultimate, and the resulting cracks are a particularly undesirable characteristic of reinforced concrete. Although such cracks may not immediately endanger the stability of the structure (since the steel resists all the tension), they permit the structure to be destroyed gradually—the concrete by chemical reaction and the steel by corrosion.

On the other hand, the very difference between the two materials can be utilized to the advantage of reinforced concrete structures over all-steel structures. The reinforcement can be designed so as to confine the deformation of concrete within reasonable limits, or, conversely, to produce stresses in the concrete that will act in the proper direction. If it is desired to counterbalance some of the deformations in steel that are expected to occur under the action of working loads, a preliminary stress may be imposed upon the concrete.

This idea of restraining the effects of stress in either material has been accepted as a possibility since reinforced concrete was first introduced, and

---

Note.—Published in September, 1937, *Proceedings*.

[1] Asst. Engr., New York City Tunnel Authority, New York, N. Y.

several structures have been built according to this principle. Only in later years, however, have designers begun an extensive and far-reaching study of all the possibilities for the purpose of utilizing it consistently in structural design and construction. One method of restraining deformations may be illustrated by the case of a concrete column with spiral reinforcement, which, for all practical purposes, is the same as a steel "envelope" that prevents the member from bulging laterally under axial loads. The same effect can be produced by steel reinforcement arranged transversely in a structural member so that its bond with the concrete will serve to establish resistance to deformation in that direction. In this case the external restraining forces exerted by the "envelopes" are replaced by the internal forces in the steel. The workability of this principle has been proved by the results of tests[2] conducted by M. Caquot and P. Brice. These investigators found that any type of transverse reinforcement increases the ultimate compressive strength of concrete in so far as it tends to retard lateral bulging due to axial pressure. Similarly, E. Freyssinet[3] has made concrete that resisted, safely, the lateral bulging caused by axial pressures of 3 550 lb per sq in. He found also that the best type of reinforcement for this purpose is two series of parallel wires set in planes normal to the axis of the loads and tied by semi-circular steel bars.

Another general method of changing deformations of either material in a desired manner may be described broadly under the term, "pre-stressing." A brilliant demonstration of the advantages of this idea is afforded by experience gained in constructing the Albert Louppe Bridge, in France,[4] and the bridge across the Rogue River, in the United States.[5] Pressure exerted by means of jacks at key points along the arches had the effect of eliminating the shrinkage stresses and this decreased, materially, the dimensions of the arches.

The principle of pre-stressing was used by A. Mesnager and T. Vevriers in 1930,[6] and, in this case, was applied both to the concrete and to the steel separately. The arches of the bridge[6] at Vesinet, France, are reinforced by steel tubes, thick enough to constitute a considerable percentage of the cross-sectional area. Ordinarily, shrinkage stresses would have stressed the steel to 12 000 lb per sq in., but, by exerting a pull on the tubes and, simultaneously, a pressure on the concrete within the tubes, the shrinkage stresses were canceled. In other words, when the concrete had shrunk, the preliminary stresses in the steel tubes had disappeared, and the full strength of the metal was utilized to resist loading.

The next progressive step would be to increase the preliminary stresses sufficiently to have a residual stress even after the shrinkage stresses have canceled it partly. This would have the effect of introducing known internal stresses in a structure at previously (and precisely) determined points.

An example of the manner in which this principle is applied to reservoirs was published[7] in 1933. The circular concrete wall of the reservoir is fitted with a series of circumferential rings, and these rings finally are covered with a layer of concrete, leaving the connecting turnbuckles revealed. As the water rises in the reservoir tensile stresses develop in the concrete, which are counterbalanced by the pressure introduced in the steel hoops by means of the turnbuckle. In this manner the compression may be made to balance the tension in the concrete, thus safeguarding the structure against the effects of cracking and leaking.

[7] *Engineering News-Record*, February 16, 1933.

This type of structure, resembling ordinary wooden tanks in principle, has recently been used quite extensively,[8] and with good results. The bond between the concrete and the steel is destroyed by coating the latter with a special asphaltic compound and the circumferential rods slip freely while strained by turnbuckles.[9] The same idea has been used for pipes, with equal success.

In Europe, the practice of pre-stressing does not involve destroying the bond, which conserves the character of the reinforced concrete as a structural unit and distributes the effect of the pre-stressing uniformly all over the length of the structure. In this manner, Professor F. Emperger applied the principle of the pre-stressing to precast pipes, and E. Freyssinet to pipes, posts, foundations etc.

It should be possible to prevent deformation in many other kinds of structures, by pre-stressing the materials of which they are composed. E. Freyssinet has stated his conclusion that reinforced concrete bridges of spans as great as 3 300 ft are possible in this manner. The development of structures of this kind may not be the problem of most immediate concern, but in ordinary engineering practice there is a wide field for economy and improvement in design by a proper application of the pre-stressing principle.

PRE-STRESSED BRIDGE STRUCTURES

Only simple slabs, beams, and girders are treated in this paper, because they are the structural elements that lend themselves most easily to pre-stressing, and in which the results are obvious and most interesting. The reinforcement along the tension face is straight and can be stretched by means of a simple device before the concrete is poured. After the concrete has set the tension is removed from the reinforcement, which then tends to return to its normal length. The result is that, through the bond between the reinforcement and the concrete, an internal force is created which, in turn, resists the deformation due to the application of external forces when the structural member is put to its final use. With respect to the concrete alone, of course, the bond in the steel constitutes an external force, and the amount of this force that remains after the concrete has set may be computed if the relation, $n = \frac{E_s}{E_c}$, is known.

The effect of pre-stressing is opposite to that of the final loading (see Fig. 1). Obviously, it is possible to pre-stress a structural member in such a way that the working load would never produce stresses great enough to cancel the internal stresses entirely. In that case, the cross-section of the beam (see Fig. 1(*c*)) would be entirely in compression.

Since there is no tension in the beam, any cracks that tend to form as a result of shrinkage, or other causes, are automatically closed by the pressure of the steel reinforcement. The net effect is to eliminate the most serious causes of deterioration in concrete, namely, penetration of water or gas and the rusting of the steel reinforcement. Furthermore, the entire cross-section of the concrete becomes effective in compression. Under such ideal conditions the dimensions of reinforced concrete members may sometimes be decreased as much as 50 per cent. The dead load is much more important in concrete structures than in steel frame structures. For larger spans the weight of a bridge, for example, increases so rapidly as to prohibit the use of reinforced concrete. By pre-stressing the reinforcement, as suggested herein, thus reducing the sectional dimensions appreciably, the limiting span for reinforced concrete structures can be increased considerably.

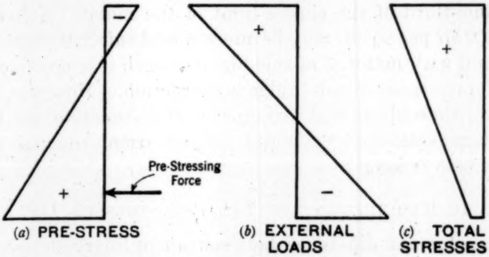
[9] "The Preload System of Concrete Construction," by J. M. Crom.



(a) PRE-STRESS (b) EXTERNAL LOADS (c) TOTAL STRESSES

FIG. 1.—STRESSES IN A PRE-STRESSED BEAM

The foregoing ideas, as applied to the introduction of initial stresses in a beam, are not new. As early as in 1907 Lund and Koenen[10] proposed placing the tensile steel in tension before placing the concrete. Bending tests with beams submitted to an initial tension of 8 500 lb per sq in. showed that the first cracks appeared when the loads exceeded by about 50% those corresponding to beams made in the ordinary manner; but the efficacy of the beams decreased greatly as time passed.

Some other attempts also failed because the preliminary stresses in the steel were not sufficient to create the desired results. Steel that has a yield point from 33 000 to 40 000 lb per sq in., ordinarily has an assumed allowable stress from 16 000 to 20 000 lb per sq in., so that the bars cannot be stressed to more than 10 000 lb per sq in. In some cases this degree of pre-stressing could not even offset the effect of accidental errors. Even the largest permissible stress imposed on the reinforcement, in such cases, would require too much steel in order to create internal stresses in the concrete sufficient to afford a saving in material. In later years, however, steel has been developed with an ultimate strength of as much as 140 000 lb per sq in., with yield point stresses as great as 110 000 lb per sq in., and the prices for this high-strength steel differ only a trifle from those of ordinary structural steel. By hardening and annealing a cold-drawn steel, and then cold drawing it again, it is possible to raise the yield point to from 185 000 to 198 000 lb per sq in.

In steel structures the alloys that are brittle and lack plasticity are avoided. Steel members with large and irregular sections can be damaged during the cooling if the alloys are too brittle. In concrete structures it is the concrete that provides the plastic element to the structure. On the other hand, small cross-sectional dimensions of reinforcement bars prevent damage, when such bars are cooled.

---

[10] *Le Génie Civil*, No. 9, 1936.

E. Freyssinet pre-stresses reinforcement so as to impose tension to between one-half and one-third of the elastic limit of the metal. A rod with a yield point of 120 000 lb per sq in. may be pre-stressed safely to as much as 80 000 lb per sq in., and with material of this high strength it is possible to utilize the advantages of pre-stressing for bridge construction. However, as far as the writer is aware, the only actual attempt in this direction has been the construction of a large-scale model of a girder by a German concern which, in 1936, tested a model 65.5 ft long.

Basic Requirement of the Pre-Stressed Design

The most important difference between an ordinary design of reinforced concrete and the "pre-stressed" design is that in the latter all the concrete in any cross-section may be kept in compression.

If external forces produce tensile stresses, they are treated merely as negative stresses, serving to decrease the compression created by the pre-stressed reinforcement. The entire cross-section of the concrete is considered effective in compression. The imposition of initial stresses should be considered in three successive stages, as follows:

Stage (1).—Before concrete is poured an external tensile force is applied mechanically to the reinforcement. This force may be termed the "preliminary" tension. After concrete has been poured, the effect of shrinkage is to restore the length of the deformed bar to a certain extent, thus releasing a part of the preliminary tension. On the other hand, the concrete is not permitted to shrink to its fullest extent, and bond stresses are created between the steel and the concrete, which have the effect of introducing an eccentric external force. Stresses from this source are not great, compared with those due to external loading, and they are not considered in ordinary design. No consideration is needed, and for the pre-stressed beam, the period in which the concrete is setting is the only time in which it is under slight tension.

Stage (2).—After the concrete has set, the preliminary tensile force is removed from the reinforcement, which then tends to shorten to its original length and is prevented from doing so only by the concrete; in this process, the shrinkage stresses are eliminated, leaving a residual eccentric force to act against the external forces that may be applied to the beam later. This eccentric force produces a direct pressure and a bending moment in the beam. If the bottom reinforcement is pre-stressed the effect is to introduce tension at the top, which, in turn, is offset by the dead weight of the beam; but before the initial pull is released from the reinforcement, this dead load is supported by forms and timbering. Upon release the beam bends upward, becoming loosened from the forms, and rests on its ends. In this stage the stresses in the beam are a combination of pre-stresses, f_p, and dead load stresses, f_D.

In the design of a pre-stressed reinforced concrete beam, the aim is to eliminate net tension in the entire cross-section and to confine the compression within allowable limits. Expressed algebraically, the following conditions must be satisfied at Stage (2):

(*A*) At the top of the beam:

$$f = f_{pt} + f_{Dt} > 0$$

(*B*) At the bottom of the beam:

$$f = f_{pb} + f_{Db} < f_{ac}$$

in which f = the combined or net unit stress; f_t = the unit stress at the top; f_b = the unit stress at the bottom; and f_{ac} = the allowable unit stress in concrete. In other words, the initial tension at the top of the beam should be absorbed by the compression due to dead load, and the initial compression exerted by the pre-stressed steel on the concrete at the bottom of the beam should be reduced to within the allowable value, f_{ac}, for concrete, by the dead load.

Stage (3).—The final stage is that in which the beam carries the full live load; the beam having been pre-stressed to offset the effects of dead load, it must have an excess of pre-stress to cancel the stresses produced by live loads. For this purpose the following conditions must be satisfied:

(*C*) At the top of the beam:

$$f = f_{pt} + f_{Dt} + f_{Lt} < f_{ac}$$

(*D*) At the bottom of the beam:

$$f = f_{pb} + f_{Db} + f_{Lb} > 0$$

(*E*) In the steel at the bottom of the beam:

$$f_s = f_{ps} + f_{Ds} + f_{Ls} < f_{as}$$

in which f_L = the unit stress due to live load; and, f_s = the unit stress in the steel.

To take full advantage of the methods described herein, the beam should be loaded temporarily up to the full dead loads before the preliminary stress in the reinforcement is released. Otherwise, the pre-stress in the reinforcement would be kept too low, limited by Conditions (*A*) and (*B*).

In analyzing the stresses in the reinforcement, two distinct factors must be taken into account: (*a*) The preliminary stress; and (*b*) the "designed pre-stress," f_{ps}, remaining after the partial loss of the "preliminary stress." This loss is due to the shrinkage, to the plastic flow, and to the compressive deformations of the surrounding concrete.

It is important to determine the "designed pre-stress" exactly. The loss of the preliminary stress, due to the shrinkage, depends on the quality of the concrete. For ordinary concrete the shortening may exceed 0.0004. This is equivalent to a decrease of 12 000 lb per sq in. in the tension of the steel. The shrinkage of compact concrete is much less.

The plastic flow should also be considered because the structure will be subject to permanent pressure. After 1 yr the plastic flow for ordinary conditions can reach a value equal to $0.13 \times \sqrt{365} \times 0.000001$, or 0.0000009 per lb per sq in. of stress.[11] The final flow after 5 yr will exceed this amount by not more than 30 to 40 per cent. Thus, if the permanent pressure in the concrete is 500 lb per sq in., the shortening of the concrete under plastic flow may reach $0.0000009 \times 1.4 \times 500 = 0.0006$, with a corresponding decrease of 18 000 lb per sq in. in the pre-stress.

A change in the pre-stress will be produced by the pre-stress itself while it is in the process of compressing the concrete. The reinforcement follows the shortening of the compressed concrete and a fraction of its stress is released. If the compression of the concrete around the bars is 500 lb per sq in., the decrease in the tension of the steel will be about 5 000 to 7 500 lb per sq in.

Thus, in time, the "preliminary stress" may lose as much as $12\,000 + 18\,000 + 5\,000 = 35\,000$ lb per sq in. and only the remaining tension in the steel should be taken into account for the design. This remainder is the "designed pre-stress." However, the structure should also be checked to meet the conditions of the first days, with a partial shrinkage and no plastic flow, to be sure that this temporary excess of the prestress will not produce an undesirable effect.

The stresses due to dead and live load will be governed by a factor of safety of 2. Ordinarily, these stresses are small compared to the designed pre-stress and range from 8 000 to 12 000 lb per sq in. Even with a factor of safety they cannot usually restore the loss in the preliminary stress.

Thus, the "designed pre-stress" may be fixed safely by deducting from 30 000 to 40 000 lb per sq in. from the yield-point value of any given steel. The "preliminary stress" should be from 5 000 to 10 000 lb per sq in. less than the yield point. The excess required for the "preliminary stress" above the "designed pre-stress" should be estimated as exactly as possible for a given structure.

As to the concrete, an ultimate strength of 2 000 to 2 500 lb per sq in. in compression is assumed in the examples of this paper. However, if the advantages of pre-stressing are to be fully utilized, special high-strength grades of concrete should be manufactured. Concrete of the highest strength can be produced most readily at a fixed central manufacturing plant, and, consequently, pre-cast beams and slabs can utilize the pre-stressing principle to the greatest advantage. Properties desirable in concrete are that: (1) It deforms at a fairly constant rate; (2) its total shrinkage is relatively slight; and (3) it possesses high strength and quick-hardening properties. The best method of obtaining these qualities is to manufacture a concrete with a minimum quantity of water and to insure that the product is placed carefully, vibrating the forms during the process. E. Freyssinet utilizes specially "treated" concrete, that is, concrete that is vibrated, pressed, and heated during setting. This improves the properties of the concrete to a remarkable extent; in tests conducted by M. Freyssinet the ultimate strength of the concrete made under pressure attained a breaking stress of 14 000 lb per sq in., and more, and a tensile stress of 150 lb per sq in. The "treated" concrete is compact, subject to only slight shrinkage, resists repeated stresses, and is suitable for pre-stressing.

---

[11] *Journal*, Am. Concrete Inst., November, 1936.

In all ordinary structures no factor of safety should be assumed; if the actual working stresses exceed the computed stresses, the resultant tension will be relatively slight and will be eliminated subsequently as the structure is restored to a normal state of equilibrium. In special cases, where it is necessary that the design be particularly conservative, allowable working stresses due to live load may be increased by some factor of safety.

THEORY OF PRE-STRESSED RECTANGULAR BEAMS

In a simple pre-stressed reinforced concrete beam there are bending moments, M, shearing forces, V, and the horizontal force, T, introduced through the reinforcement, to be considered. All the concrete in any cross-section is considered as acting in compression. The cross-section of steel may be replaced, for purposes of computation, by the equivalent concrete area as in ordinary reinforced concrete design.

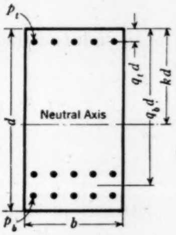


FIG. 2

Referring to Fig. 2, let $p =$ the percentage of steel in the entire cross-section of a beam (p_t referring to the steel at the top of the beam and p_b to the steel at the bottom); $d =$ depth of a beam; and $b =$ width of a beam. Furthermore, let the distance from the top of the beam to the centroid of the top reinforcement be $q_t\, d$, and to the centroid of the bottom reinforcement, $q_b\, d$. The distance down to the neutral axis of the section is $k\, d$, and the effective area of the beam is:

$$A = b\,d + (n-1)(p_t + p_b)\,b\,d = b\,d\,[1 + (n-1)(p_t + p_b)] = K\,b\,d \quad \text{. . (1)}$$

Taking moments about the top of the beam:

$$A\,k\,d = \frac{b\,d^2}{2} + (n-1)(p_t\,q_t\,d + p_b\,q_b\,d)\,b\,d \quad \text{. . . . . (2)}$$

from which,

$$k = \frac{\frac{1}{2} + (n-1)(p_t\,q_t + p_b\,q_b)}{K} \quad \text{. (3)}$$

The moment of inertia of the section about the neutral axis, after simplifying, is:

$$I + bd^3 \left\{ \frac{1}{12} + \left(\frac{1}{2} - k\right)^2 + (n-1)[p_t(k - q_t)^2 + p_b(q_b - k)^2] \right\} = C\,b\,d^3 \quad \text{. . . . . (4)}$$

Finally, the stresses due to the working loads are:

$$f_t = \frac{M}{I}\,k\,d = \frac{k\,M}{C\,b\,d^2} \quad \text{. . . . . (5)}$$

$$f_b = \frac{M}{I}\,(d - k\,d) = -\frac{(1-k)\,M}{C\,b\,d^2} \quad \text{. . . . . (6)}$$

and,

$$f_s = -\frac{M\,n}{I}\,(q_b\,d - k\,d) = -\frac{M\,n(q_b - k)}{C\,b\,d^2} \quad \text{. . . . . (7)}$$

If there is no top reinforcement, the expressions for k and C become correspondingly simplified. In the case of a slab of unit width, $b = 1$ in Equations (5), (6), and (7).

The pre-stresses are determined in a similar manner. Thus, subtracting the area of the bottom reinforcement, the effective area resisting the pre-stresses is:

$$A_1 = b\,d + (n-1)\,p_t\,b\,d - p_b\,b\,d = b\,d\,K_1 \ldots\ldots\ldots\ldots (8)$$

Taking moments about the top of the beam, and simplifying:

$$k_1 = \frac{1}{K_1}\left[\frac{1}{2} + (n-1)\,p_t\,q_t - p_b\,q_b\right] \ldots\ldots\ldots\ldots (9)$$

The moment of inertia of the section about the neutral axis, after simplifying, is:

$$I_1 = b\,d^3\left[\frac{1}{12} + \left(\frac{1}{2} - k_1\right)^2 + (n-1)\,p_t\,(k_1 - q_t)^2 - p_b(q_b - k_1)^2\right] = C_1\,b\,d^3 \ldots\ldots\ldots\ldots (10)$$

Stresses produced by the eccentric force, P, consist of uniformly distributed compression, $\frac{P}{A_1}$, and the bending stress, which varies from $-\frac{P\,d(q_b - k_1)}{I_1}\,k_1\,d$, at the top to $+\frac{P\,d(q_b - k_1)}{I_1}\,(d - k_1\,d)$, at the bottom. The area of the bottom reinforcement is $p_b\,b\,d$, and the value of the pre-stressing force is,

$$P = -\,f_{ps}\,p_b\,b\,d \ldots\ldots\ldots\ldots (11)$$

Consequently, the pre-stress at the top of the beam is expressed by:

$$f_{pt} = P\left(\frac{1}{A_1} - \frac{q_b - k_1}{I_1}\,d^2\,k_1\right) = -\,f_{ps}\,p_b\left(\frac{1}{K_1} - \frac{q_b - k_1}{C_1}\,k_1\right) \ldots (12)$$

and the pre-stress at the bottom is:

$$\begin{aligned} f_{pb} &= P\left[\frac{1}{A_1} + \frac{(q_b - k_1)(1 - k_1)\,d^2}{I_1}\right] \\ &= -\,f_{ps}\,p_b\left[\frac{1}{K_1} + \frac{1}{C_1}(q_b - k_1)(1 - k_1)\right] \ldots\ldots\ldots\ldots (13) \end{aligned}$$

If there is no top reinforcement, the factors, C_1, K_1, and k_1 in Equations (9), (10), (12), and (13) become:

$$C_1' = 0.083 + (0.5 - k_1)^2 - P_b(q_b - k_1)^2 \ldots\ldots\ldots\ldots (14)$$

$$k_1' = \frac{1}{K_1}\left(\frac{1}{2} - p_b\,q_b\right) \ldots\ldots\ldots\ldots (15)$$

and

$$K_1' = 1 - p_b \ldots\ldots\ldots\ldots (16)$$

As before, b = unity in the case of a slab. As an approximation, the effect of subtracting the area of the bottom steel may be neglected, with the following results:

$$C_1'' = 0.083 + (0.5 - k_1)^2 + (n - 1)\, p_t (k_1 - q_t)^2 \ldots\ldots\ldots (17)$$

$$k_1'' = \frac{1}{K_1''}\left[\frac{1}{2} + (n - 1)\, p_t\, q_t\right] \ldots\ldots\ldots (18)$$

and

$$K_1'' = 1 + (n - 1)\, p_t \ldots\ldots\ldots (19)$$

If the member has no top reinforcement, $p_t = 0$, and Equations (17), (18), and (19), are simplified accordingly. Substituting these simplified values in Equations (12) and (13):

$$f_{pt} = 2\, f_{ps}\, p\, (3\, q - 2) \ldots\ldots\ldots (20)$$

and

$$f_{pb} = -\, 2 f_{ps}\, p\, (3\, q - 1) \ldots\ldots\ldots (21)$$

As the design of pre-stressed beams and slabs is confined mostly to cases in which there is reinforcement on one side of the beam only, and as the effect of ignoring the steel area is slight, Equations (20) and (21) will be the formulas most commonly used.

The bending capacity of the pre-stressed beam can be determined from Conditions (*C*) and (*D*). For the most part, the first condition governs, that is,

$$\frac{k}{C}\,\frac{M}{b\,d^2} - 2 f_{ps}\, p\, (3q - 2) \gtreqless f_{ac}$$

Hence,

$$M \gtreqless [f_{ac} + 2\, f_{ps}\, p\, (3q - 2)]\, \frac{C}{k}\, b\, d^2$$

The bending capacity of the conventional reinforced concrete beam is,

$$M' = f_{ac}\, \frac{k'\, j\, b\, (qd)^2}{2}$$

and the ratio,

$$\frac{M}{M'} \gtreqless \left[1 + 2\, \frac{f_{ps}}{f_{ac}}\, p\, (3q - 2)\right] \frac{C}{k}\, \frac{2}{k'\, j\, q^2} \ldots\ldots\ldots (22)$$

Assuming that $f_{ps} = 45\,000$ lb per sq in.; $f_{ac} = 800$ lb per sq in.; $p = 0.009$; $k' j = 0.347$; $q = 0.9$; $n = 15$; and $\frac{C}{k} = 0.186$, $\frac{M}{M'} \gtreqless 2.26$. That is, the bending capacity of the pre-stressed beam is greater about twice that of an ordinary beam.

BOND

Bond stresses between the reinforcement and the concrete develop only when the stress in the steel changes in value from one point to the other, as when the external forces vary. The preliminary stress introduced in the reinforcement is constant from one end to the other. Considering only the bending moment due to the external load, the bond stress between two sections, a distance, Δx, apart is:

$$u\, \Sigma o\, \Delta x = \Delta f_s\, A_s \ldots\ldots\ldots (23)$$

in which Σo is the total perimeter of the steel bars, and Δf_s is the change in the steel stress due to the bending moment. As a limiting value,

$$u = \frac{A_s}{\Sigma o} \frac{d f_s}{dx} \quad \text{(24)}$$

In the conventional design, the appearance of cracks must be anticipated, in which case all the tension is carried by the steel, to balance the compression in the concrete at the top of the section. In that case, $f_s = \frac{M}{A_s \, j \, d_1}$, and,

$$u_1 = \frac{1}{\Sigma o \, j \, d} \frac{dM}{dx} = \frac{V}{j \, d_1 \, \Sigma o} \quad \text{(25)}$$

which is the well-known expression for bond. When the steel has been properly pre-stressed, however, the concrete over the entire section is always under compression.

The tension induced by the external loads, through the bending moment, is distributed over the concrete area as well as over the steel, with the result that the steel stress, and, consequently, the bond stress (which are proportional to Δf_s) are decreased considerably.

Referring to Equation (7) for the value of f_s, the bond is expressed by,

$$u_2 = \frac{A_s \, n \, (q - k)}{\Sigma o \, C \, d^2 \, b} \frac{dM}{dx} = V \frac{A_s \, n \, (q - k)}{\Sigma o \, C \, d^2 \, b} \quad \text{(26)}$$

and the ratio of bond values for the pre-stressed design and the conventional design is:

$$\frac{u_2}{u_1} = \frac{j \, d_1 \, A_s \, n \, (q - k)}{C \, b \, d^2} \quad \text{(27)}$$

Substituting for A_s its equivalent, $p \, d \, b$ and $d_1 = qd$, and simplifying:

$$\frac{u_2}{u_1} = \frac{j \, q \, p \, n \, (q - k)}{C} \quad \text{(28)}$$

which is always less than one. In Example 1 it proves to be 0.53, which indicates that, for this case, the bond stress to be designed for in the pre-stressed beam is only 53% as severe as in the conventional design. In fact, in most cases of pre-stressed beams, the bond to be provided is relatively weak and need not be considered. If it is desired to check the bond stresses the following formula may be used:

$$u = V \frac{p \, n(q - b)}{C \, \Sigma o \, d} \quad \text{(29)}$$

Toward the end of a beam the reinforcement is stressed in a manner similar to that in the vicinity of tension cracks in the conventional design. Theoretically, the bond stress is infinitely great across a crack but, actually, the steel slips, thus gradually transferring excessive stresses to the concrete at that point. As is known, concrete is plastic enough to "flow" under applied load as in the case of columns, the effect being to "repair" changes in the relation between particles, thus avoiding rupture. This phenomenon has not been studied adequately, but it is extremely important in problems involving the design of reinforced concrete.

In the case of pre-stressed concrete, by which preliminary forces are introduced in the reinforcement, there is a section of the steel at both ends, beyond the point at which the forces were applied, where the induced stresses are equal to zero. Theoretically, the transition between zero pre-stress and full design pre-stress occurs over a very short length of bar, and over this length the bond is infinitely great. As a matter of fact, the distance over which this transition occurs is appreciable because of the fact that the bars slip. E. Freyssinet, who conducted tests with preliminary stresses as high as 256 000 lb per sq in., does not report any difficulties in dealing with this problem. At the joint meeting of the Institution of Structural Engineers and the Société des Ingénieurs Civils de France in 1937, he explained that adhesion is not a question of the concrete sticking to the steel, but that it is a wedging action under the effect of the transversal deformations of the concrete, similar to the gripping of a bar in a wedge clamp. Its intensity and its efficacy depend on the quality of the concrete and the packing of the concrete around the bars. In the case of "treated" concrete, very restricted lengths (approximately 10 or 20 diameters) are sufficient to assure anchorage, provided there is a sufficient thickness of concrete and that the surface of the metal is not smooth in the zone of anchoring.[12] In particular cases, the use of vertical end anchor-plates can be recommended. If the reinforcement is designed to pass through such plates so that the ends are fastened securely at the outside surfaces, the preliminary stress at the end will then be divided between bond and the direct pressure against the concrete at the end section.

DIAGONAL STRESSES

In conventional reinforced concrete design, diagonal stresses are of great importance and a complicated system of special reinforcement is usually designed to offset them. The value of these stresses is expressed as follows:

$$f_d = \frac{1}{2} f_l \pm \sqrt{\frac{1}{4} f_l^2 + v^2} \qquad \text{.................... (30)}$$

in which f_l and v are the longitudinal stress and the shear, respectively, produced by the bending moment at a given section. If f_l is tension, the diagonal stresses at the point will vary from maximum tension, which will sometimes be considerably greater than the computed longitudinal stress, to a maximum compression which will be comparatively small. The longitudinal stress, f_l, decreases from the center of the beam to the support and from the bottom of the beam to the neutral axis, but combined with the effect of the shear, v, this stress can produce diagonal tension great enough to be unsafe. Consequently, diagonal reinforcement is designed to meet this condition. In the pre-stressed beam, conditions are entirely different. The longitudinal stress is always compressive, and the second term of Equation (30) gives usually only a negligible excess above the first term.

For an approximate estimation, the second term may be replaced by the two first terms of the corresponding series because, for the prevailing values of

---

[12] *Structural Engineer*, May, 1937.

f_l and v, the series will be converging. Then,

$$f_d = \frac{1}{2} f_l - \left(\frac{1}{2} f_l + \frac{v}{f_l} \right) = - \frac{v}{f_l} \quad \text{(31)}$$

In the pre-stressed design f_l varies from f_{ac} at the top to zero or some positive value at the bottom, making at the neutral axis about $\frac{1}{2} f_{ac}$. For $f_l = 300$ lb per sq in. and $v = 150$ lb per sq in., the diagonal tension will be only $- \frac{150}{300} = - \frac{1}{2}$ lb per sq in., which is absurd.

Thus, the diagonal stresses need not be considered. They eliminate the bending of the longitudinal bars and considerably simplify the reinforcement. The use of stirrups, however, is desirable, because the pre-stressed beam is under permanent compression and the stirrups will play the rôle of hoops in columns. Correspondingly, stirrups should form rings restraining the effect of the bulging in concrete and should be placed along the entire span of the beam.

If a particular structure requires absolutely no tension in the concrete, the stirrups near the support may be pre-stressed as well.

DEFLECTION

The pre-stressing design introduces a direct pressure and new bending moment in addition to the bending moment of loading. The direct pressure uniformly distributed over a transverse section does not affect the deflection. The "pre-stress" bending moment acts in the direction opposite the loading and induces an upward deflection. Therefore, it may be stated that the pre-stress decreases the deflection of a beam.

In the customary balanced design, with the unit stress at the top of the concrete, f_{ac}, and at the reinforcement, f_{as}, the unit length of the top fiber will decrease by $a = \frac{f_{ac}}{E_c}$ and the unit length of the reinforcement will increase by $b = \frac{f_{as}}{E_s}$. This tends to bend the beam and the radius of curvature, r, referred to the top of the beam, will be computed from the equation,

$$\frac{r + q\,d}{r} = \frac{1 + b}{1 - a} \quad \text{(31}a\text{)}$$

in which $q\,d$ is the distance between the top fiber and the reinforcement.

Transformation of Equation (31*a*) gives,

$$r = q\,d \frac{1 - a}{a + b} \quad \text{(31}b\text{)}$$

In the "pre-stress" design, the unit length of the top fiber will decrease by a, as a maximum, and the bottom fiber will decrease too, or, in the extreme case, will not change. As before,

$$\frac{r_1 + d}{r_1} = \frac{1}{1 - a} \quad \text{(31}c\text{)}$$

Hence,

$$r_1 = d\,\frac{1-a}{a} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31d)$$

The ratio of both radii is,

$$\frac{r_1}{r} = d\,\frac{1-a}{a} \times \frac{a+b}{q\,d(1-a)} = \frac{a+b}{qa}$$

Assuming that $f_{ac} = 800$ lb per sq in.; $f_{as} = 20\,000$ lb per sq in.; $E_c = 2\,000\,000$ lb per sq in.; and, $E_s = 15\,E_c$; $q = 0.9$; $a = 0.0004$; $b = 0.00067$; and $\frac{r_1}{r} = 2.95$. On the other hand, the pre-stressed beam can carry about twice its normal load. If equal loads are considered, the deflection for the pre-stressed beam will be from five to six times less than for the conventional beam.

Peculiar Form of Pre-Stressed Beams

To eliminate the tensile stresses completely, Conditions (A) to (D) must be satisfied at every point along the span. If the section of the beam is designed in such a manner that these conditions are satisfied for the center of the span, it may be unsatisfactory for other points of the span where the outside bending moment is less than the maximum. Indeed at the top of the beam, the compression due to dead load (which must absorb the tension created by the pre-stressing) decreases to zero at the support where the outside bending moment is zero. Under such conditions, there could be a residual preliminary tension at the top of the beam near the support where Condition (A) would not be satisfied. Similarly, residual preliminary compression along the bottom of a beam may not have been adjusted to the allowable limit for compression with the result that Condition (B) would not be satisfied.

This difficulty can be overcome easily by varying the section. The bending moment due to dead load varies along the span according to the parabolic law, $x(1-x)$. To satisfy Condition (A), the pre-stress, f_{pt}, should be made to vary according to the same law by changing p or q, or both, in Equation (20). This is accomplished by increasing the width or the height of the beam. The reinforcement under preliminary tension is fixed in position in cross-sectional area and cannot be utilized to adjust the pre-stressed condition.

For simple beams and slabs the best method is to increase the depth, without changing the position of the steel. In this case, the depth, d_x, of a section at a distance, x, from the support, is determined theoretically by the expression (see Equation (20)):

$$2\,f_{ps}\,p\,\frac{d}{d_x}\left(3\,\frac{d}{d_x} - 2\right) = x(1-x)2\,f_{ps}\,p\left(3\,\frac{d}{d_x} - 2\right) \ldots\ldots (32)$$

or,

$$\frac{d}{d_x}\left(3\,\frac{d_b}{d_x} - 2\right) = x(1-x)\left(3\,\frac{d_b}{d} - 2\right) \ldots\ldots\ldots\ldots (33)$$

in which $d_b = qd$ is the permanent distance from the top of the beam to the steel. For the ends of the beam, where $x = 0$, or $x = 1$, Equation (33) reduces to $3\frac{d_q}{h_0} - 1 = 0$; or,

$$d_0 = \frac{3}{2} d_b \qquad (34)$$

Equation (34) is the algebraic expression for the well-known rule that when an eccentric force is applied at the third point of a section, the stresses at the farthest edge of that section are equal to 0. Condition (*B*) is usually satisfied when the depth is determined by Equation (34). The addition to the depth of a beam decreases rapidly from the supports and for $x = \frac{1}{4} l$, this addition is quite small. It is probably better to select a beam of the type shown in Fig. 3 rather than the parabolic shape dictated by the strict theory.

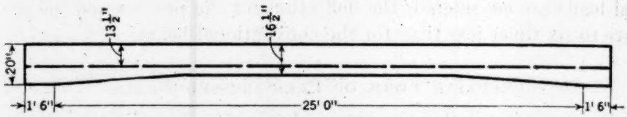

FIG. 3.—PRE-STRESSED SLAB BRIDGE

A second solution consists in lowering the top of the beam so that at the support the reinforcement is at a depth of $\frac{2}{3}\, d$ from the top. The distance from the bottom of the beam to the reinforcement is then represented by $d - q\,d$, and the depth of the beam at the support should be,

$$d' = 3\,d\,(1 - q) \qquad (35)$$

In the case of beams and slabs, Equation (35) yields values for depth which are too small, and difficulties are encountered due to high compressive pre-stresses and shearing stresses near the support. In the case of large girders, however, this solution of the problem is worth considering.

Continuous beams and rigid frames present the same problem to an even greater degree because in this case negative moments occur over the supports. The pre-stressing must absorb tension at the top and compression at the bottom of the beam. For this purpose the depth of the beam over the support must be increased to $d_b < \frac{2}{3}\, d_0$ or, even if the negative moments are large, to $d_b < \frac{1}{2}\, d_0$. In the latter case the sign of the "pre-stressed" moment changes and its effect upon the beam reverses.

Consequently, for the continuous beams and rigid frames the middle section is designed as for a simple beam, and the values of d_b and d are computed according to the foregoing equations. At the point of inflection, d increases to the value of $\frac{3}{2}\, d_b$. At the supports, the section is designed for negative moment and the same formulas are simply reversed, changing the top and bottom. In this case, the lowering of the top of the beam toward the support can be of great use because it augments the relative eccentricity of the pre-stress.

If the span of a bridge is great and if rectangular beams are not economical, I-shaped girders should be used. In the conventional reinforced concrete design such girders are not used because the bottom flange would be useless inasmuch as it would tend to crack regardless of its dimensions. Consequently, the T-beam section has been adopted; but with pre-stressing the I-shaped girder becomes as convenient and as economical in reinforced concrete design as it is in structural steel design.

The foregoing theory of the pre-stressed beam is easily applied to the I-beam shape. Final formulas and conditions for the design are the same and only the coefficients, K, k, and C, differ, according to the special shape of sections.

The method of meeting the change in the outside moments by varying the depth of the beam (that is, the eccentricity of the pre-stress), is identical with that described herein.

There are cases in which the principle of pre-stressing cannot be applied because it is impossible to select a value for the preliminary stress that will satisfy all the required conditions at the same time. This is true when the live load is considerably greater than the dead load, such as in the case of floor-slabs. The maximum ratio between live load and dead load for purposes of pre-stressing can be determined as follows: By Condition (D) the minimum pre-stress at the bottom required to absorb the maximum tension due to the loading is expressed by,

$$f_{bp} = -f_{bD} - f_{bL} \dots\dots\dots\dots \text{(36)}$$

Since f_{bL} is equal to $f_{bD}\,\dfrac{L}{D}$, Equation (36) can be written in the form:

$$\frac{f_{bp}}{f_{bD}} = -\left(1 + \frac{L}{D}\right) \dots\dots\dots\dots \text{(37)}$$

On the other hand, by Condition (A), the tensile pre-stress at the top must be absorbed by the compression due to dead load. Consequently, $f_{pt} = -f_{Dt}$; or, $\dfrac{f_{pt}}{f_{tD}} = -1$; from which,

$$\frac{f_{bp}\,f_{tD}}{f_{bD}\,f_{pt}} = 1 + \frac{L}{D} \dots\dots\dots\dots \text{(38)}$$

The relation, $\dfrac{f_{bp}}{f_{tp}}$, between the pre-stress at the bottom and at the top, by Equations (20) and (21), becomes,

$$\frac{f_{bp}}{f_{tp}} = -\frac{3\,q - 1}{3\,q - 2} \dots\dots\dots\dots \text{(39)}$$

and the relation between the stresses at the top and at the bottom, due to dead load, is,

$$\frac{f_{tD}}{f_{bD}} = -\frac{k}{1 - k} \dots\dots\dots\dots \text{(40)}$$

Multiplying Equations (39) and (40):

$$\frac{f_{bp}\,f_{tD}}{f_{tp}\,f_{bD}} = \frac{3\,q - 1}{3\,q - 2}\,\frac{k}{1 - k} \dots\dots\dots\dots \text{(41)}$$

Finally, by combining Equations (38) and (41) and solving for the ratio, $\dfrac{L}{D}$:

$$\frac{L}{D} = \frac{k\,(3\,q - 1)}{(1 - k)\,(3\,q - 2)} - 1 \dots\dots\dots\dots \text{(42)}$$

In other words, if the ratio between live load and dead load exceeds the value represented by the right-hand member of Equation (42), the preliminary stresses in the concrete cannot absorb the maximum tension at the bottom, and, at the same time, the stresses to be absorbed at the top by the minimum compression. Therefore, it is impossible to design the beam for complete elimination of tension in the concrete. At the values of $k = 0.55$, $q = 0.9$, and $\frac{L}{D} \leqq 2$.

The following illustrative problem will demonstrate the tremendous saving and improvement in design possible by introducing preliminary stresses.

Example 1.—To demonstrate the manner in which pre-stressing can influence the dimensions of a reinforced concrete structure, consider a pre-cast, slab bridge. At present, the excessive weight of pre-cast slabs limits their use to comparatively small spans, and any method of decreasing the thickness of such slabs would permit increasing the span length; for example, consider a bridge[13] with a clear span of 25 ft composed of separate units 29 ft long and 16 ft wide. Each slab is pre-cast in a central plant, transported to the site, and placed in position by cranes. For a slab 28 in. thick, the effective span may be assumed equal to $25 + 2.33 = 27.33$ ft. The dead load is 415 lb per sq ft, and for an element 1 ft wide the bending moment due to dead load is,

$$M_D = \frac{415 \times 27.33^2}{8} = 38\,600 \text{ ft-lb}$$

The live load consists of a 20-ton truck with one pair of wheels, arranged as shown in Fig. 4, for maximum live load moment. The value of this moment,

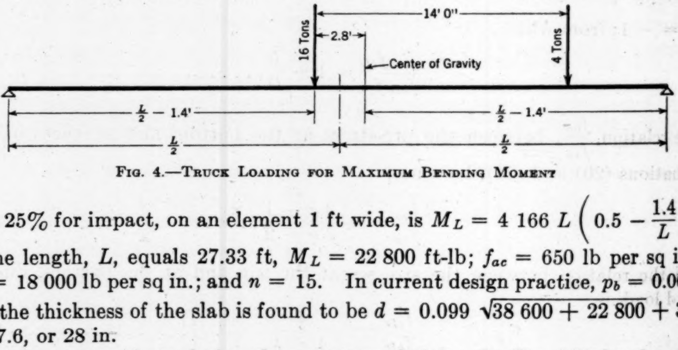

FIG. 4.—TRUCK LOADING FOR MAXIMUM BENDING MOMENT

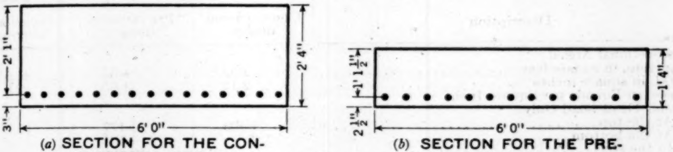
plus 25% for impact, on an element 1 ft wide, is $M_L = 4\,166\, L \left(0.5 - \frac{1.4}{L}\right)$. If the length, L, equals 27.33 ft, $M_L = 22\,800$ ft-lb; $f_{ac} = 650$ lb per sq in.; $f_{as} = 18\,000$ lb per sq in.; and $n = 15$. In current design practice, $p_b = 0.065$, and the thickness of the slab is found to be $d = 0.099 \sqrt{38\,600 + 22\,800} + 3.0 = 27.6$, or 28 in.

The next step is to design the pre-stressed slab. In Fig. 5(*b*) let $d = 16$, $p_b = 0.0086$, and $f_{as} = 45\,000$ lb per sq in. The effective span length, L, is $25 + 1.33 = 26.33$ ft; the dead load is $1.33 \times 150 + 65 = 265$ lb per sq ft; and the bending moments are computed to be, respectively, $M_D = 22\,900$ ft-lb; and $M_L = 21\,700$ ft-lb. Since there is no top reinforcement, $p_t = 0$ and $q_t = 0$. Furthermore, $q_b = \frac{13.5}{16} = 0.844$; and by Equation (3), $k = 0.537$ and C (in

---

[13] "What the D. L. & W. R. R. Is Doing in Concrete Design", by M. Hirschthal, M. Am. Soc. C. E. *Railway Review*, October 9 and 16, 1926.

Equation (4)) equals $0.0833 + 0.037^2 + 14 \times 0.0086 \times (0.844 - 0.537)^2 = 0.096$. By Equations (5), (6), and (7), the stresses are computed to be (in pounds per square inch): $f_{tD} = 500$; $f_{bD} = -430$; $f_{sD} = -4\,290$; $f_{tL} = +473$; $f_{bL} = -408$; and, $f_{sL} = -4\,060$. By Equations (12) to (16), the stresses in the slab due to introducing preliminary stress in the steel are: $D_1 = 0.9914$; $k_1 = 0.497$; $C_1 = 0.0843$; $f_{tp} = -0.00885\,f_{ps}$; and $f_{bp} = -0.0265\,f_{ps}$. These five values must coincide with Conditions (*A*), (*B*), (*C*), (*D*), and (*E*), and the best method of checking the selected section is, first, to determine, from Conditions (*C*) and (*D*), what "designed pre-stress" in the reinforcement would impose the required stress in the concrete under full working load; and then, by Condition (*E*), to make sure that this preliminary stress is not excessive for steel. By Condition (*C*): $F_t'' = +0.00885\,f_{ps} + 500 + 473 \leqq 650$, and, therefore, $f_{ps} \leqq -36\,500$ lb per sq in.; by Condition (*D*): $F_b'' = -0.0265\,f_{ps} - 430 - 408 \geqq 0$, and, therefore, $f_{ps} \leqq -31\,600$ lb per sq in.; and, by Condition (*E*): $-F_s'' = -(f_{ps} - 4\,290 - 4\,060) \leqq +45\,000$, and, therefore, $f_{ps} \geqq -36\,650$ lb per sq in. The similarity between the optimum values of the "designed pre-stress" to be imposed in the reinforcement, in order to utilize concrete (see Condition (*C*)) and steel (Condition (*E*)) to the best advantage, indicates that the section is well balanced in this respect. Conditions (*A*) and (*B*), for dead load only, will be usually satisfied if Conditions (*C*) and (*D*), for full loading, are satisfied. Nevertheless, all these conditions should be checked independently.



(*a*) SECTION FOR THE CONVENTIONAL DESIGN

(*b*) SECTION FOR THE PRE-STRESSED DESIGN

FIG. 5.—COMPARISON BETWEEN THE CONVENTIONAL AND THE PRE-STRESSED DESIGNS

From Conditions (*C*) and (*E*) it is possible to state that $-36\,650 \leqq f_{ps} \leqq -36\,500$ lb per sq in.; and, assuming that $f_{ps} = -36\,500$ lb per sq in., the stresses due to dead load are (see Conditions (*A*) and (*B*)): $F_t' = +0.00885 \times (-36\,500) + 500 = +177$ lb per sq in.; and $F_b' = -0.0265 \times (-36\,500) - 430 = +538$ lb per sq in. It is unnecessary to compute the value of F_s' because the reinforcement is always stressed more under full loading.

Under maximum live load the corresponding stresses are: $F_t'' = +177 + 473 = 650$ lb per sq in.; $F_b'' = +538 - 408 = +130$ lb per sq in.; and $F_s'' = -36\,500 - 4\,290 - 4\,060 = -44\,850$ lb per sq in.

It will be noted that the design is especially well balanced. Tension can never occur in the concrete and the compression stresses are a minimum (+ 177 lb per sq in. at the top, and + 130 lb per sq in. at the bottom). This margin should be sufficient to absorb any accidental inaccuracies introduced by computations or assumptions, before tension stresses would appear in the concrete. Before the live load is applied, the reinforcement is under a tension of 40 790 lb per sq in. The live load adds only 4 060 lb per sq in., an unimportant increase of 10 per cent.

The advantages of pre-stressing, compared with the conventional design, are demonstrated in Table 1. The analysis indicates that the depth of the slab should be increased from the center toward the supports, where it reaches a maximum value of $d_0 = \frac{3}{2}\, q_b\, d = \frac{3}{2} \times 13.5 = 20.25$ in. At the supports the stresses in the concrete are zero at the top and, at the bottom:

TABLE 1.—ADVANTAGES OF PRELIMINARY STRESSES

Description	Conventional design	Pre-stressed design	Percentage, decrease
Cross-Sectional Areas:			
Concrete, in square feet	2.33	1.33	41.5
Steel, in square inches	2.12	1.65	22.0
Stresses, in Pounds per Square Inch:			
Under Dead Load Only:			
At the top	+409	+177	....
At the bottom	*	+538	....
In the steel		−40 290	....
Under Full Load:	−11 300		
At the top	+650	+650	....
At the bottom	*	+130	....
In the steel	−18000	−44 850	....
Percentage increase in steel stress under live load	59	10	....

* Tension cracks.

$$-2\,\frac{P}{A} = \frac{2\, f_{ps}\, p_b\, bd}{b\, d_0} = 2 \times 36\,500 \times 0.0086 \times \frac{16}{20.25} = 498 \text{ lb per sq in.}$$

Instead of computing the theoretical curve of the bottom of the slab, or beam, it is simpler to design sections for several points along the span. In the present case (see Fig. 5), the depths are found to be as follows:

x, as a ratio of:	d, in inches
$0.05\, l$	19.0
$0.1\, l$	17.8
$0.2\, l$	16.9

The total weight of the pre-stressed slab unit is about 19 tons, 37% less than for the conventional design.

Example 2.—Consider the same pre-cast slab (Fig. 5*b*) as in Example 1, except that it has double reinforcement. Let $d = 13$ in.; $p_t = 0.012$; and $p_b = 0.0105$. The dead load is $1.08 \times 150 + 65 = 227$ lb per sq ft; $M_D = \frac{1}{8} \times 227 \times 26.08^2 = 19.200$ lb-ft; and, $M_L = 4\,166 \times 26.08 \left(0.5 - \frac{1.4}{26.08}\right)^2 = 21.500$ lb-ft. By Equations (3) and (4), $k = 0.495$ and $C = 0.1208$; and by Equations (5), (6), and (7), $f_t = +\,0.0242\, M$; $f_b = -\,0.0247\, M$; and $f_s = -\,0.258\, M$.

Stresses due to external loads are (in pounds per square inch) computed as: $f_{tD} = +\,465$; $f_{bD} = -\,475$; $f_{sD} = -\,4\,950$; $f_{tL} = +\,520$; $f_{bL} = -\,531$; and $f_{sL} = -\,5\,550$. By Equations (8), (9), and (10), $K_1 = 1.157$, $k_1 = 0.447$, and $C_1 = 0.0988$. By Equations (12) and (13), the pre-stresses are: $f_{pt} = +\,0.00993\, f_{sp}$ and $f_{pb} = -\,0.0325\, f_{sp}$. On the other hand, the pre-stress in the steel required by Conditions (*C*), (*D*), and (*E*) (in pounds per square inch), is:

$$F_t'' = +\,0.00993\, f_{sp} + 465 + 520 \leq +\,650; \quad \text{or,} \quad f_{sp} \leq -\,33\,700$$

$$F_b'' = -\,0.0325\, f_{sp} - 475 - 531 \geq 0; \quad \text{or,} \quad f_{sp} \leq -\,32\,700$$

and

$$F_s'' = -\,(f_{sp} - 4\,950 - 5\,550) \leq +\,45\,000; \quad \text{or,} \quad f_{sp} \geq -\,34\,500$$

which indicates that f may be selected between − 33 700 and − 34 500 lb per sq in. Assuming that $f_{sp} = -\,34\,000$ lb per sq in.:

$$F_t' = +\,0.00993 \times (-\,34\,000) + 465 = +\,127$$

and,

$$F_b' = -\,0.0325 \times (-\,34\,000) - 475 = +\,631$$

For full loading:

$$F_t'' = +\,127 + 520 = +\,647 \text{ lb per sq in.}$$

$$F_b'' = +\,631 - 531 = +\,100 \text{ lb per sq in.}$$

and,

$$F_s'' = -\,34\,000 - 4\,950 - 5\,550 = -\,44\,500$$

Thus, all conditions are satisfied. The cross-section of concrete required is only 1.08 sq ft which is less than 50% of the area required by conventional design. The cross-section of steel is 3.51 sq in. which is 66% greater than conventional design. Such a design may be recommended only if the thickness or the weight of the bridge must be decreased in order to meet local conditions.

The slabs can be made even thinner by introducing a concrete of higher strength; for example, if the allowable stress in the concrete can be increased to 1 500 lb per sq in., the pre-stressed slab in Problem 1 will be 10 in. thick, with a steel ratio of $d = 0.021$.

TESTS ON PRE-STRESSED CONCRETE

To test the practicability of introducing preliminary stresses in reinforced concrete, E. Freyssinet constructed beams reinforced symmetrically with different kinds of steel bars and wires, including piano wire with an elastic limit of 284 000 lb per sq in. Initial tensile forces were applied such as to produce stresses from 99 600 to 256 000 lb per sq in. Mortar was placed in small portions and vibrated; samples were tested by bending; and the results were very favorable. Rupture occurred at loads much greater than were theoretically computed. In some cases the samples failed in the steel and, in some cases, in the concrete; but in the latter cases, too, it was the steel that produced the rupture by exceeding its yield-point stress. The deflections were small, being almost always only about one-fifth of the deflection observed in conventional design. What is of a special importance as applied to reinforced concrete, the deformations were completely reversible. No cracks appeared until tensile stresses due to working loads exceeded the initial compression stresses by from 280 to 430 lb per sq in.

In 1935, E. Freyssinet conducted reversed bending tests[14] on a post 40 ft long, fixed for a length of 6 ft 7 in. from the base. Repeated loads were applied from

---

[14] *Memoires* de la Société des Ingénieurs Civils de France, September-October, 1935.

+ 1 000 to − 1 000 lb at the rate of eight times per minute. A controlling post of the conventional design, heavily reinforced with 286 lb of steel, was fissured after a few hundred deflections and broke after a few thousand deflections. A "pre-stressed" post of the "treated" concrete with only 110 lb of steel was subjected to 500 000 deflections without any alteration.

In 1934, W. K. Hatt, M. Am. Soc. C. E., tested a series of 8 by 14-in. beams, 13.5 ft long, reinforced with two rods 0.816 in. in diameter. These beams were loaded to produce bending moments from zero to 260 000 in-lb.[15] The bond between the rod and the concrete had been destroyed with an asphaltic coating and, after setting, the reinforcement was pre-stressed to loads of 8 372, 11 151, and 15 372 lb per sq in. Stresses in the concrete and in the steel were measured exactly. A beam of the same section, but not pre-stressed, was also tested.

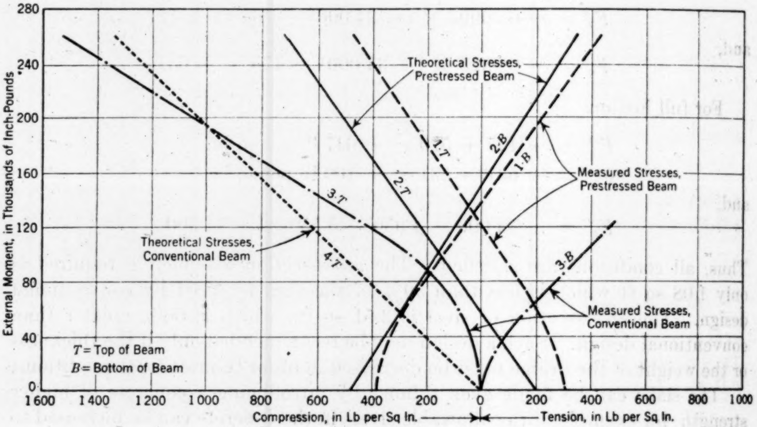


Fig. 6.—Unit Concrete Stresses

Figs. 6 and 7 show the unit stresses at the top and at the bottom of the concrete and in the steel: (1) Measured exactly, in tested pre-stressed beams; (2) computed by the theory of the pre-stressed beam; and (3) measured exactly, in a tested conventional beam. The computed stresses at the bottom of the concrete agree well with tests. Some greater difference is observed for the top of the concrete where the actual effect of pre-stressing proved to be greater than the computed value. Measured deflections follow strictly theoretical conclusions. The pre-stressing first produced upward bending. Under the bending moment of 100 000 in-lb, the beam regained its initial form. The conventional beam deflected under the same load as much as 0.035 in. Then the load was increased so as to produce a unit stress of 1 050 lb per sq in. in the concrete in the conventional beam; and the deflection measured in the conventional beam was 4.4 times that in the pre-stressed beam.

---

[15] *Engineering News-Record*, September 13, 1934.

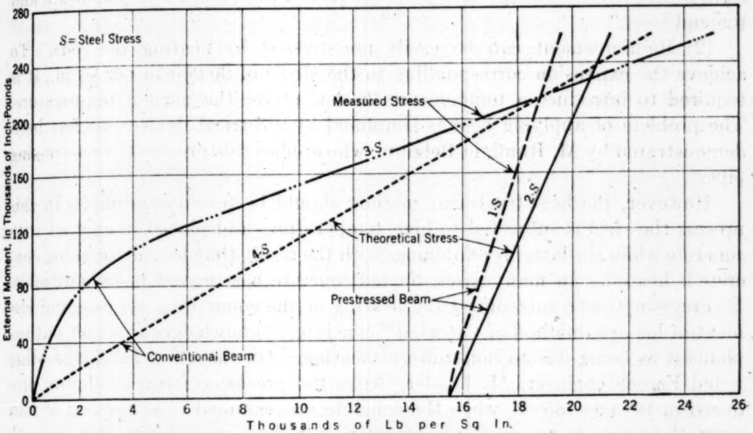

FIG. 7.—UNIT STEEL STRESSES

A most interesting test was conducted in 1936, in Germany.[16] A model girder, 65.5 ft long, varying in depth between 33 in. and 46 in. was used. Both the horizontal and the vertical reinforcement was pre-stressed to 70 000 lb per sq in. The working unit stress in the concrete was 2 056 lb per sq in. in compression and, at the steel, 78 000 lb per sq in. The girder weighed only 150 lb per lin ft, and carried a load of 940 lb per lin ft. Under repeated loading the girder acted like a perfectly elastic body and disclosed no signs of fatigue. Reinforced with steel having an elastic limit of 140 000 lb per sq in., the girder had a factor of safety of 2 in the steel and of about 4 in the concrete. The deflection was unusually small.

The details of this experiment have not been made public, but, on the basis of this test, it is concluded that a girder of 327 ft span, with an average depth equal to 0.05 *L*, could be built economically. Such a girder would carry 600 tons of its own weight and 300 tons of useful load. The deflection would be only one-third of that in a steel structure of the same dimensions.

METHODS OF PRE-STRESSING THE REINFORCEMENT

Three methods can be used to pre-stress the material required:

(1) Mechanical devices of various forms can be devised. Ends of the reinforcement bars can be hooked and connected to the special anchor-beams by means of these hooks, intermediate hooked bars and clamps being fixed on the anchors. One of the anchor-beams is subjected to the action of jacks held against a strong abutment. In this manner the reinforcement bars are stretched to a predetermined value. Devices of this type are suitable for the manufacturing of precast structures in a concrete yard where supports can be built permanently.

For field work, it may be preferable to use the forms as supports, strengthening them with end blocks and struts and carrying loads from one end of the form to the other. In this case, jacks are placed between the anchor-beam and the end block.

---

[16] *Concrete and Constructional Engineering*, April, 1936.

(2) Reinforcement can be easily pre-stressed by heating the rods. To achieve the expansion corresponding to the stress of 90 000 lb per sq in., it is required to introduce a temperature 260° C above the normal temperature. The problem of applying heat is simplified by electrical devices, as has been demonstrated by M. Ruml, in Belgium, who applies this process to pre-stressing pipes.

However, the heat-treatment method should be tested carefully. In this process the steel is subjected to high temperature, and placed in contact with concrete while the latter is hardening, with the result that the surrounding concrete is heated. In many cases, heated concrete has proved to be unreliable. E. Freyssinet, who introduced the heating of the concrete as an essential element of his new method of "treated" concrete, acknowledges this fact but explains it as being due to non-uniform heating. On the other hand, the other noted French engineer, M. Lossier,[17] cites the precast electric insulators produced in 1913 at 185° F, when the concrete was rammed. At the end of four years they were in an excellent condition, but three years later their strength was reduced much below that of ordinary insulators. It appears possible that initial heating is injurious to chemical actions over long periods of time. If it results in destroying the bond between the steel and the concrete even "in the long run," heat cannot be used for pre-stressing.

(3) An ingenious method of "self-prestressing" was used by E. Freyssinet for piles in combination with his "treated" concrete. Piles were manufactured in place in sections between two cylindrical moulds. The external mould consisted of half-collars which were fixed with screw clamps. The internal mould is made of a steel tube surrounded by an envelope of india rubber with a cotton armor. The space between moulds is closed by an annular plate with holes for rods and for placing the concrete, and rods are clamped on the top of the plate. The concrete is poured between the moulds and vibrated by external vibrators. The excess water escapes through joints between the collars of the external mould. Then the vibration is stopped and a hydraulic pressure of 285 lb per sq in. is exerted in the internal mould between the steel tube and the rubber envelope. This pressure is transmitted to the concrete and through it to the top closing plate because, immediately after vibration, the concrete acts as a liquid. The plate rises and stretches the rods that are fixed to its top, almost to their elastic limit. The pressure is maintained for 20 min, the water leaks freely through the joints, and the reinforcement is pre-stressed as required.

CONCLUSIONS

From studies made by the writer and described in this paper, six broad conclusions seem to be justified, as follows:

1.—In reinforced concrete design, there are great advantages in increasing or decreasing, artificially, the stresses in one or the other materials involved. One of the methods consists in introducing preliminary tension in the reinforcement and tests by E. Freyssinet and others show that this method is practicable.

---

[17] *Concrete and Constructional Engineering*, August, 1936.

2.—Invariably the results of introducing pre-stressed reinforcement in beams and girders are favorable when the preliminary stresses can be designed so as to counterbalance the stresses produced by dead loads and live loads.

3.—Pre-stressed designs may result in exclusively great savings of material or they may permit considerable increases in maximum span length. In either case, the structures are more reliable than in the case of conventional design because the tensile stresses in concrete are completely canceled and the compressive stresses that occur over the entire cross-section tend to prevent the occurrence of cracks.

4.—The arrangement of the reinforcement is simplified considerably because the diagonal tension is appreciably less than in the conventional design, and in continuous beams, reinforcement is not necessary at the top.

5.—In order to gain the greatest advantages from the principle of prestressing, it is important that the reinforcement have a high yield-point stress and that special devices for applying the preliminary stresses be available. The cost involved in both cases is not serious.

6.—The effect of introducing the pre-stressed design into reinforced concrete will be to develop much lighter, more reliable, cheaper, and simpler structures, thus increasing the field of usefulness of this material considerably.

APPENDIX

NOTATION

The following symbols, which conform to the Symbols for Mechanics, Structural Engineering, and Testing Materials[18] approved by the American Standards Association in 1932, are offered for the guidance of readers and discussers of this paper:

A = effective area; A_1 = effective area that resists pre-stresses.
a = a subscript denoting "allowable".
b = breadth, or width, of a beam; as a subscript, b denotes "bottom".
C = a constant.
c = a subscript denoting "concrete".
D = dead load; as a subscript, D, denotes "dead load".
d = depth of a beam; dx = depth, d, at a distance, x, from the left support,
E = modulus of elasticity.
f = net unit stress; f_c = unit stress in concrete; f_s = unit stress in steel; $+ f_p$ = unit pre-stress (initial compression); $- f_p$ = unit pre-stress (initial tension); f_D = dead load stress; f_t = unit stress at the top of a beam; f_b = unit stress at the bottom of a beam; f_a = allowable unit stress; f_L = unit stress due to live load.
I = moment of inertia of the effective area; I_1 = moment of inertia that resists pre-stresses.
j = ratio of lever arm of the resisting couple, to the distance between the outer compressive fiber and the point of application of the resultant tensile stress.

---

[18] A. S. A.—Z10a—1932.

K = a substitution factor = $1 + (n - 1)(p_t + p_b)$; K' = the substitution factor for no top reinforcement = $1 - p_b$.
k = ratio of distance from the neutral axis to the top fiber of a reinforced concrete beam, to the depth of the beam.
L = live load; as a subscript, L denotes "live load".
l = length; as a subscript, l denotes "longitudinal" stress.
M = moment.
n = ratio, $\frac{E_s}{E_c}$.
P = a concentrated load; a "designed pre-stress" force applied to a member.
p = percentage of steel in the entire cross-section of a beam; p_t = referred to the top steel; p_b = referred to the bottom steel.
q = ratio of distance from the center of the reinforcement to the top fiber of the beam, to the depth of the beam.
s = a subscript, denoting "steel".
t = a subscript, denoting "top".
u = unit bond stress.
V = total shear.
v = unit shear stress.

DISCUSSION

Charles S. Whitney,[19] **M. Am. Soc. C. E. (by letter).**—The pre-stressing of reinforcing steel is of considerable advantage in the case of some special uses of concrete and has very interesting possibilities. The writer believes that Mr. Rosov is over-enthusiastic regarding the general application of the method to concrete structures. It may be that the author emphasizes its theoretical advantages without full consideration of the practical limitations.

Concrete is a very imperfectly elastic material, and any attempt to estimate the actual stresses in a pre-stressed member under loading conditions is certain to result in a very rough approximation. Pre-stressing improves the behavior of concrete under load by reducing the cracking, but because of the large strains which occur before failure, pre-stressing will have practically no effect on the ultimate strength of the member. Therefore any increase in allowable load due to pre-stressing will reduce the factor of safety against ultimate failure. No doubt this is warranted in some types of structures because of an increase in the useful strength limit.

The difference between the two slabs indicated in Fig. 5 cannot be justified by pre-stressing the steel, but is largely due to the inadequacy of the conventional design method used.

Applying the formulas recently proposed by the writer,[20] and assuming the concrete cylinder strength, $f_c' = 2\,000$ lb per sq in., and the steel elastic limit, $f_s = 40\,000$ lb per sq in., the ultimate bending strength of the conventional design (Fig. 5*a*) per foot width of slab, expressed by[20]:

$$M = b\,d^2\,p\,f_s\left(1 - \frac{p\,f_s}{1.7\,f_c'}\right) \qquad (43)$$

is equal to 1 945 000 in-lb. For balanced reinforcement[20]:

$$p = 0.456\,\frac{f_c'}{f_s} \qquad (44)$$

or $p = 0.0228$; and the ultimate moment, as expressed by[20]:

$$M = \frac{b\,d^2\,f_c'}{3} \qquad (45)$$

will be $12 \times 25 \times 25 \times \frac{2\,000}{3} = 5\,000\,000$ in-lb. The author's conventional design, therefore, has a factor of safety of $\frac{1\,945\,000}{12 \times 61\,400} = 2.64$ against steel failure and a factor of safety of $\frac{5\,000\,000}{12 \times 61\,400} = 6.8$ against concrete failure.

According to the author's statements an allowable unit stress of 35 000 lb per sq in. in the steel for the pre-stressed design would require an elastic limit of about 90 000 lb per sq in. Assuming this value of f_s and applying the writer's formulas to the design shown in Fig. 5(*b*), the percentage of steel required for balanced reinforcement would be (see Equation (44)), $0.456 \frac{2\,000}{90\,000} = 0.0101$. The author's design provides: $p = \frac{1.65}{12 \times 13.5} = 0.0102$.

[19] Cons. Engr., Milwaukee, Wis.

[20] "Design of Reinforced Concrete Members Under Flexure or Combined Flexure and Direct Compression," by Charles S. Whitney, *Journal*, Am. Concrete Inst., March–April and September–October, 1937, Equations (7), (8), and (6), respectively.

The ultimate strength by Equation (45) is $12 \times 13.5 \times 13.5 \times \frac{2\,000}{3} = 1\,458\,000$ lb per sq in. The factor of safety of the author's design against ultimate failure is, therefore, $\frac{1\,458\,000}{12 \times 44\,600} = 2.72$, whether or not the steel is pre-stressed. The pre-stressing will reduce the amount of cracking in the concrete, but that can also be reduced by using more steel, which could then have a lower yield point and which would provide lower bond stresses. For ordinary structures the pre-stressing procedure does not appear advantageous.

Karl W. Lemcke,[21] Assoc. M. Am. Soc. C. E. (by letter).—Pre-stressed reinforced concrete is somewhat similar to the jacking of moments into truss members in order to nullify or greatly decrease objectionable secondary stresses. In each case the capacity of the member involved is increased without adding to its section. The author has presented an interesting and timely paper.

Although considerable progress has been made, the writer believes that reinforced concrete as a structural material is capable of much further development. While American engineers are generally in the forefront of progress, in the matter of conceiving long-span concrete bridges they seem to be behind European engineers. As against the 460-ft reinforced concrete arch span of the George Westinghouse Bridge, at Pittsburgh, Pa., the French have the 612-ft arches of the Plougastel Bridge, near Brest. Freyssinet, the designer of the latter structure, has very ably stated the reasons why greater progress has not been made in long-span concrete construction.[22]

Referring to pre-stressed concrete design, Mr. Rosov states in effect that, for long spans an I-shaped girder should be used, but that in conventional concrete design such girders are not used because the bottom flange would be useless, due to its tendency to crack. One such concrete girder bridge of conventional design and I-section was designed and built across Salt Creek in Humboldt County, California.[23] Reinforced concrete was chosen in preference to structural steel because it was felt that, due to the heavy fogs and moisture at the site, structural steel would be subject to great corrosion. The concrete design was also cheaper. The bridge was a two-span continuous one, 284 ft long. The girders were 12 ft deep, the top flanges, 2 ft wide, the bottom flanges, 1.5 ft wide, and the web varied in thickness from 7 in. to 18 in. As this structure was built about 1920 it would be interesting to know how it has withstood the elements, and whether the bottom flanges have cracked.

The author gives some interesting comparisons of designs for a highway loading and a 25-ft clear span, referring also to the conventional designs of the Delaware, Lackawanna and Western Railroad, as of 1926. In this connection the reinforced concrete grade-crossing designs of the Canadian National Railways might be of interest.[24] Among other types, single spans as long as 60 ft, both precast and poured in place, have been developed to carry Cooper's E-60 live load. It is stated that economies of from 30% to 55% are shown by these structures over those built in the past; if designed of pre-stressed reinforced concrete they would probably show a still greater saving.

[21] With Robinson & Steinman, New York, N. Y.

[22] *Civil Engineering,* February, 1932, p. 96.

[23] *Engineering News-Record,* February 26, 1920, p. 427.

It seems to the writer that the 10-in. slab thickness mentioned for a 25-ft clear span is rather shallow even for pre-stressed reinforced concrete construction, and might produce excessive deflections; also that 2 000-lb to 2 500-lb concrete was a rather low grade to use, although the author may have taken it purposely.

The advantages of having no bends in the steel reinforcement would probably be offset by the increased cost of forms, due to having to increase the depth or width of the members.

On jobs that are poured in the field the pre-stressing of the reinforcement might be quite expensive due to the high wages of labor, but this cost would probably be reduced materially after the operation had been standardized.

In conclusion, the writer believes that Mr. Rosov's paper should call to the attention of the profession the advantages and economies of pre-stressed reinforced concrete, and should also further its development.

DEAN F. PETERSON, JR.,[25] JUN. AM. SOC. C. E. (by letter).—The method of analysis to be used in beams containing pre-stressed steel has been presented clearly in this paper, and Mr. Rosov has opened for discussion a subject, which, pending further mathematical and experimental investigation, may lead to some appreciable economy in reinforced concrete design.

The writer does not agree with Mr. Rosov's analysis of the principal stresses. Applying Equation (31) with $v = 150$ and $f_l = -300$, he determines f_d as equal to $-\frac{1}{2}$. However, if these values are substituted in Equation (30), from which the author derives Equation (31), $f_d = -150 \pm \sqrt{150^2 + 150^2}$; or -362 and $+61.5$ in which $+$ denotes tension.

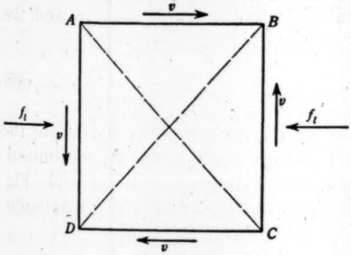

FIG. 8.

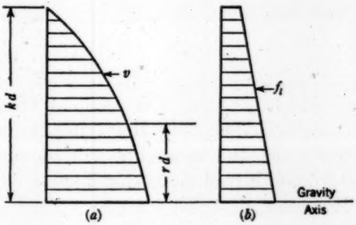

FIG. 9.

Analysis of Diagonal Tension.—Consider a longitudinal stress that is always compressive for pre-stressed beams. The stress on Plane *BD* (see Fig. 8) is minimum tension or maximum compression, and that on Plane *AC* is maximum tension or minimum compression. The former case is not important since, as Mr. Rosov states, the maximum value of f_l does not occur at a point of maximum unit shear stress, v, and the diagonal compression will never be much in excess of the allowable. In the case in which the principal stress occurs on Plane AC, f_d will always have a tensile value if shear exists. Writing,

---

[24] *Engineering News-Record*, July 19, 1934, p. 65.

[25] Salt Lake City, Utah.

$$f_d = -\frac{1}{2} f_l + \frac{1}{2} f_l \left(1 + \frac{v^2}{\frac{1}{4} f_l^2} \right)^{\frac{1}{2}} \ldots\ldots\ldots\ldots\ldots\ldots (46)$$

which may be expanded to,

$$f_d = -\frac{1}{2} f_l + \frac{1}{2} f_l \left(1 + \frac{2\, v^2}{f_l^2} - \frac{2\, v^4}{f_l^4} + \cdots \right) \ldots\ldots\ldots\ldots (47)$$

The series in Equation (47) is convergent only if $\frac{4\, v^2}{f_l^2} < 1$, or if $v < \frac{1}{2} f_l$. For values of v greater than, or equal to, $\frac{1}{2} f_l$, the series does not define the radical. For the first approximation,

$$f_d = \frac{v^2}{f_l} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

instead of $\frac{v}{f_l}$ as in Equation (31). As an example choose $v = 100$ and $f_l = 400$; then, $f_d = \frac{100 \times 100}{400} = 25$ lb per sq in. If the series is carried to the second approximation, $f_d = 23.44$. The value of f_d is between the first and second approximations, since the series is alternating. Equation (30) gives $f_d = 23.6$. The purpose of the foregoing comment is merely to show that the assumption expressed by Equation (31) is not valid. There is no gain in using Equation (48) for purposes of computation. Appreciable diagonal tension may occur near the end of the pre-stressed beam, although not to the extent that it would occur on ordinary beams of the same depth.

Assuming the section to be entirely in compression, the unit shear, v, may be determined at any point by using the transformed section and the formula,

$$v = \frac{V\, Q}{I\, b} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (49)$$

in which Q = the first moment about the gravity axis of that portion of the transformed cross-section lying above the point for which v is to be determined. Since the end moments will be small the stress diagram will resemble Fig. 9(*b*), and it is obvious that a value of r will occur in which f_d will be a maximum. However, if,

$$\frac{d\left(\frac{v^2}{f_l}\right)}{dr} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (50)$$

is taken, assuming a parabolic variation of v and a straight-line variation of f_l, a fifth-degree equation in r results, and it is probable that it would be easier to investigate three or four points on the section for v than to attempt to find r for each section.

Effect of Shrinkage and Plastic Flow.—It is also to be emphasized that the designed pre-stress is not the initial tension imparted to the bar. The effect of shrinkage will be to reduce the pre-stress directly, with no effect on the concrete, except to close the cracks and release the tension. The reduction in f_{ps} due to shrinkage is $m\,E_s$ in which m is the coefficient of shrinkage. The elastic deformation of the beam will further reduce pre-stress. The change in length of the concrete fibers, ΔL_c, must equal the change in length of the steel, ΔL_s, in any unit length of beam; but

$$\Delta L_c = \delta_1 + \delta_2 \qquad (51)$$

in which δ_1 and δ_2 = changes in length due to rotation (moment), and, shortening (direct stress), respectively. Furthermore,

$$M_{ps} = T_1 (q_b - k_1)\, d \qquad (52a)$$

and,

$$\theta = \frac{1}{R} = \frac{M}{E\,I} = \frac{T_1\,(q_b - k_1)\,d}{E_c\,C_1\,b\,d^3} \qquad (52b)$$

in which, T_1 is the pre-stressing force remaining on the section; but,

$$\theta = \frac{\delta_1}{(q_b - k_1)\,d} \qquad (53)$$

from which,

$$\delta_1 = \frac{T_1\,(q_b - k_1)^2}{E_c\,C_1\,b\,d} = \frac{A_s\,f_{ps1}\,(q_b - k_1)^2}{E_c\,C_1\,b\,d} \qquad (54a)$$

and,

$$\delta_2 = \frac{T_1}{E_c\,K_1\,b\,d} = \frac{A_s\,f_{ps1}}{K_1\,E_c\,b\,d} \qquad (54b)$$

in which f_{ps1} is the unit pre-stress acting on the section. Finally,

$$\Delta L_s = \frac{f_{ps0} - m\,E_s - f_{ps1}}{E_s} \qquad (55)$$

in which f_{ps0} is the unit pre-stress imparted to the reinforcement before placing the concrete. Equating $(\delta_1 + \delta_2) = \Delta L_c = \Delta L_s$, and reducing,

$$f_{ps1} = \frac{f_{ps0} - m\,E_s}{1 + p\,n\left(\dfrac{(q_b - k_1)^2}{C_1} + \dfrac{1}{K_1}\right)} \qquad (56)$$

is the value of f_{ps1} before the effect of plastic flow has occurred. Since the member is under compression from the effect of the pre-stressing force the fibers adjacent to the steel will tend to shorten due to plastic flow. This effect will occur progressively with time. The ultimate plastic flow modulus is approximately 1 000 000, which, when combined with E_c, will give a secant modulus, N, representing the combined effect of flow and elasticity of $N = 750\,000$, and a ratio of $\frac{E_s}{N}$, n', of 40. The dead loads will also have an effect on the designed pre-stress due to flow. The longitudinal shortening of the member will tend to release the designed pre-stress, and the sagging of the member will tend to increase it. The deformation of the unit length of fiber at the steel due to the dead load will be,

$$\delta = \frac{M_D\,(q_b - k_p)}{N_c\,C_p\,b\,d^2} \qquad \text{(57)}$$

in which C_p is based on n'. Equating the deformation of the concrete to the deformation of the steel,

$$\frac{f_{ps0} - E_s\,m - f_{ps2}}{E_s} = \frac{A_s\,f_{ps2}}{N_c\,b\,d}\left(\frac{(q_b - k_{1p})^2}{C_{1p}} + \frac{1}{K_{1p}}\right) - \frac{(q_b - k_p)\,M_D}{N_c\,C_p\,b\,d^2} \qquad \text{(58a)}$$

and,

$$f_{ps2} = \frac{f_{ps0} - m\,E_s + \dfrac{M_D\,(q_b - k_p)\,n'}{C_p\,b\,d^2}}{1 + p\,n'\left(\dfrac{(q_b - k_{1p})^2}{C_{1p}} + \dfrac{1}{K_{1p}}\right)} \qquad \text{(58b)}$$

in which f_{ps2} is the residual stress remaining after the effect of shrinkage, elastic, and ultimate plastic deformations have occurred, and the beam is carrying the total dead load moment. The beam at this stage still behaves elastically as far as the external loads are concerned, the effect of the plastic deformation being entirely represented in the pre-stress. The tension in the steel due to dead loads, the beam behaving elastically, is $\dfrac{M_D\,(q_b - k)\,n}{C\,b\,d^2}$. The pre-stress is then:

$$f_{ps1} = \frac{f_{psc} - m\,E_s + \dfrac{M_D\,(q_b - k_p)\,n'}{C_p\,b\,d^2}}{1 + p\,n'\left(\dfrac{(q_b - k_{1p})^2}{C_{1p}} + \dfrac{1}{K_{1p}}\right)} - \frac{M_D\,(q_b - k)\,n}{C\,b\,d^2} \qquad \text{(59)}$$

As an example of the possible effects of plastic flow Example 1 of the paper is investigated (see Fig. 5). The values of the section functions are given by Mr. Rosov. The plastic functions are $k_p = 0.586$, and $C_p = 0.113$. K_{1p}, k_{1p}, and C_{1p} are equal to K_1, k_1, and C_1, respectively. A designed pre-stress of $-$ 36 500 lb per sq in. is to be used. Substituting the proper values in Equation (56), assuming $m = 0.0004$, and making the necessary algebraic transpositions, $f_{ps0} = 60\,000$ lb per sq in. After ultimate plastic deformation has occurred, the effective tensile pre-stress in the steel is found by Equation (59):

$$f_{ps1} = \frac{60\,000 - 12\,000 + \dfrac{(0.844 - 0.586)\,(22\,900)\,(12)\,(40)}{(0.113)\,(12)\,(16)\,(16)}}{1 + 0.0086\,(40)\left(\dfrac{0.347^2}{0.0843} + \dfrac{1}{0.9914}\right)}$$

$$- \frac{22\,900\,(0.307)\,(12)\,(15)}{0.096\,(16)\,(16)\,(12)} = 26\,300 \text{ lb per sq in.}$$

Then, $f_{tp} = -0.00885\ (26\,300) = -230$ lb per sq in.; and, $f_{bp} = 0.0265\ (26\,300) = +700$ lb per sq in. For dead loads: $F_t' = -230 + 500 = 270$ lb per sq in.; $F_b' = 700 - 430 = 270$ lb per sq in.; and, for live loads: $F_t'' = 270 + 478 = 748$ lb per sq in.; and, $F_b'' = 270 - 408 = -162$ lb per sq in. At this condition, cracks would occur, and it is evident that the compression area would no longer extend over the face of the section and the foregoing analysis would be invalid. The condition tends to approach that of an ordinary beam, somewhat "under-designed." It is to be noted that the effect of plastic deformations due to dead load is opposite to the effect of plastic deformations due to pre-stressing. The case investigated is designed for a dead load greater than 50% of the total load. In cases where the dead load is less significant, the effect of reducing the pre-stress due to flow will be even greater.

Spirally Reinforced Columns.—Another application of the possibility of using a designed pre-stress to advantage might occur in the case of spirally reinforced columns. Shrinkage of the columns will induce compressive stresses of from 12 000 to 18 000 lb per sq in. in the longitudinal steel, with zero stress in the concrete. This compressive stress in the steel will be further increased by plastic flow of the concrete under dead load, with the result that when full-load conditions for the column are reached, the steel may be stressed from 20 000 to 30 000 lb per sq in.[26] This is borne out by the fact that test columns usually fail when the longitudinal reinforcement reaches its yield point and bulges. By pre-stressing the steel in tension, more of the stress would be transferred to the concrete, or, at least, the stresses in the steel due to shrinkage and the flow could be neutralized. It would be desirable, of course, to introduce a greater percentage of spiral reinforcement to restrain the additional deformations of the concrete. This is a matter for thorough investigation by experiment.

In conclusion, it seems to the writer that, although stress control due to induced pre-stress in beams may be a means of saving in design, the effect of deterioration of the pre-stress by plastic flow should be considered and an attempt made to evaluate it. Further investigation of the specific effect of flow on pre-stressed beams is needed. Although the particular beam investigated by this discussion apparently develops a rather unfavorable condition due to plastic flow it may be possible, using high-strength steel, to design beams of greater economy by using the principle of pre-stress, the limiting condition being that the stresses before and after plastic flow has occurred will be within the allowable limit. It is also concluded that appreciable diagonal tension may develop in spite of pre-stress, and that its occurrence should be fully investigated, especially since the unit shear will increase as the depth of the beam decreases.

M. Hirschthal,[27] M. Am. Soc. C. E. (by letter).—The pre-stressing of reinforced concrete in bridge construction, as suggested by Mr. Rosov, is very interesting, but it is to be feared that it is purely academic, particularly for members that are cast in place. To the writer, the most interesting angle is that referring to the elimination of shrinkage stresses in slabs and beams by means of pre-stressing.

---

[26] "Principles of Reinforced Concrete Construction," by F. E. Turneaure, Hon. M. Am. Soc. C. E., and E. R. Maurer, Chapter VII, 1932.

[27] Concrete Engr., D. L. & W. R. R., Hoboken, N. J.

In this connection, it may be interesting to note that the writer has requested the personnel of several university experiment stations to make tests on a form of pre-stressing, with special application to pavement slabs. The shrinkage (or temperature) reinforcement of a concrete slab (similar to a concrete pavement slab) is to project beyond the slab ends and be restrained from responding to normal shrinkage action which puts this steel in compression and the concrete in tension, thus causing the shrinkage cracks. The action resulting from the foregoing restraint would tend to put the steel reinforcement in tension and the concrete in compression—the normal action of reinforced concrete. In practice, two adjoining slabs would have the projecting reinforcement bars interlock.

However, in bridge work that is cast in place, the assumption that the reinforcement is free at the construction joints is a false assumption, in the main, because practically all construction joints are specified to be made at sections of minimum shear. This is invariably the point of maximum moment where the bars are certainly continuous through the joint because even the necessary laps in bars are excluded at such points or sections in careful design.

In the author's method of operation at Stage (2) when the tensile force is removed, there is a great probability of high concentration of bond stresses at the ends of the beams or slabs, and although Mr. Rosov notes that Freyssinet reported no difficulty in this connection, the 150-lb tensile strength for the very high-strength concrete indicates otherwise.

Moreover, pre-stressing is applicable only to a material assumed to be homogeneous and elastic. Although every designer specifies that concrete shall be of a composition and grading such as to result in a "homogeneous mass" when thoroughly mixed, the writer feels that the results, even with the best of care, fall far short of homogeneity. Any material of this character cannot be perfectly elastic even within the limits of working stresses. When the stresses approach the ultimate, the material may begin to fail from strains characteristic of a composite material such as concrete. The failure may result from fracture of the coarse aggregate, from fracture of the matrix that binds it, or by loss of adhesion or bond between the aggregate and the matrix. This type of material is not an ideal one for the application of pre-stressing. The material (concrete) is very different from mortar, on the action of which, under tests by Freyssinet, the author bases his assumption. Mr. Rosov cites Freyssinet's tests of treated concrete, in which a strength of 14 000 lb per sq in. in compression was developed, but the tensile strength was as low as 150 lb per sq in. Such concrete would not be very effective in bond and, when used with 45 000-lb per sq in. working stresses in steel reinforcement, would require an inordinate amount of embedment of the steel, or provision against the heavy bond stress developed on release of the "pre-stress."

The author's analysis is confusing at times; assuming the concrete section as taking tension at one time, then assuming the entire section to be in compression;

taking into consideration the reinforcement, and then dropping it. If the final assumptions in the paper are made at the beginning, Equations (20) and (21) could be derived directly instead of by means of the intervening steps. Mr. Rosov does not apply his test (*D*) for stresses at the bottom of the beam after having completed that of Condition (*C*). Incidentally, at the beginning of the derivation of the formulas the author assumes the entire concrete section to be in compression; and yet he indicates the neutral axis in the proximity of the center, implying it to be the gravity axis and so computing his moments of inertia of the section.

On the subject of economy, the author seems to be too optimistic as to the cost of special steels. He would find that a specification calling for steel reinforcement suitable for a working stress of 45 000 lb per sq in. would result in quotations that could scarcely be considered "only slightly" higher than, say, standard intermediate grade reinforcement which is usually specified.

In the author's comparison of slabs, he selects one, citing the writer's series of articles on pre-cast bridge slabs, published in 1926.[13] Some of these structures were designed as early as 1909, and the structure selected by Mr. Rosov is purely hypothetical since the overhead highway bridges there described consist of pre-cast T-beam units with clear spans varying from 30 ft $8\frac{1}{2}$ in. to 35 ft 6 in.; and corresponding depths of 2 ft 6 in. and 2 ft 8 in. These bridges were designed in 1913, when a concrete having a 6-bag cement content (the 1 : 2 : 4 variety) was computed as having a working stress of 650 lb per sq in. Had the author made a comparison with an actual design in the articles referred to and selected a railroad bridge at Lackawanna Place, Millburn, N. J., with pre-cast slabs continuous over a center support and having a maximum length of 60 ft $3\frac{1}{2}$ in., with maximum spans of 28 ft 0 in., from the center support to the inner edge of the abutment, such comparison would not have been so favorable to the "pre-stressed design." (In effect, a pre-stressed design is based on the assumption that pre-stressing leaves the entire concrete section above the tensile reinforcement in compression much after the assumption made by Charles S. Whitney, M. Am. Soc. C. E., in 1936,[28] without the requirement of pre-stressing.) The slabs have a depth at the center of 2 ft 4 in., and 2 ft 2 in. at the edges (thus providing drainage). They are subjected to a maximum bending moment of 104 400 ft-lb per ft of width for live load and impact as against the 21 700 ft-lb selected by the author for his slab—a moment more than $4\frac{1}{2}$ times as great.

In recent years, many methods have been followed to reduce the slab depths. Among them are the use of compressive reinforcement, continuity, end restraint (practically the same effect as pre-stressing), the use of higher-strength concrete, two-way, or multi-way, reinforcement combined with continuity, and end restraint. A girderless flat-slab bridge, carrying railroad loadings for spans about 30 ft, center to center of columns, required a slab thickness of only 2 ft.

Another comparison that would not have been so favorable to pre-stressing, would be the use for the moment in the author's slab, of a working stress of 45 000 lb per sq in. in the reinforcement in tension and the $0.4 f_c'$ allowable for a concrete with a 6-bag cement content—a concrete with a water-cement ratio of 6 gal per bag. Under these conditions, the ultimate strength is 3 500 lb, or $f_c = 1\,400$ lb per sq in., and $f_s = 45\,000$. Then:

---

[28] *Journal*, Am. Concrete Inst., 1936.

$$k = \frac{12 \times 1\,400}{45\,000 + 12 \times 1\,400} = 0.272;$$

$$j = 0.909;$$

$$K = \frac{0.272 \times 0.909 \times 1\,400}{2} = 172;$$

$$d = \sqrt{\frac{44\,600}{172}} = 16 + 2.5 = 18.5 \text{ in.}$$

(which gives a somewhat higher dead load moment);

$$A_s = \frac{44\,600}{0.909 \times 16 \times 45\,000} = 0.82;$$

and, $p = 0.00425$. If 4 500-lb concrete were used, the value of f_c would be 1 800, and,

$$k = \frac{12 \times 800}{45\,000 + 21\,600} = 0.324;$$

$$j = 0.892;$$

$$K = \frac{0.324 \times 0.892 \times 1\,800}{2} = 260;$$

$$d = \sqrt{\frac{44\,600}{260}} = \pm\, 13 \text{ in.},$$

or 16 in. total; and $p = 0.006$. (For a value of $n = 1$, d becomes 13.5 in., giving a total depth of 16 in., which is the same as in the author's example.)

Aside from these considerations, the practical difficulties encountered on a structure in connection with pre-stressing would be almost insuperable, and probably only in a casting yard could such installation be considered.

Although the writer has cited his objection to the use of pre-stressing in this particular case (bridge construction), he realizes the value of such treatment for structures such as reservoirs, tanks, and poles. This paper will have accomplished a valuable service if it leads to research activities, so that possibly shrinkage stresses may be counteracted in concrete—an undoubted incipient cause of deterioration and final failure of reinforced concrete.

A. **Floris,**[29] **Esq.** (by letter).—The problems of pre-stressing steel in reinforced concrete structures are treated in this interesting paper. In the methods described therein the pre-stressing is done by mechanical devices or by heat. However, in certain cases, the same results can be achieved quite naturally, without external influences.

In reinforced concrete trusses, for instance, the steel of the compression members can be embedded in concrete during construction, but the steel of the tension members is left exposed. After the forms are removed and the structure is under full load, the tension steel is covered with concrete.

---

[29] Dipl.-Ing., Los Angeles, Calif.

The advantage of this method, due to Dr. Ulrich Finsterwalder,[30] is that cracks, otherwise unavoidable in the tension members, are almost eliminated and the appreciable secondary stresses are reduced considerably, because of the flexibility of the exposed reinforcement in the tension members. In this manner the angular changes at the joints, caused by the weight of the structure, take place almost without restraint.

A. A. EREMIN,[31] ASSOC. M. AM. SOC. C. E. (by letter).—The possibility of pre-stressing concrete is important in the economic design of reinforced concrete structures. However, the methods of pre-stressing are still very little known.

An interesting method of pre-stressing a reinforced concrete tunnel lining was used in 1930 in the outlet tunnels of the dam across Dordogne River, in France.[32] At their lower ends these tunnels were bored through the ground formation with rock of inferior strength which was incapable of resisting the hydraulic pressure produced by a water head of 335 ft. Designed according to common practice, without pre-stressing, the tunnels would have required a concrete lining 3 ft 3 in. thick, which would have made the cost prohibitive. M. Mary developed a method of pre-stressing which reduced the lining to a thickness of only about 12 in. The arrangement is shown in Fig. 10. The concrete lining, with an inside diameter of 14 ft 5 in., is reinforced with steel cables placed 19 in. between centers. The ultimate strength of the cables was 242 tons. The computed maximum stress, produced by the hydraulic static pressure, was 30 tons per cable, and the maximum stress developed by hammer action was about 10 tons per cable. The cables were pre-stressed to 152 tons. which was considered sufficient to resist internal hydraulic pressure in the tunnel and to reduce

shrinkage cracks in concrete. A small coefficient of safety was used because design assumptions were successfully verified by testing a full-sized model concrete cylinder 20 ft long. The cables were pre-stressed by hydraulic jacks placed at the horizontal diameter of the tunnel, in such a manner that the original circular form of the cables was changed to an elliptical one. The forces from the jacks were transmitted to the concrete lining through steel bar anchors. After pre-stressing, a cement mortar was poured around the cables and bearing plates. The jacks were removed when the cement mortar had set sufficiently to reach the prescribed strength.

[30] "Untersuchungen über Knicksicherheit, die elastische Verformung und das Kriechen des Betons bei Bogenbrücken," von Dr.-Ing. Fr. Dischinger, *Der Bauingenieur*, September 3, 1937, p. 551.

[31] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

[32] *Annales des Ponts et Chaussees*, April, 1936, p. 423.

In developing the method of pre-stressing considerable attention was given to reducing the bond stresses between the steel cables and the concrete. Bond stresses generally increase in proportion to the increased stresses in the cables during pre-stressing, and are affected by the change in length of the cables as shown by Equation (23). Special provisions for reducing the bond stresses in a concrete lining were found necessary. Heavy asphalt coating of the cables was not considered sufficient; and, furthermore, asphalt reduces the resisting strength of concrete. Finally, it was decided to place the cables in steel pipes permitting them to slide freely. The design and construction of the outlet tunnels at Dordogne Dam provide a valuable demonstration of the possibilities of pre-stressing reinforced concrete and serve to support the author's conclusions.

IVAN A. ROSOV,[33] M. AM. SOC. C. E. (by letter).—The pre-stressing of reinforced concrete is a new idea which marks great progress in this branch of engineering. It is only natural that a new idea should meet objection on the grounds that it is purely academic, impractical, difficult to embody in practice, and not suitable to the material.

The writer should acknowledge that his contribution was almost purely theoretical, when it was written early in 1934. Since that time, however, practice has completely justified his suggestions. Several pre-stressed bridges and roof trusses have been built and have developed exceptionally good properties. The writer has already mentioned the girder constructed in Germany in 1936,[16] which fully confirmed all expectations. This girder (which was actually tested) was followed by a design of a girder 198 ft long with a depth of only one-sixteenth of the span.

The Saale Bridge, at Alsleben,[34] Germany, with a span of 223 ft, is an example of a pre-stressed bowstring bridge. The success of this structure encouraged the construction of many other pre-stressed arched structures—especially hangars with spans longer than 320 ft.[35] Trusses are represented by hangars of the Caquot type constructed in France,[36] in which pre-stressing is done in a manner similar to the method described by Mr. Floris. For the most advanced design one should mention the Gerber (girder) Bridge, "Drei Rose," at Basle, Switzerland. Pre-stressing permitted increasing the span of this bridge to 410 ft, which is extremely unusual for a simply supported concrete structure. It is seen that pre-stressed bridges and roof trusses are already well established, at least in Europe. They can no longer be considered "academic."

[36] *Travaux* (*Science et Industrie*), 1936.

As to the practical difficulties of pre-stressed construction, stated by Mr. Hirschthal as being "almost insuperable," the writer has already outlined the methods involved. Some of them are very simple, as is the lengthening of the reinforcement by means of electrical heating. The method described by Mr. Floris is even simpler and requires only that the compression members be poured first and the tension members later. In M. Freyssinet's method, which embodies the "treatment"[37] of the concrete, the pre-stress is obtained as a by-product of the latter procedure. This method was used under the difficult conditions presented by a narrow foundation at the Marine Station, at Havre, France. The work of fabricating and sinking the pre-stressed piles attained a speed of 25 ft per working day. Plant equipment was almost automatic and, as is stated by M. Freyssinet, "expenditure in material and labor was much less than for the ordinary process."[38]

Possibly the most complicated was the case of the aforementioned girder in which the degree of pre-stressing varied along the span; the stirrups were also pre-stressed and the concrete was "treated."[16] Even in this case the only additional equipment required, beyond the customary compressors, jacks, and mixers, was a stretching beam and a 5-ft section of a special steel form. To complete the operation for one 5-ft section (which included pouring the concrete, vibrating, hydraulic pressing, and heating) required only 2 hr. The entire girder, consisting of twelve sections, required 60 hr.

This case, and the foregoing list of structures already built, indicate that "insuperable" difficulties do not exist and that progress in methods of pre-stressing is rapid. The new "sursulfaté" cement developed in France is very promising.[39] This cement expands after hardening, the expansion reaching 0.003 in. per in., and the reinforcement, if embedded, would resist it creating an initial compression in the concrete.

Mr. Hirschthal states that the writer was too optimistic regarding the cost of special steels. The extra cost is actually small if proper methods are used to produce such steels. For bars $\frac{5}{8}$ in., or less, in diameter, M. Freyssinet used a mechanism, that he developed, which unrolled bunches of steel, welded the ends, and stretched the steel in one operation. At the cost of a "few centimes per kilogram," straight endless rods (which were tested at every point, including welds) with yield points of 114 000 lb per sq in. were obtained. The general cost for pre-stressed structures, as a rule, is considerably less. Mr. Eremin should be commended for his striking example of a tunnel lining that would be prohibitive in cost unless pre-stressing were used.

The writer cannot agree with those who state that pre-stressing is not adaptable to concrete because that material is not homogeneous and elastic. This general defect handicaps any concrete structure, those that are subjected to tension being affected much more severely than others. In the latter case the bond between particles is decreased (often entirely destroyed), and will not be restored if the tension is removed. This makes concrete unsuitable for repeated stresses which involve a wide range of tensile stress. On the other hand, if concrete is compressed, the particles approach one another, the bond is increased, and releasing it merely restores the concrete to its initial condition.

[37] *Memoires et Compte Rendu des Travaux* de la Société des Ingenieurs civils de France, September–October, 1935.

[38] Rept. to Joint Meeting of Inst. of Structural Engrs. and Société des Ingenieurs civils de France, March, 1936.

[39] *Bulletin Technique* de la Suisse Romande, January, 1937.

Concrete can even heal minute cracks by chemical conversion of calcium hydroxide to calcium carbonate,[40] and permanent compression aids this process. Freyssinet describes a case in which a pre-stressed pipe subjected to an internal pressure, ten times greater than normal, at last "failed," resulting in seepage and the appearance of fissures. However, after the head had been reduced, the fissures closed at once, and a few weeks later, the concrete having sealed the fissures, the pipe was as good as before.[16]

Pre-stressing eliminates tension entirely. Professor Dischinger states that a "reinforced concrete body subjected to compression only, has, like natural stone, almost unlimited life."[35] Mr. Hirschthal's reference to the lack of homogeneity and elasticity in the concrete should be of concern to designers of customary structures much more than to designers of pre-stressed structures.

The writer's method of analysis inspired Mr. Peterson's very interesting contribution containing a more detailed calculation of the loss in pre-stressing. However, when Mr. Peterson refers to the writer's example, and subtracts from the designing pre-stress the loss due to the plastic flow, he did not notice that this had already been done. In the text of the paper preceding the heading, "Theory of Pre-Stressed Rectangular Beams," the writer considered possible losses, including the plastic flow, estimated them as 35 000 lb per sq in., and noted that this loss should be subtracted from the "preliminary pre-stress" to give the "designing pre-stress." The preliminary pre-stress in the writer's example is 36 500 + 35 000 = 71 500 lb per sq in., not 60 000 lb per sq in., as Mr. Peterson assumes. The example then remains intact. It is gratifying that Mr. Peterson's calculation for the loss gives 60 000 − 26 300 = 33 700 lb per sq in., which is almost identical with the writer's estimate of 35 000 lb per sq in. Plastic flow, however, has not been studied sufficiently, particularly for "treated" concrete. Such a study would be valuable in connection with pre-stressing. For this kind of concrete Mr. K. Lenk accepts the entire loss as only 21 000 lb per sq in.[41]

For diagonal tension, Equation (31) should be rewritten as $f_d = -\frac{v^2}{f}$. Tensile stresses exist although they are much smaller than for conventional design. In order to cancel them entirely the stirrups are also pre-stressed. In this manner, compression is introduced along two perpendicular axes and the problem of diagonal stresses is eliminated.

Replying to Mr. Hirschthal, the pre-stressed section is compressed at any point. This is the basic principle of the design. Bending moments acting over the section produce compression on one side of the section and tension on the other side. However, the tensile stresses are absorbed by counteracting compression and do not develop cracks. The area of the section remains constant, unlike the conventional case in which, after cracking, the section is decreased and the stresses are redistributed. The stability of the section permits the use of the law of superimposition and the separate consideration of the direct pressure and the bending moments produced either by loads, or by pre-stressing. This fact was ignored by Mr. Hirschthal. However, it is common practice to consider combined direct stresses and bending in the case when the entire section is under compression. If the writer assumed the concrete section as taking tension at one time, and then assuming the entire section to be in compression, it was because he considers superimposed bending moments separately in the former case and all stresses together in the latter case. The writer also "assumes the entire concrete section to be in compression; and yet he indicates the neutral axis in the proximity of the center, implying it to be the gravity axis and so computing his moments of inertia." This was because the neutral axis is considered for the bending moments only and, if the section is not cracked, it is the gravity axis and, of course, the moment of inertia should be computed about this axis.

---

[40] *Concrete*, April, 1937.

[41] *Beton und Eisen*, May 20, 1937.

Mr. Hirschthal considers "confusing" the fact that the writer takes the reinforcement into consideration and then drops it. The writer "drops" the reinforcement in two cases: When he considers the action of outside load, he takes the full section, including the reinforcement; but when he considers the action of the pre-stressing, he subtracts the area of the reinforcement, because the pre-stress is the force produced by the steel and is acting on the concrete in the form of bond between the two. The second case is that in which the writer passes from the general design with both top and bottom reinforcement to a design with bottom reinforcement only. He "drops" the top reinforcement, making $p = 0$. In either case, it could not be done otherwise.

Mr. Hirschthal wants Equations (20) and (21) derived directly. The writer selected the most logical method. He considered the general case and then passed to particular cases, equating some quantities to zero. This is the common method of solving problems. Equations (20) and (21) represent only a special case when $p = 0$ and the reinforcement is small. Certainly, every special case can be derived directly but there seems to be no need of complicating the problem with each separate solution.

Mr. Hirschthal's last remark is that the writer does not apply Test (*D*) to his examples. The writer applied this test (see text following Fig. 5 and Table 1) and found that Test (*D*) does not control, because higher pre-stressing is required by Test (*C*). Therefore, only the latter was considered.

Mr. Whitney prefers to compare the pre-stressed design with his method. The writer made his comparison with a commonly used method because it was the only way to reveal clearly the advantages of pre-stressing. Recently, many new methods of designing reinforced concrete have been offered by Professor Emperger,[42] Professor Steuerman,[43] Dr. Gebauer,[44] Professor Saliger,[45] Mr. Whitney, and others. New methods differ widely from conventional design and are objected to by many concrete authorities.[46] This is not the proper place for discussing them. Personally, the writer is inclined to accept Mr. Whitney's method as logical and well adjusted to tests. However, his formulas cannot be used for pre-stress design without revision. They are based on the assumption that $\frac{a}{d} = 0.59$, which is taken from the tests of Messrs. Slater and Lyse,[47] Mr. Glanoille,[48] U. S. Geological Survey,[49] and Messrs. Humphrey and Losse.[50] In all these tests the steel had a yield point of 38 000 to 58 000 lb per sq in. Only the tests conducted by Messrs. Slater and Lyse considered steel with a yield point of 64 800 lb per sq in., but in this case also the steel was not stressed beyond 40 000 lb per sq in. No empirical assumption may be extended beyond the limits of tests. Mr. Whitney's formulas cannot be applied to stresses in steel as high as 90 000 lb per sq in. The writer believes that such stresses in the steel would induce cracks much wider and longer than those in conventional structures; therefore, the ratio, $\frac{a}{d}$, will be smaller, the "compression block" will decrease, and the breaking point for a conventional design will be much lower than that calculated by Mr. Whitney's method. On the other hand, if the reinforcement is pre-stressed, the outside moment should overcome: (1) The resisting moment due to pre-stressing; and (2) compression at the bottom due to the direct pressure from pre-stressing, before cracks would appear—a stage that occurs at the beginning in conventional design. This will delay the breaking of the concrete considerably. Since the stress in the steel increases only 90 000 − 45 000 = 45 000 lb per sq in. from the first tension in the concrete to the breaking point, the cracking will not be greater than for a design with ordinary steel, and the compression block will be about the same. It would be very interesting to see Mr. Whitney's method developed to include a design involving steel with high yield point and based upon pre-stressing. However, until this is done, it will be impossible to use this method in appraising pre-stressed structures.

[45] Mitteilungen über Versuche d. Oesterr. Eisen Beton Ausschlusses.

Some discussers would replace pre-stressing by the customary methods of reducing slab depths, such as by continuity, end restraint, the use of stronger concrete, etc.; but pre-stressing is entirely compatible with these methods; it is based on an entirely different principle and can be combined with each of these methods to great advantage in design. As Mr. Lemcke suggests, the writer purposely used low concrete stresses and simple structures as examples so as not to obscure the advantages of pre-stressing by other elements. More complicated examples were eliminated from the paper as an unnecessary contribution to its length. Among examples that might have been cited was an alternate design of a continuous bridge with a span of 30 ft. Contrary to the opinion expressed by Mr. Hirschthal the comparison was as favorable as for simple structures. The volume of concrete was reduced 20%, the decrease in the depth at the center was 40%, and the reinforcement was straight and simple. Another example included a pre-stressed I-girder as an alternate to a T-beam design for the Delaware, Lackawanna and Western Railroad. The construction proved to be much more economical and expedient, saving 47% in concrete and 42% in steel.

[46] *Concrete and Constructional Engineering,* 1937 (Discussions).

[47] *Journal,* Am. Concrete Inst., June, 1930.

[48] *Concrete and Constructional Engineering,* March, 1937.

[49] *Journal,* Am. Concrete Inst., 1920.

[50] *Technological Paper No. 2,* National Bureau of Standards, 1912.

The writer takes the opportunity, presented by Mr. Hirschthal's design of a non-pre-stressed slab with high-strength concrete and high yield-point steel, to demonstrate once more the effect of the pre-stressing.

In general, the use of steel stresses as high as 45 000 lb per sq in. would create important defects in the conventional slab. The concrete cracks when it cannot follow the uniform elongation of the reinforcement. Any increase in the elongation of the steel involves a much greater increase in cracking. At present, working stresses in the reinforcement are not exceeding 27 000 lb per sq in.[51] Raising them 70% would produce a badly cracked structure. The deflection also depends on the elongation of the bottom fibers. It is doubtful whether the construction of such a shaky and cracked slab would be allowed.

Moreover, the saving is not large enough in proportion to the quality of the concrete, because the ratio, $n = \frac{E_s}{E_c}$, decreases considerably. Mr. Hirschthal assumed $n = 12$, but this value does not correspond to that for high-strength concretes. Usually n is taken as $\frac{30\,000}{f_c'}$, in which f_c' is the crushing strength of concrete.[52] In England, n is assumed as $\frac{40\,000}{f_{cs}'}$ in which f_{cs}' is the "cube strength" of concrete.[53] Since f_{cs}' is $1\frac{1}{3}$ to $1\frac{1}{2}$ times f_c', the European method gives almost the same value of n as is accepted in the United States. Hence, in Mr. Hirschthal's first example, n should be taken as $\frac{30\,000}{3\,500} = 8.6$ instead of 12. With this correction, and taking into account the additional dead load, the depth of the slab should be as follows: $k = \frac{8.6 \times 1\,400}{45\,000 + 8.6 \times 1\,400} = 0.211$; $j = 0.930$; $K = \frac{0.211 \times 0.930 \times 1\,400}{2} = 137.5$; $d = \sqrt{\frac{50\,600}{137.5}} = 19$; and, $D = 19 + 2.5 = 21.5$ in. compared to 27.5 in. in the design with plain concrete and steel. The saving is not so great as to warrant sacrificing the stability of the structure.

Now, consider the pre-stressed slab. The depth of the slab is assumed as 10.5 in.; $p = 0.0155$; $n = 8.6$; and $q = \frac{8}{10.5} = 0.761$. From Equation (19), $K = 1 + 7.6 \times 0.0155 = 1.116$; from Equation (18), $k = \frac{1}{1.116} \times (\frac{1}{2} + 7.6 \times 0.0155 \times 0.761) = 0.527$; and, from Equation (17), $C = 0.083 + \overline{0.027}^2 + 7.6 \times 0.0155 \times \overline{0.234}^2 = 0.090$. The dead load is $0.875 \times 150 + 65 = 196$ lb per sq ft; $M_D = 22\,900 \times \frac{196}{265} = 16\,950$ ft-lb; $M_L = 21\,700$ ft-lb; and the total, $M = 38\,650$ ft-lb.

---

[51] *Concrete and Constructional Engineering*, September, 1933

[52] New York City Building Code.

[53] *Concrete and Constructional Engineering*, January, 1937.

Stresses due to loading, from Equations (5), (6), and (7), are:

$$f_t' = \frac{38\,650 \times 0.527}{0.090 \times 12 \times \overline{10.5^2}} = 1\,702 \text{ lb per sq in.};$$

$$f_b = -\,1\,702 \times \frac{0.473}{0.527} = -\,1\,535 \text{ lb per sq in.};$$

and,

$$f_s = -\,\frac{38\,650 \times 8.6 \times 0.234}{0.090 \times 12 \times \overline{10.5^2}} = -\,6\,620 \text{ lb per sq in.}$$

Stresses due to pre-stressing, from Equations (20) and (21), are: $f_{pt} = 2 \times 0.0155 \times (3 \times 0.761 - 2) \times f_{ps} = 0.00877\ f_{ps}$; and, $f_{pb} = -\,2 \times 0.0155 \times (3 \times 0.761 - 1) \times f_{ps} = -\,0.0398\, f_{ps}$.

Conditions to determine the pre-stress required, are:

(*C*) $F_t = +\,0.00877\ f_{ps} + 1\,702 \leq 1\,400$; hence, $f_{ps} \leq -\,34\,400$ lb per sq in.

(*D*) $F_b = -\,0.0398\, f_{ps} - 1\,535 \geq 0$; hence, $f_{ps} \leq -\,38\,400$ lb per sq in.

and,

(*E*) $F_s = -\,(f_{ps} - 6\,620) \leq +\,45\,000$; hence $f_{ps} \geq -\,38\,400$ lb per sq. in.

Conditions (*D*) and (*E*) are controlling; therefore: $-\,38\,400 \leq f_{ps} \leq -\,38\,400$ and the final stresses are as follows: $F_t = 1\,702 - 336 = +\,1\,366$ lb per sq in. $\leq +\,1\,400$; $F_b = -\,1\,535 + 1\,535 = 0$; and, $F_s = -\,38\,400 - 6\,620 = -\,45\,000$ lb per sq in.

Compared to Mr. Hirschthal's design the pre-stressed slab: (*a*) Saves about 51% of concrete; (*b*) eliminates tension and cracking completely; and (*c*) decreases the deflection to a small amount because the steel stresses vary only within the narrow limit of 6 620 lb per sq in.

It is clear that pre-stressing is justified by results achieved by practice; it is not costly; and it results in exceptionally economical structures. Mr. Lenk who observed the German tests with the pre-stressed girder adds to this, the statement that, "the complete lack of cracks and a surface as hard as glass makes the pre-stressed concrete resistant to air, gases, and humidity. Its water-tightness is unrivaled. The expense of maintaining pre-stressed concrete structures is considerably less than other types."[54]

LEVEES IN THE LOWER MISSISSIPPI VALLEY

BY SPENCER J. BUCHANAN,[1] ASSOC. M. AM. SOC. C. E.

SYNOPSIS

A levee may be defined as an earth embankment constructed along the margin of a stream to restrain its flow within a desired course during flood stages. The system of levees, as it exists to-day in the Lower Mississippi Valley, is one of Man's greatest works, involving approximately 761 000 000 cu yd of material throughout its length of 1 615 miles. The type used is similar in many respects to modern earth dams. In fact, it is natural that there should be a close similarity because a levee is merely an earth dam of great length, designed to function during relatively short intervals, after long lapses of time. This paper is concerned with the general features considered in the design of a levee and the use of the relatively new tool, Soil Mechanics, in solving unusual problems arising in connection with levee design.

INTRODUCTION

The first levee on record, to be constructed in the Lower Mississippi Valley, was built in the vicinity of New Orleans, La., by De la Tour under the orders of the founder of the city, Sieur de Bienville. The date of this work was between 1717 and 1727. It was a modest start as compared to the present system, but it proved so successful that, in 1743, the French Colonial Government ordered all land owners in that vicinity to "follow suit" and gave them one year to complete their units under penalty of forfeiture of their holdings immediately to the Crown. With the development of the Valley grew a haphazard system of levees which provided uncertain protection from the floods of the river. The resultant confusion, together with growth of national interest in the matter, resulted in the creation of the Mississippi River Commission by an Act of Congress in 1879, for the co-ordination of the efforts of the local interests and for the administration of the work of the National Government in controlling and improving the river.

The growth of the system under the administration of this Commission has been tremendous and its efforts have been marked with success as indicated by the satisfactory confinement of the 1929 and 1937 floods. The extent of the system at present is shown by Fig. 1. Accompanying this growth there has been a corresponding reduction in the area of the floodway and natural storage basins; greater flood stages have resulted, requiring higher levees. The average height at this time is approximately 22 ft. However, this height is as great as 50 ft at isolated points where the line crosses lakes or bayous. As the growth in size progressed, the experience of those directing the work broadened. The weaknesses in design became apparent under actual flood conditions and sufficient revision was made to insure stability.

---

[1] Associate Engr., U. S. Waterways Experiment Station, Mississippi River Comm., Vicksburg, Miss.

During the past few years the methods of levee construction have changed, the value of property protected has been enhanced, and the demand for designs complying with strict engineering practices has increased. The results of these changes have been many. For example, the change in construction methods makes it possible to complete the new and larger levees in a fraction of the time formerly required with mules and wagons or with men and wheel-barrows. Consequently, the foundations are loaded more rapidly and with heavier loads, and the chances of their failure are increased. When the circumstances are such that stable foundations are evident, and material is available with which sufficient experience has been accumulated, designs based on experience have been adequate. However, when the limits of the location are restricted, and it is necessary to construct a unit across an old lake bed or on some poor foundation, then the use of the new tool, Soil Mechanics, serves a need of long standing. The use of this branch of civil engineering permits design to be founded on a strength-*versus*-stress basis.

FIG. 1.—LEVEE SYSTEM, MISSISSIPPI RIVER, 1936

ESSENTIAL FEATURES OF DESIGN

The ultimate design of a levee requires consideration of the following essential features: Side slopes, foundation, and control of seepage. The first two of these features are of the utmost importance because, more than anything else, the structures must be stable for any conditions. The control of seepage is important and justifies discussion because of its effect on the stability of the structure. However, the volume of water lost is of little importance as its conservation is rarely desired in a flood control system. Furthermore, the normal drainage system of the areas adjacent to levees is generally more than adequate for the disposal of water accumulating through seepage.

Side Slopes.—The side slopes adopted for the standard sections of the levees over the period from 1882 to date, are shown by Fig. 2. The elevation of the maximum probable flood is that contemplated by the Flood Control Project authorized by Act of May, 1928. It may be noted that, as the size of the structures has increased, there has been a gradual reduction of the inclination of the land-side slope. The river-side slope has remained practically unchanged from the beginning. The broken land-side slope, as indicated for the banquette sections used between 1896 and 1914, was found to be undesirable in certain respects for the high levees on the Lower River. The steep land-side slope above the banquette proved unstable in some instances when confining the maximum floods for which they were designed. This unstable condition was probably due to the hydrodynamic forces created by the seepage, acting on the stepped slopes. In many instances slides or general sloughing actually occurred. For the Lower River, the levee section was altered to give a straight land-side slope.

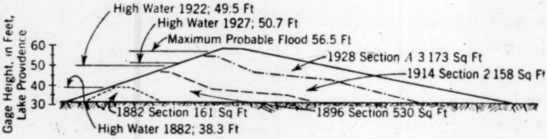

FIG. 2.—STANDARD LEVEE SECTIONS, LOWER MISSISSIPPI RIVER

The slopes in use at present vary somewhat with the material available in the borrow-pit areas. Table 1 shows this variation for the basic materials, sand, silt, and clay.

TABLE 1.—SLOPES FOR CLAY, SILT, AND SAND

Section	Predominating material	Crown width, in feet	River-side slope*	Land-side slope* containing assumed topmost flow line of following slope
A	Clay (75%)	10	1 on 3.0	1 on 6.0
B	Silt	10	1 on 3.5	1 on 6.5
C	Sand (75%)	12	1 on 5.0	1 on 8.0

* Topmost flow line assumed to spring from river-side slope, 1 ft below crown of structure.

The stability of these standard sections has been investigated, by the method described subsequently, and for normal conditions was found to vary between 1.5 to 3.5. This factor of safety is considerably greater than the average for earth structures of the levee type. The *B* section (Table 1) predominates throughout the Mississippi Valley. It has been found that the use of clay, of the richness requiring the *A* section, is generally undesirable. Consequently, the *A* section is rarely used. The foregoing sections have been developed over a long period of time and are based upon experience gained with the soil existing in the Valley. They should not be considered applicable to other localities where the material available may be entirely different although bearing the same local classification.

For situations in which new levees necessitate the use of material with which there has been little experience, the application of soil mechanics makes it possible to develop a levee design, based on the strength of the material, to give any factor of safety desired. The method of design depends on the nature of the material, on whether it is cohesionless, as a sand, or cohesive, as a silt and clay. For the slopes of structures formed of sands or like materials, the inclination must not be greater than the angle of internal friction. Their failure is by sloughing along the surface of the slope when this criterion is exceeded rather than in the manner described subsequently that applies to cohesive silts and clays. The stability of slopes formed of cohesive materials depends upon the shearing strength of the material along a deep-seated cylindrical surface. This cylindrical surface generally extends from a point just back of the crown of the slope, down through the section, and through the toe of the structure. The segment of the slope lying above this arc, in failing, appears to slide downward, rotating about the center of the arc. The method of locating the approximate position of this center of rotation for various slopes as established by W. Fellenius[2] and amplified by Charles Terzaghi,[3] M. Am. Soc. C. E., has been found to be satisfactory. Evidence of this type of failure in shear due to the over-stressing of the material has been observed in innumerable cases, particularly in levees constructed of material too wet for use.

The steps taken in the design of a slope, neglecting the effect of seepage on its stability, are relatively simple and much in accord with the prevailing practice. They are as follows: (1) The approximate position of the center of rotation for the arc of failure is determined; (2) the part of the slope of unit thickness, above this surface, determined by the arc of failure, is subdivided into vertical segments (the number—usually ten or twelve—depends upon the size of the structure); and (3) the gravitational force acting on each segment is determined and resolved into its normal and tangential components acting along the arc at the vertical projection of the center of gravity of the segment on the arc of failure.

Summation of the tangential components gives the force, T, tending to produce displacement. The force resisting this tendency is the summation of the frictional and cohesive forces acting along the arc. The total frictional force is determined by adding the normal components and multiplying the sum, N, by the tangent of the angle of internal friction, ϕ. The cohesive force is determined by multiplying the length of the arc, l, by the unit cohesive strength, c, of the material. The cohesive strength is obtained by a shear test performed upon a specimen of the material, prepared in a condition to simulate the most adverse situation expected. Cohesive strength is considered to be entirely independent of the pressure, depending solely upon the material and its condition. Thus, the stability of a slope or its factor of safety against sliding, may be determined by the expression:

$$\text{Factor of safety} = \frac{N \tan \phi + c\, l}{T} \dots\dots\dots\dots\dots (1)$$

The foregoing procedure is repeated until the center of rotation and radius of curvature are found, that give a minimum value of the factor of safety for the slope in question. The corresponding arc is then accepted as the critical surface upon which failure is most likely to occur. Several slopes are analyzed by this method and the one having the desired factor is selected.

[2] "Jordstatiska beräkningar med friktion och kohesion för cirkular cylindriska glidytor", W. Fellenius, Kungl. Väg- och Vallenbyggnadskårens 75-årsskrift, pp. 79–127, Stockholm, 1926.

[3] "The Mechanics of Shear Failures on Clay Slopes and the Creep of Retaining Walls", Charles Terzaghi, *Public Roads*, Vol. 10, No. 10, December, 1929, pp. 177–192.

A factor of unity for the stability of the side slopes indicates a balance of the forces. However, a slight deviation of less than unity can not be taken as a direct indication that failure is imminent. Values of less than 0.75 may be taken as indicative of an unsatisfactory situation and values greater than 1.25 can be taken as assurance of stability. Although this method of analysis may have its limitations, it does provide an excellent yardstick whereby analysis may be made of a situation about which engineers have had previously only rule-of-thumb methods to serve as guides.

Another element enters into the stability of the land-side slope after seepage through the structure has developed, or for the river-side slope following the passing of a flood and the removal of the impounded water. Failures have been observed of the river-side slopes of levees under just such conditions. The hydrodynamic force created by the seepage water, either flowing into or out of the section, produces an overturning moment in the part of the slope lying above the arc of failure. For example, considering a levee through which flow has fully developed, the flow and equipotential lines being arranged as shown by Fig. 3, the loss of head, h_f, occurring through the part above the arc of failure, $b\,d\,e\,f$, is due to the friction overcome by this seepage water in flowing through the material. The net effect of this loss of head is considered as a force acting in the general direction of the tangential component tending to produce failure and should rightfully be considered in such an analysis. (In Fig. 3, F_f is the force tending to cause displacement in the direction of flow, equal to h_f times unit weight of water times area surface, fb, of unit thickness.

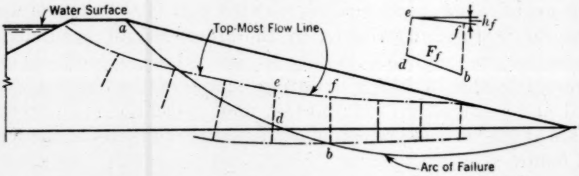

FIG. 3.—HYDRODYNAMIC EFFECT OF SEEPAGE ON STABILITY OF SLOPES

Although further research must be completed before definite conclusions may be safely drawn, a tentative method of analysis considering the effect of seepage water upon the stability of side slopes was advanced in a memorandum of the U. S. Waterways Experiment Station[4] this year. This analysis is similar to that reported by E. Meyer-Peter[5] and concurred in by D. W. Taylor, Assoc. M. Am. Soc. C. E.

Foundations.—It has been stated that the prime requisite of a levee was stability under all conditions. After the stability of the side slopes has been determined, the next essential feature to be considered is the foundation. It is not unusual that a setback unit of a levee, required by some channel change or improvement such as a cut-off, is constructed in one season or during a few months just prior to the annual flood period. It is then that a reliable method of design to assure stability is fully appreciated.

---

[4] A Report of Experiments and Investigations to Determine the Efficacy of Sub-Levees and Berms in the Control of Seepage, *Technical Memorandum No. 101-2*, July 1, 1937.

[5] "Beitrag zur Berechnung der Standsicherheit von Erddämmen", von E. Meyer-Peter, H. Favre, and R. Müller, *Schweizerische Bauzeitung*, Vol. 108, No. 4, July 25, 1936, pp. 35–37.

In the past, one method[6] of dealing with a weak foundation where the lateral flow of an unconsolidated stratum of plastic material could be expected, was to build up the section and await the anticipated failure. After failure occurred, the placement of dirt was renewed, and the process continued until all the soft material was either squeezed out or until the levee had become stable for other reasons. This procedure required time and plenty of resources. An empirical method was developed about 1933 for the design of berms, which proved to be a very good remedy for this problem. This work was done by T. A. Middlebrooks, Assoc. M. Am. Soc. C. E., and was based entirely upon experience with such problems. His method of analysis had its limitations and has been supplanted by one described in the following paragraph.

In this case, again, the methods developed in the field of soil mechanics can be brought into play and the structures designed so that the stresses created by the structure will not exceed the strength of the foundations. The method of analysis contributed by Leo Jürgenson[7] makes it possible to compute the stresses created by this type of structure. Either the quick direct shear test, or the squeeze test, on specimens from undisturbed samples, can be used to obtain the ultimate strength of the material *in situ*. With these data it is a relatively simple matter to determine the stability of a foundation or the necessary adjustment of the design to give the factor of safety desired.

An application of this method of analysis to three full-scale levee structures is interesting and worthy of mention. This investigation was made in May, 1935, for the purpose of corroborating methods used in the design of the foundations of numerous earth dams in the Muskingum Valley, in Ohio. Of the three units, founded on similar material, one had been found stable and the other two had experienced complete failure, due to the over-stressing of their foundations. The first of these units was constructed after 1930 and the latter two prior to that date. The results of this application are illustrated in Table 2.

The evidence indicated by the analysis of the first two units appears to justify confidence in this method. Although that for the third, Milliken Bend, unit appears to fail in proving the desired point, it was the only one of the group whose original cross-section departed appreciably from the triangular shape. The analysis applies to triangular cross-sections. A comparison of the computed values of shear with those measured in models by photo-elasticity shows a variation of 1%, 2%, and 30% for the units in the order shown (Table 2). Thus, it is indicated that this method of analysis has its limitations when applied to a section deviating from the true triangular shape. Further use of this method of analysis on other projects has been made since 1935 and to date (1937) no difficulties have arisen. The structures have been satisfactory in every respect when the basic assumptions have been met.

[6] "The Improvement of the Lower Mississippi River for Flood Control and Navigation", by D. O. Elliot, *Bulletin*, U. S. Waterways Experiment Station, May 1, 1932, Vol. 2, p. 177.

[7] "The Application of Theories of Elasticity and Plasticity to Foundation Problems," by Dr. Leo Jürgenson, *Journal*, Boston Soc. of Civ. Engrs., Vol. XXI, No. 3, July, 1934, pp. 206–241.

Settlement is an important factor in levee construction, as it is in building construction. However, the effect is quite different, for little damage, if any, is experienced by a levee through its settlement. The principal benefit from the predetermination of this factor is in the economy effected. A reliable estimate permits the gross grade to be adjusted at the time of initial construction to allow for the settlement. Thus, no subsequent enlargements are necessary to maintain the desired net section or grade. It has not been unusual for these structures when placed across old lake beds or bad swampy areas to experience 3 to 5 ft of settlement. Of course, allowance is made at the time of construction for the normal shrinkage of the fill. However, when in addition to this shrinkage a settlement occurs, the section must be restored. The cost per unit of fill for the enlargements is naturally greater than the initial unit cost. In addition, emergency protection may be required during a major flood. This emergency protection is in the form of sand bags or mud boxes placed in depressions caused by settlement, and is very expensive.

TABLE 2.—SAFETY FACTORS FOR THREE LEVEES

Item No.	Name of unit	Basic Dimensions, in Feet			Increase in pressure caused by structure, in tons per square foot	Maximum stress, in tons per square foot	Measured strength, in tons per square foot	Factor of safety
		Height	Base width	Depth of underlying soft stratum				
1	Halpino Levee*	36	432	27.0	1.8	0.113	0.152	1.34
2	Duckport Levee	30	270†	32.5	1.5	0.183	0.165	0.90†
3	Milliken Bend Levee	37	270	27.0	1.8	0.313	0.163	0.53‡

* No difficulty was experienced with this levee.

† After this levee failed the section was successfully reconstructed to a new base width of 347 ft, changing the factor of safety to 1.16.

‡ Structure failed, as was to be expected. The structure was successfully reconstructed to a new base width of 416 ft, changing the factor of safety to 0.80.

The detection of portions of a new unit in which excessive settlement may be expected is not a difficult matter. The site of a proposed unit as well as the borrow-pit areas are explored in a routine manner by borings, prior to the completion of the initial design. Adequate samples are taken during this exploration and subjected to tests as described later in this paper to check the general condition of the foundation, and to detect both the extent and depth of strata of cohesive material containing an apparent excess of water. Analysis of the evident weak spots by the Terzaghi theory of consolidation, combined with data from the consolidation tests of a few well-selected undisturbed samples, is sufficient to form the basis of an adjusted gross grade. The method for determining the settlement of a levee is illustrated subsequently in the solution of a typical problem.

Control of Seepage.—Seepage through the levees in the Lower Mississippi Valley, and its control, have formed the bases for the design of the standard sections previously described. It has been assumed, on the basis of past experience, that the topmost flow line of seepage through a section traveled on slopes of 1 on 6 to 1 on 8, depending on the material. The position of the point of entrance on the river side is fixed by the free-board desired, usually 1 ft of free-board being allowed for the super-flood anticipated. It was further assumed that the seepage through the structures would develop fully during the flood period. In so far as the records to the present time show, the duration of this period has not exceeded 120 days, while, of course, the flood waters would remain at the assumed free-board height for a small fraction, say, 15% of the time.

The shape of the section has been made to contain the topmost flow lines just mentioned. During an inspection of some of the levee units in the vicinity of Memphis, Tenn., the writer observed no evidence of serious seepage coming through the levee section. Although difficulties were experienced with the seepage through the foundations at some locations, this can not be attributed to any weakness in the design of the section. Pervious strata frequently exist in the foundations of levees and are the source of some trouble of local nature. Control of this excessive seepage is achieved by the use of sub-levees, or by placing a ring of sand bags so as to isolate the small local spots. Either of these means of control develops a negative hydrostatic head neutralizing or reducing to a harmless quantity the water leaking through the foundation. Thought is now being devoted to methods of sealing such pervious foundation strata so that this undesirable condition may be remedied.

Problems involving structures founded on pervious material are analyzed with the aid of models constructed in a glass-sided flume. The conditions under which these experiments have been conducted were arranged to simulate various positions of ground-water. The data from these tests are used to estimate both the position of the topmost flow line in, and the quantity of flow through, the section.

Structures founded on impervious strata may now be analyzed by methods such as one developed by Glennon Gilboy,[8] Assoc. M. Am. Soc. C. E. This problem is usually complicated by the fact that no selection of material is exercised in the construction of a levee. Hence, the usual assumption that the structure is a homogeneous mass is not justified. The state to which the material in the structure may be compacted is a variable that will affect the flow through the section. This variable can be judged only by experience gained through observation of structures recently completed; a limited number of observations and tests have been made. The details of this type of analysis are treated in the solution of a typical levee problem outlined subsequently in this paper.

The rate of development of seepage through a section of levee is a matter of importance. The maximum period of flood as estimated previously is 120 days, and it is only for a short part of this time that the maximum flood prevails. The rate of seepage development has been a matter of conjecture. Some interesting data have been obtained through observations of the development of the flow through an earth dam at the United States Waterways Experiment Station, at Vicksburg, Miss. These data throw some light on the subject. The dam is 35 ft high, with side slopes of 1 on 3.7 for both up-stream and down-stream faces. It is constructed of loess, a remarkably homogeneous material typical of the Vicksburg area, and is founded upon the same material. The loess, while unlike in some respects to the alluvial soils in the Valley, has, nevertheless, permeability characteristics similar to a great proportion of the material used in the levees, that is, the silts requiring the standard *B* section. The material was placed by trucks in layers 6 in. thick, and compacted only by the repeated passage of these vehicles. No exact control was exercised over the compacting operation. The elevation of the impounded water in the reservoir has been maintained at 164.5 ft (mean Gulf level) since May, 1935. The dam was constructed in February and March, 1935, with the spillway crest at Elevation 165.0 (mean Gulf level). A duplicate set of observation wells were placed in the structure at the time of its construction. The locations are shown by Fig. 4. Tests showed that the desired compaction was obtained by the constant passage of the trucks over the spread material. The results of the observations are shown by Fig. 5, which indicates that ten months were required for the full development of the seepage through this structure.

[8] "Hydraulic-Fill Dams," by Glennon Gilboy, 1st Congress of Large Dams, Vol. 4, Rept. No. 46, pp. 231-267.

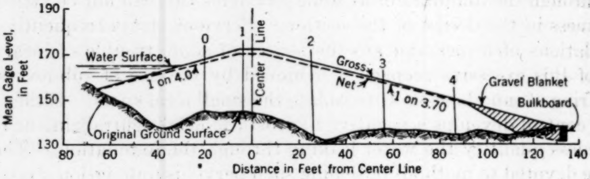

FIG. 4.—LOCATION OF OBSERVATION WELLS, STATION 0 + 66

The results of these observations show that seepage development is exceedingly slow, and tend to indicate that for sections formed of relatively impervious materials, silts, or finer, the flow does not develop during the flood period. Consequently, sections designed to comply only with the requirements of stability are satisfactory. In the past, numerous instances were reported in which the seepage through the standard banquette section did develop, outcropping at the upper edge of the banquette, and causing damage. The path of flow through the present section is two or three times as long and, consequently, requires a greater time to develop.

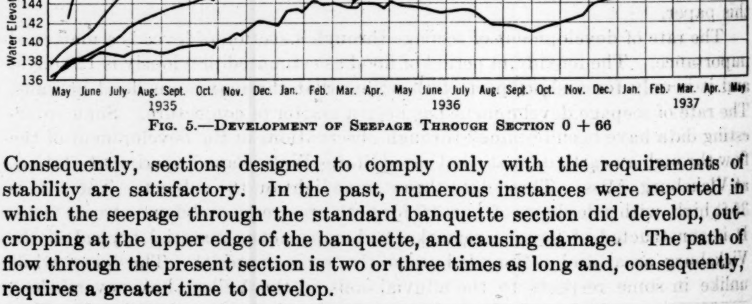

FIG. 5.—DEVELOPMENT OF SEEPAGE THROUGH SECTION 0 + 66

For the situation of pervious structures, formed of sand, the seepage may develop during the flood period. However, a unique method for controlling the seepage through this type of levee has been applied in some instances. This control is provided by means of impervious clay blankets, 3 ft thick, placed on the river-side slope and extended through pervious surface strata into an extensive impervious stratum in the foundation. Information as to the effectiveness of this control is provided by observations made by the U. S. Engineer District Office, in Vicksburg, of the pervious levee closing the gap formed by the famous Mounds Landing Crevasse that occurred during the 1927 flood. These observations were made before and after the placement of the clay blanket, that is, in 1933 and 1937; the crests of the floods of these years were within 0.5 ft of the same elevation at this unit. The seepage, as collected and measured by a system of weirs at the land-side toe for a part of the levee, 920 ft long, was 0.3 cu ft per sec in 1933 and 0.06 cu ft per sec in 1937. The atmospheric conditions during the 1933 flood were not the same as those that existed in 1937; that is, the precipitation in 1937 was the greater. Consequently, part of the measured seepage of 0.06 cu ft per sec may be attributed to drainage of rain water.

The Design of a Levee Unit

The design of levees, as accomplished through the application of soil mechanics, is basically the same as that used for earth dams about which much has been written recently. However, the attack of this problem becomes unique through consideration of several essential features: Location of levee, source of materials, placement of materials, and control of seepage.

Unfavorable locations along a line, as far as foundation conditions are concerned, cannot be avoided as readily as by shifting a dam up stream or down stream a short distance. Deviation from the shortest practicable route, to avoid crossing filled sloughs or lakes, increases the cost of the structures tremendously. Furthermore, the local interests, who are naturally desirous of obtaining protection for a maximum amount of their land, contribute toward the cost of the levees. Consequently, their desires must be given consideration and complied with in so far as is possible. Formerly, to simplify the enormous task when extensive programs have been undertaken, sections, based upon empirical designs, have been standardized with ample allowance for local "sore" spots in the foundations, both as regards unstable conditions and excessively pervious materials. Now, it is possible, through the application of soil mechanics, to alter the design to fit the conditions encountered.

The material adjacent to the river-side toe of the levee must be used for its construction, whether it is sand or clay. The principal reason for its use is the economy effected. The use of the material directly opposite the section minimizes the distance it must be transported, eliminating over-haul. The borrow-pits, being on the river side, are thus located in areas where land values are low and the borrow material is cheap. For the enlargement of sections, this results in even greater savings than for the original construction as the borrow areas have already been adjusted. In general, any attempt toward the selection of material would be fruitless due to the supply, of what is generally reckoned as suitable according to current practice in earth dam design, not being equal to the demand. In some regions, especially the lower part of the river, that at hand is just as suitable as any within about a mile. This situation makes it necessary to design the structures on the basis of the weakest of available materials. Although this often requires large sections with flat slopes when compared to some dams recently designed and constructed, the problem is simplified and solved at a low cost.

It is important that no borrow-pits or excavations be made adjacent to the levees on the land-side to expose pervious strata extending through to the river side. Exposure of such strata invites trouble from increased under-seepage, certainly; and from destruction of the levee structure due to piping, possibly. Although, in some instances, borrow-pits have been made on the land side, they are the source of never-ending trouble.

Control over the placement of the material in levees, in so far as its condition and state of compaction are concerned, has not been exercised as is the practice in the construction of earth dams. Most of the present system had been completed, or was under construction, at a time when little was known regarding the compaction of fills, antedating 1930. This date (1930) apparently marks the actual beginning of efforts to control compaction. To encourage low bids and costs, it has been necessary to minimize the restrictions on methods of construction. If the compaction of the material had been undertaken, it has been estimated that a direct increase in cost of about 4 to 6 cts per yd would have resulted, causing an increase in the cost of the structure of as much as 70% in some cases. Such an increase has not appeared to be justified for structures designed by empirical methods. Then, too, no selectivity of material has been exercised in the past, and, as the compacting of materials depends to some extent upon their uniformity, efforts toward control of condition and state would not have been marked with great success. Large allowances have been made for the shrinkage of the structures, as follows:

Equipment for construction:	Percentage, shrinkage allowance
Cableway (locally termed "tower machine")	25
Dragline	25
Tractor (wagons, tractrucks, or trucks)	15
Hydraulic fill	8

Uncertainty as to the condition and state of compaction of the material, and assumptions as to conditions and placement that need not be considered generally in earth dam construction, make the design of these structures difficult. For instance, the cohesive strength, as used for the design of side slopes, is usually neglected completely when it is known that draglines or cableways are to be used for the construction of a unit.

The control of seepage through the levee sections has been the prominent feature of their design. This has not been due to a demand for the conservation of water, as is generally the case for dams, but because of the manner in which they have been constructed. The application of the criteria in current use has resulted in designs which have proved satisfactory from the standpoint of stability. It has been shown that most of the material for their construction is silt or a similar soil which is considered as fairly impervious; also that the duration of the flood periods are relatively short as compared to the periods of high reservoir stages for dams. Consequently, the opinion that full seepage through the sections may not develop seems justified. Through the application of soil mechanics it is possible to attack the problem of design more directly; that is, to determine the stability of the structure on the basis of the strength of the materials used and, in addition, to estimate the seepage and its effect on the stability of the slopes.

The design of a levee, whether based upon empirical or stress-*versus*-strength analysis, depends upon the nature of both the material to be used for its construction and the foundation medium. Consequently, the first step is to explore the materials in the borrow-pit areas by means of borings, so that definite information concerning the available material for construction will be at hand. The material to form the foundation for the structure must be explored in a similar manner. The current practice is to make a system of preliminary borings along lines parallel to the route of the proposed levee, so that the lines divide the area into three parts. The borings are made in pairs on these lines, 1 000 ft apart. The depth of these borings is not great, but it is sufficient to explore the volume of material required for the structure adjacent to their location. In addition, borings are made at 1 000-ft intervals along the center line of the proposed levee, directly opposite those in the borrow-pits, to explore the foundation medium for sufficient depth to assure the non-existence of unconsolidated and apparent unstable material. When such a condition is indicated by the preliminary borings, or the features of the terrain, additional borings are made to trace adequately the extent of such weak formation. The spacing may be reduced to intervals of 100 ft.

The borings for the exploration of the borrow-pit areas and foundations are generally 3 or 4 in. in diameter. They are made with earth augers operated by hand. It has been found that this means of exploration is practicable, permitting the use of unskilled labor and requiring very simple equipment. The samples of the material are obtained directly from the augers as the work progresses and preserved in pint fruit jars which are properly labeled for identification in the classification laboratory.

For the situations requiring special consideration or where no experience has been had with the materials, a primary system of borings is made to supplant the preliminary system just described. The purpose is to provide samples for analysis of the strength of the materials in the borrow-pits and foundations. These samples are obtained from 6-in. borings, using special equipment designed for obtaining undisturbed samples. These large borings are also made, in most cases, by hand-operated augers. A casing of suitable size is used in this work to prevent the caving of the materials penetrated and to exclude the ground-water; thus the materials are sampled "in the dry". The device used for obtaining the undisturbed samples was developed under the auspices of the former Committee on Earths and Foundations of the Society by Professor Gilboy and the writer. The details of this device are shown by Fig. 6. Complete descriptions of the technique of boring and sampling, for both the general and undisturbed samples, are contained in other publications[9] of the writer.

[9] *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., *Paper A-23*, by S. J. Buchanan, Vol. 2, p. 72–81, June, 1936; "Technique of Soil Testing", by S. J. Buchanan, *Civil Engineering*, Vol. 7, No. 8, August, 1937.

The samples of material obtained by the preliminary exploration are subjected to classification tests, both as to kind of material and general condition. An experienced technician, trained in this work, first classifies the material by visual inspection. The samples are then grouped and such mechanical analyses and water content determinations as are necessary are made of representative members of these groups. Whenever a question arises as to the correctness of visual classification, additional tests are made to dispel any uncertainty. The Atterberg limits, liquid and plastic, are made of a few selected samples so that an index of their general condition, *in situ*, may be had. Thus, the general natures of the materials available for construction, as well as of those in the foundation, are established.

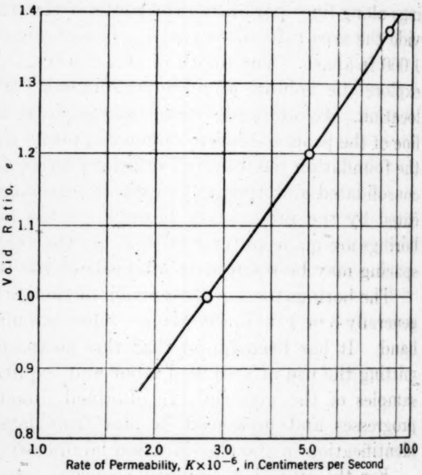

FIG. 7.—PERMEABILITY DIAGRAM

The strengths of the materials are next determined by tests of a representative specimen. The delayed shear test for ascertaining the angle of internal friction, ϕ, and cohesive strength, c, as required for the design of the side slopes of the structure, are made of a representative specimen of the borrow-pit materials. Complete descriptions of this, and subsequent tests mentioned, are available elsewhere.[10] The maximum side slopes of the structure are thus established. The strength of the foundation is determined by quick, and squeeze, shear tests of undisturbed samples of the cohesive materials in this medium. Then, the combined consolidation-permeability test is made so that the settlement and under-seepage can be estimated. The final shape of the structure is established, on the basis of information obtained from the latter group of tests.

---

[10] "Laboratory Procedure in Testing Soils and Sediments", *Bulletin*, U. S. Waterways Experiment Station, November 1, 1936.

Basic Data.—The physical features of the problem to be considered are:

Elevation of natural ground surface at the site, in feet (mean Gulf level)	347
Elevation of net grade or crown, in feet (mean Gulf level)	377
Net height of structure, in feet	30
Free-board for maximum designed flood, in feet	1.0
Percentage allowance for shrinkage (construction by tractors)	15
Gross height, in feet, considering shrinkage (30 × 1.15)	34.5
Thickness of plastic zone in foundation, in feet	23
Factor of safety desired for side slopes	1.5
Factor of safety desired for foundation	1.25

The borrow-pit material is a clayey silt, and other characteristics are as follows:

Percentage of water content (natural state on dry weight basis)	31.5
Void-ratio (natural state on dry weight basis)	1.20
Absolute specific gravity	2.68
Unit weight, in pounds per cubic foot, when placed (judged by experience)	100
Angle of internal friction, ϕ (test result), in degrees	19.4
Cohesive strength, *c*, in tons per square foot	0.13
Permeability, in centimeters per second (result of tests)	5×10^{-6}

It is evident from the inspection of the conditions indicated by the log of boring, Fig. 8, that the only questionable material, in so far as strength is concerned, is the clay between Elevations 344 and 321. The data obtained from this material are shown as follows: The strength of this material, *in situ* (quick shear tests), equals 0.155 ton per sq ft. Its consolidation and permeability characteristics are as shown in Fig. 9.

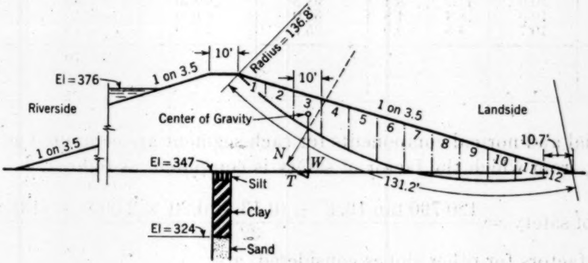

FIG. 8

Design of Side Slopes.—In the computations for a slope of 1 on 3.5, the position of the center of rotation and the radius of critical arc are both determined by methods referred to previously. These data are shown by Fig. 8. The weight of the material in the structure is assumed to be 100 lb per cu ft. It is assumed that 20% of the cohesive strength of material will be active. The

$\Sigma\Delta T$	....	..	..	....	....	32 870	....
$\Sigma\Delta N$	....	..	..	....	....	....	120 790

tangential and normal components for each segment are computed as shown in Table 3, from which the factor of safety is computed, as follows:

$$\text{Factor of safety} = \frac{120\,790 \tan 19.4° + (0.13 \times 0.20 \times 2\,000) \times (131.2)}{32\,870} = 1.51$$

The factors for other slopes considered, are:

Slope	Factor of safety
1 : 3	1.32
1 : 3.5	1.51
1 : 4	1.70

Foundations.—Probable settlement is estimated in the following steps:

(1) The increase in vertical pressure on the foundation, in tons per square foot $\left(\frac{34.5 \times 100}{2\,000}\right)$ = ... 1.725

(2) The pressure, in tons per square foot, by which the clay stratum has been previously consolidated (estimated from Fig. 9(*a*)) . 0.315

(3) Void-ratio corresponding to initial conditions.................. 2.04

(4) Void-ratio corresponding to final condition..................... 1.64

(5) Thickness of compressible stratum, in feet...................... 23

(6) Total settlement, in feet[11] $= h \frac{e_i - e_f}{1 + e_i} = \frac{23\ (2.04 - 1.64)}{1 + 2.04}$...... 3.0

(7) New gross height, in feet, considering allowance for settlement (= 34.5 + 3.0) 37.5

A recheck of the settlement, using the new gross height (37.5) gives a new value of 3.1 ft, which is sufficiently correct for the purpose; and a recheck of the side slopes shows the factors of safety for the new condition practically unchanged.

The stability of the foundation is determined as follows:

(*a*) Vertical pressure, P, in tons per square foot, created at center of structure $\left(= \frac{37.5 \times 100}{2\,000} \right)$........................... 1.875

(*b*) Thickness, d_a, in feet, of plastic zone in foundation (see Fig. 10). . 23.0

(*c*) Measured strength, in tons per square foot of foundation (test result)... 0.155

(*d*) Allowable working strength of foundation material, in tons per square foot, to give a factor of safety of 1.25 $\left(= \frac{0.155}{1.25} \right)$ . . 0.124

(*e*) Base width of structure required, b_b, in feet,

$\left(= \frac{P\,da}{\text{Allowable stress}} = \frac{1.875 \times 23}{0.124} \right)$.................. 348

(*f*) Ratio of horizontal to vertical side slope required, allowing for crown width of 10 ft and height of 37.5 ft $\left(= \frac{348 - 10}{2 \times 37.5} \right)$...... 1 : 4.5

Side slopes of 1 : 4.5 are necessary because of the foundation condition, superseding the 1 : 3.5 as required for the material placed in the structure proper. Had the standard side slope for the *B* section, river-side slope, 1 : 3.5 (see Table 1), been used, the factor of safety of the foundation would have been 0.98.

Seepage.—The factors involved in determining the height of emergence of the topmost flow line above the base of the levee (using basic equations advanced by Professor Gilboy) are: H = head of water to be impounded; α = angular inclination of land-side slope; b_s = horizontal distance from land-side toe of section to vertical projection of intersection of river-side slope with water surface at a height, H, above the base of the structure; and $m\,H$ = the vertical distance above the foundation of the outlet point of the topmost flow line.

---

[11] Progress Rept. of Special Committee on Earths and Foundations, *Proceedings*, Am. Soc. C. E., May, 1933, p. 788.

These factors are connected by the following implicit function (see Fig. 10 for values):

$$\frac{2b_s}{H} = m \cot \alpha + \frac{\sqrt{1 - m^2 \sin^2 \alpha}}{m \sin \alpha} - m \sin \alpha \log_e \frac{1 + \sqrt{1 - m^2 \sin^2 \alpha}}{m\,(1 + \cos \alpha)} \ldots (2)$$

The solution of Equation (2) for the value of m, using known values for the factors, b, H, and α, establishes a value of 0.34. The height of emergence above the base is equal to $m\,H = 0.34 \times 29.0 = 9.9$ ft.

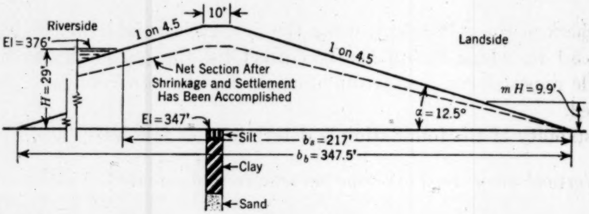

FIG. 10

The quantity of seepage per foot length of levee per second is expressed by:

$$Q = K\,m\,H \sin \alpha \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Substituting the proper values in Equation (3): $Q = \frac{5 \times 10^{-6}}{2.54 \times 12} \times 9.9 \times 0.217 = 0.35 \times 10^{-6}$ cu ft per sec per ft of levee, or 0.11 cu ft per min per mile of levee, indicating that little concern is warranted regarding the quantity of seepage to be encountered.

Conclusions

The present levee system for the Lower Mississippi Valley was designed and constructed at a time when the science of soil mechanics was "in its swaddling clothes". The system as a whole has proved satisfactory under the test of actual use. However, the empirical methods of design were based upon long experience with such structures, the heights of which have increased as have the consequent stresses developed. For subsequent improvements, such as further enlargements or changes in locations that may have become necessary, economical designs may be predicated upon a strength-*versus*-stress basis, to better advantage. Time and funds are no longer necessary to develop empirical designs. The fund of knowledge available permits the problem to be attacked by this new method which has already "won its fighting pants" in other fields.

The net effect of applying knowledge gained through soil mechanics appears to be toward the elimination of such practices as actually producing failures of foundations and later repairing them. Also, it is indicated that the size of the sections may be reduced safely through steepening of the present standard land-side slopes. For new units involving materials with which there has been no experience, savings in time and cost are possible through the application of soil mechanics.

Acknowledgments

In addition to the acknowledgments and references embodied in the text, the writer wishes to thank the Director of the U. S. Waterways Experiment Station, Paul W. Thompson, Lieutenant, Corps of Engineers, U. S. Army, Jun. Am. Soc. C. E., for his co-operation in making this paper possible. Much valuable assistance was given by the staffs of the Mississippi River Commission and the U. S. Engineer District Office, of Vicksburg, Miss., for which the writer is grateful. He wishes also to acknowledge the assistance of members of his laboratory staff, in particular the following: William L. Wells, Jun. Am. Soc. C. E., Robert M. German, Junior Engineer, and William J. Rowland, Chief Technician, in the preparation of the paper.

QUABBIN DIKE BUILT BY HYDRAULIC-FILL METHODS

By Stanley M. Dore,[12] M. Am. Soc. C. E.

Synopsis

The thorough investigations of materials available for earth dam construction furnish not only the proper information by which to decide the type, dimensions, and cost of the earth dam to be built, but they furnish sufficient data to enable contractors to bid intelligently. Such bidding tends toward more economical and satisfactory construction.

The proper supervision of the construction of a full hydraulic-fill dam is of primary importance. The engineer strives to have the structure built safely and economically, at the same time securing the best quality, the materials available and the difficulty of securing and placing them being carefully considered. The control of construction operations by the engineer to obtain satisfactory results is influenced to a large extent by laboratory investigations and tests of samples from the borrow-pits and from the shoulders and the core of the dam.

The design of a hydraulic-fill dam and the supervision of construction, are influenced considerably by the rate of consolidation of the core material that will occur during and after the sluicing operations. As far as is known there is no existing method of computing this rate of consolidation during construction, other than the semi-empirical method presented herein which was developed from data accumulated on the Quabbin Dike. This method may be used for estimating core consolidation on another project when certain laboratory test data pertaining to that project are available.

Introduction

The Quabbin Reservoir[13] of the Boston, Mass., Metropolitan Water District (capacity, 415 000 000 000 gal), will be formed by a main dam and a dike. Both are full hydraulic earth dams, the former being 2 640 ft long, 170 ft high above the old river bed, and containing more than 4 000 000 cu yd of embankment above the original surface, and the latter being 2 140 ft long, 135 ft high, and containing 2 500 000 cu yd. A typical cross-section of the Quabbin Dike is shown in Fig. 11.

FIG. 11.—TYPICAL CROSS-SECTION OF DIKE EMBANKMENT, QUABBIN RESERVOIR

Borrow-Pit Investigations

The quantity and quality of the over-burden in each area easily accessible to either the Main Dam or the Dike were first investigated by 2.5-in. bore holes and by test pits, 6 to 10 ft deep, dug by hand. The bore holes were driven to reasonable depths to ascertain the extent of the earth cover, and dry samples, at least every 5 ft apart vertically, were taken from each of them. These holes were located frequently enough (generally at least 400 ft apart) to serve as a good index of the materials in the area. The bore-hole investigation also revealed very approximately, the number and size of boulders to be expected. The test pits, to supplement the bore-hole program, were located on hillsides and in areas where the earth cover was known or expected to be thin. Samples from both places were tested for grain size, permeability, and porosity in the soil laboratory. From these investigations, studies and estimates were made for each borrow area, to determine the quality and the cost of the structure that should be obtained.

Areas that seemed to be promising, from the standpoint of quality and cost, were further investigated by shovel cuts; that is, excavations made, with a power shovel, into the hillside at one or two critical places in each prospective borrow area. The excavation of each cut was continued into the hillside or slope until a face from 20 to 30 ft high was opened, and representative samples were tested in the soil laboratory for grain size, permeability, and porosity. The cost of these cuts averaged $1 200 each, four being made for the Dike and ten for the Main Dam. Large cuts of this nature offer a very satisfactory exhibit to indicate to the prospective bidder the type of materials to be expected. They pay for themselves many times over on a large job by eliminating from the bidder's mind much of the uncertainty as to exactly the qualities of materials with which he must work. By eliminating as much as practicable of this uncertainty, the sum that the careful and preferred bidder adds to offset his risk, is correspondingly decreased.

Materials from some of these cuts, in addition to the soil laboratory tests, were tested in the "sluicing bin" shown in Fig. 12, where they were washed down on to the beach of the bin with nozzle streams, the finer particles going into a pool at the end. The test subjected the materials to working conditions similar to those encountered in actual construction. The qualitative and quantitative properties of the materials considered for hydraulic-fill construction, can be studied more extensively on the basis of tests made with this bin. The results give definite relative values as to the suitability of any material for use in the construction. For example, by measuring the quantities of materials sluiced and the quantities deposited in sections of the sluicing bin corresponding to the beach and core sections of the dam, estimates of the yield of beach and core materials from a particular class of borrow material can be made. Furthermore, porosity, grain size, permeability, specific gravity, and microscopic tests can be made on samples taken from the beach and from the core sections of the sluicing bin, and the results can be taken as indicative of the properties of the hydraulic-fill embankment that will be obtained from that borrow material. A larger yield of suitable core materials is required for the upper parts than for the lower parts of a dam. The sluicing-bin tests can be used to indicate which

material or which mixture of materials is the proper one to use in any particular height.

The results of these investigations aided appreciably in the study of several methods of building each embankment and in estimating the costs of the various layouts. The methods that seemed satisfactory and feasible, and practicable economically, were offered to the bidders as suggestions, only to aid them in tendering a fair and intelligent proposal. After the contract for each dam had been awarded, the successful bidder was required to submit for approval his own plan of operation, which might, or might not, be one of those suggested.

The samples obtained from bore holes, test pits, or shovel cuts are valuable in influencing the design of the dam or the layout of the construction plant, and the proper design and the prices obtained in the construction contract depend to a large extent upon an adequacy of these samples. The Soil Laboratory enhances the value of the samples by analyzing the properties and presenting the results in a classified and summarized manner so that the results can be used easily and intelligently. Such work eliminates much of the guesswork and

difference of opinion that accompanies the visual examination. If soil laboratory results and the classification of samples for various dams already built are available, comparative studies can be made of the materials available for construction and of those used elsewhere.

Fig. 13, with Table 4, shows a comparison of grain-size analyses curves for borrow-pit materials used in Quabbin Dike with those for some other large dams. A "full hydraulic" dam is an earth dam built by transporting the material on to the dam by pipes or flumes, in suspension in water and depositing it in the dam by water, a separation of sizes taking place during deposition. A "semi-hydraulic" dam is similar to "full hydraulic" except that the material is transported on to the dam in some other manner, usually in a "dry" state in cars, trucks, or wagons.

Control During Construction

To control the deposition of material in a hydraulic-fill dam is a complex process, and many features must be properly co-ordinated to obtain the best results. The analysis of "hog-box" samples and of core and beach samples at regular intervals is a valuable part of this control. Periodic tests for grain size, permeability, and porosity give indications that the structure is, or is not, being built satisfactorily, and they reveal the properties of all parts of the structure.

By the analysis of the hog-box samples the builder is enabled to anticipate the borrowing operations, and the engineer is enabled to regulate them properly so that poor construction conditions and results may be avoided. These analyses indicate, directly, to both builder and engineer, any lack of "coarses" for the shoulders or of "fines" for the core, any presence of too large a quantity of any one size, and other unsatisfactory size conditions. Any conditions of size deficiency or excess can be remedied or corrected as soon as it is indicated by the laboratory analyses, by borrowing materials of differently tested characteristics from other parts of the borrow area.

The analyses of core samples, taken at frequent intervals from the dam itself, indicate definitely the existence of any coarse tongue or intrusion into the core or fine deposit in the shoulders so that corrective measures may be taken before construction advances too far. By co-ordinating the result of rod-pipe soundings made along the edges of the core and pool with the size analyses made from the materials there, an inspector can learn to judge the quality of the core material by the resistance offered to the penetration of his rod. Thus, he can feel any coarse tongue that projects into the core. With routine testing the grain-size test acts as a constant check on his judgment. If these tests are made reasonably close (say, every 100 ft along the edges of the pool) and are supplemented by the rod-sounding work, unsatisfactory conditions can be ascertained for correction.

Glacial sands and gravels usually have such high internal frictional resistances, that shear tests are not necessary to the design, because a conservative cross-section obtained by using reasonable up-stream and down-stream slopes normally has ample volume and weight to withhold the pressures from the core during and, of course, after construction. For some types of materials, such as those obtained from alluvial deposits, shear tests should be used extensively to determine the qualities of the shoulders of the dam or the foundations under it, and in such cases the results will control many features of the design. However, an occasional shear test for any type of material is a valuable check of the qualities already judged suitable by visual inspection. In the case of control during construction, shear tests on the core material of a hydraulic-fill dam have a definite utility, as the frictional value of the core increases with the consolidation. If, from tests, the shear is determined for various degrees of consolidation of the core material, the safe rate of progress of construction and the rate at which the width of the core can be decreased safely can be controlled more intelligently. At Quabbin Dike the shearing resistance of the core materials, even a few days after being deposited, was sufficiently large so that it was unnecessary to limit the rate of construction or the rate of decreasing the core width.

Core samples should be analyzed for moisture contents (or porosity) at frequent intervals to determine the rate at which the core consolidates during construction. These specimens can be obtained by sinking a pipe well into the core and taking samples, at various elevations, in as near an undisturbed condition as practicable. Although the core materials may vary in properties over a wide range, the results of the moisture content determinations, in conjunction with grain-size analyses curves, will show a definite trend of the rate of consolidation.

At Quabbin Dike a steel pipe of 0.5-in. plate, 36 in. in diameter, was built vertically in the core during the construction (see Fig. 14) and this well was equipped with ports through which samples can be taken at various elevations. If desired the samples can be taken several feet away from the observation well by the use of long tubes. Samples from the ports of this well were taken at regular intervals (approximately one month) and tested for grain size and porosity. The results indicate that certain definite laws operate to control the rate at which the core materials consolidate during construction.

In the very first stages of the consolidation considerable water is released from the part of the core near the bottom of the pool through vertical springs into the pool; but for parts of the core covered substantially, the drainage is mostly horizontal. The edges of the core consolidate more rapidly than the center for two reasons: First, they are nearer the coarse, and free-draining, parts of the dam, and the water squeezed out of the pores is quickly carried away; and second, they usually contain the coarser of the core deposits which will yield its water relatively quickly because the permeability coefficients are correspondingly higher.

Disregarding this more rapid consolidation of the edges, and assuming that there is only one consolidation rate for the core over its entire width, for each increment of height, the degree of consolidation during construction can be expressed by an equation involving the quantity of water squeezed from the core material, to effect a certain consolidation, as follows:

$$Q = K \frac{H}{0.25\,b} A\,t \qquad \text{(4)}$$

FIG. 14.—DETAILS AND SECTIONS OF OBSERVATION WELL

in which Q = the rate of discharge, in cubic feet per day; K = permeability coefficient of the core material at the given location; H = head of water from the surface of the pool to the elevation considered, in feet; b = breadth, or width, of the core at the given elevation, in feet; A = area, in square feet; and t = time required to drain the necessary water to secure a given consolidation, in days. The core material is not of uniform permeability, but as it is deposited in horizontal layers, the changes in permeable characteristics are horizontal, and a strip the entire width of the core would tend to have nearly the same permeability although different from the adjacent strip above or below.

If A = a unit area of 1 sq ft, Equation (4) becomes,

$$Q = \frac{4\,K\,H\,t}{b} \qquad (5)$$

Although it is known to be a mathematical approximation, Equation (5) is believed to be sufficiently correct in making determinations of consolidation during construction because, during that period, the core material has usually not reached a state in which the compressibility of the material affects the consolidation rate to an appreciable degree. Observations made on the core of the Quabbin Dike indicate the practicability of its use (see Fig. 15).

Equation (5) is used as follows:

(1) Estimate the permeability of the core material, for the location considered, for varying degrees of porosity or water content. The data for such estimation are obtainable from permeability tests on core material made by the soil laboratory. A constant value cannot be used, as permeability varies appreciably with porosity.

(2) Assume increments of reduction of porosity as consolidation progresses, and solve for the value of ΔQ corresponding to such reductions (the smaller the increments the more accurate the determination).

(3) Substitute ΔQ for Q in Equation (5) and the proper values of K, H, and b. The time, Δt, required to effect the increment consolidation due to the squeezing out of the water, ΔQ, can then be computed.

(4) Add the values of Δt. The total time required to effect the consolidation between any two given porosities can be obtained for the particular conditions of pool level. As the pool level usually changes during this period, a time-pool-level curve should be plotted and, progressively from that curve, the proper H to be used in each increment determination can be estimated.

(5) The beginning of any period considered should be taken when the material is no longer in complete suspension in the water. This state is represented by a different porosity for coarser than for finer core materials (about 65%, 60%, and 55% for materials containing 30%, 20%, and 10% less than the 0.01 mm size, respectively).

Fig. 15 shows a series of curves of the time of consolidation plotted against porosities for materials of various characteristics found in the core of Quabbin Dike. The curves were computed theoretically by means of Equation (5). The circles indicate observed porosities of samples taken from the core, and the line and arrows indicate the difference between the theoretical and the observed

The differences between the two are minor in the upper parts of the diagram, and the use of Equation (5) should be limited to construction conditions in which the core materials are in a highly saturated state, and in which the degree of consolidation has not progressed far enough to permit great support of the overlying load to be carried by the solids of the core.

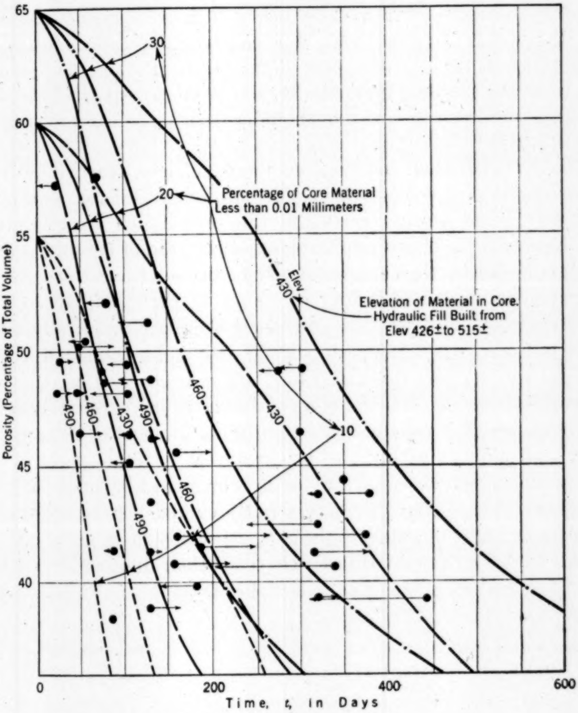

FIG. 15.—CONSOLIDATION DIAGRAM

The load above any volume of core materials is transmitted through it in two ways: Through the water, which is compressed and squeezed out as fast as the permeability of the core will permit; and, after sufficient relief by drainage of such excess water, through the solid particles of the core. The transition from the condition of full load carried by the water to load carried almost entirely by the core solids is usually an extremely gradual one because of the slow drainage of the tight core materials. However, the average construction condition is such that the entire load is not transmitted through the water. This state is one that exists when the solids are suspended in the water and occurs only in the materials in or near the bottom of the pool. This suspended state is quickly relieved by vertical drainage into the pool itself. The core materials are then in a state such that the solids are not suspended, but rest lightly upon each other, receiving some light and partial support through the solids beneath. It is this condition, or a similar one, which exists in the core as long as the pool is maintained full of water for the subsequent construction operations above; and Equation (5) is usable for just such conditions. This is the reason why H is the head of water. The excess weight of the liquid core over that of the water is neglected because of the partial support the solids obtain from each other and from those below in their loose and unstable state.

Thus, the writer believes that this construction consolidation formula (Equation (5)) can be used on other dams for regulating the speed of construction, when the shoulder materials are not as good as at Quabbin; or it may be used in making less conservative shoulder designs, in those instances, than are at present in use.

After the pool is drained and the excess water is slowly carried away, there is a slow transition into an entirely different condition in which support of the load above is largely, if not entirely, carried by the core solids. For this latter state, of course, Equation (5) is not applicable, and the rate of consolidation then is appreciably affected by the compressibility of the solid matter in the core.

However, for a silt or rock-flour core such as that at Quabbin where the percentage of true clay is very low and where there are practically no colloids, the texture of the core is a fine-grained solid one; and a condition in which the core particles will support the entire load above is reached relatively quickly after the pool is drained. Instead of a great number of years before most of the consolidation is secured, tests indicate that probably most of the core is almost completely consolidated within two or three years. Some parts of the core, such as those which have material 30% or 35% finer than 0.01 mm, will probably settle for many years before reaching a fairly compact state approaching the limiting or stable state; but most of the core, especially those parts with material coarser than 20% finer than 0.01 mm, will reach their limiting state much more quickly. Observations made on samples taken from the core indicate that such periods are approximately as follows:

Percentage of core material finer than 0.01 mm	Time required for consolidation to reach its limiting state, in years
10	1 to 2
15	1.5 to 3
20	3 to 5

In each case t is measured from the time the pool is first drained of water. Comparisons made with the consolidation formula[14] introduced by Glennon Gilboy, Assoc. M. Am. Soc. C. E., indicate that much longer periods would be expected but the result of tests of the core materials of Quabbin Dike leads the writer to believe that the rate of consolidation of solid-grained core materials of specific gravity of 2.6 to 2.7 similar to those in Quabbin Dike will be much more rapid than Professor Gilboy's formula indicates.

The consistency of core materials in a hydraulic fill when a fairly stable state of consolidation is reached, has been the subject of much discussion. Observations made to date (1937) on the core indicate that, for material of a size 25% finer than 0.01 mm, or coarser, the stable state will be at least that of a stiff putty. Even the finer portions will be in a putty-like state, but softer; and there will be no such condition as a permanent liquid or semi-liquid core condition.

[14] "Mechanics of Hydraulic Fill Dams," by Glennon Gilboy, Assoc. M. Am. Soc. C. E., *Journal*, Boston Soc. of Civ. Engrs., July, 1934, p. 187.

The impression that the lower parts of the core consolidate more quickly, due to the pressures from above, is not entirely true, because the width of the core is narrower near the top and consolidation occurs quickly at low pressures because the excess water can soon reach the permeable shoulders. Observa-

tions to determine the porosities of core samples indicate that after the pool has been drained, the rate of consolidation is fairly uniform throughout the core and that the pressure due to the depth does not then cause faster consolidation in the lower sections probably because, with the greater width, a relatively longer time is required to carry away the excess water even if it is under a greater pressure.

The qualities of the hydraulic fill obtained from the borrow-pit materials indicated in Fig. 13 are summarized in diagrammatic form in Figs. 16 (with Table 5), 17, and 18. Fig. 16 with Table 5 shows also a comparison of the core material of Quabbin Dike with those of other similar structures. More than 8 000 samples (4 500 from the core and 3 500 from the beach) were analyzed for grain size in the Soil Laboratory and Fig. 19 gives the average percentage of these samples finer than the 100-mesh sieve (0.149 mm), the 200-mesh sieve (0.074 mm) and the 0.01-mm size for various locations in the core and shoulders of the dike.

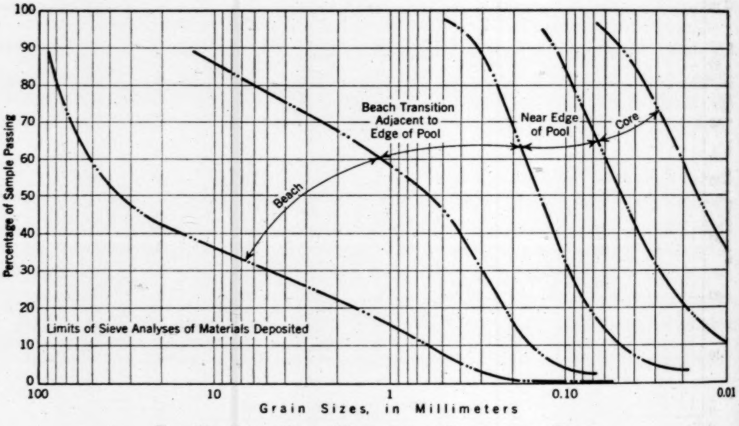

FIG. 17.—GRAIN SIZES; MATERIALS IN BEACHES AND CORE

SEEPAGE ESTIMATES

The quantities of water that will seep through the earth core of Quabbin Dike will be extremely small, but estimates were made to determine reasonable requirements for water-tightness of the core materials and reasonable dimensions to which to build the core, the qualities of the available borrow materials considered. The flow net method[15] was used in these estimates. It consists of establishing the location of the seepage flow lines, from them determining the equipotential loss-of-head lines, and computing the seepage from the latter in terms of the assumed permeabilities of the core and beach materials. The result is expressed in terms of *K*, the coefficient of permeability of the core materials; and by substituting the values of *K* that are considered as reasonable in the result, seepages for different qualities of cores can be secured. The locations of the flow lines were made mathematically by "cut and try" methods, and were checked experimentally by use of a laboratory model similar in some general respects to that described in 1934 by Hibbert M. Hill, Assoc. M. Am. Soc. C. E.[16]

FIG. 18.—PROPERTIES OF MATERIALS IN BEACHES AND CORE

This model was a small water-tight wooden tank with a heavy plate-glass front (see Figs. 20 and 21). As the beach materials are many times as permeable as the core, the slope of the flow lines up stream and down stream from the core are exceedingly flat; and a satisfactory check on the location of the flow lines can be obtained by finding their position in and through the core itself. For this reason the sections tested were those of the core only. Several sections of core were considered, and their patterns were cut from aluminum plates about 0.1 in. thick.

When tested, the plate was set next to the glass front, and held at a uniformly short distance from it by metal shims. It was then backed up by a wooden, water-tight bulkhead which divided the tank into two parts. Water to the equivalent reservoir level was maintained in one-half the tank and to the equivalent tail-water level in the other half.

The first tests showed that laminar or stream-line flow was obtained throughout when the spacing between the glass front and the core plate was 0.006 in., or less, although a spacing of 0.012 in. could be used with only a small amount of turbulent flow occurring near the caisson cut-off. For greater spacing the area of turbulence increased in size. As the seepage of water through soil is laminar or stream-line flow, the spacing during testing was limited to less than 0.006 in.

---

[16] *Civil Engineering*, January, 1934, p. 32.

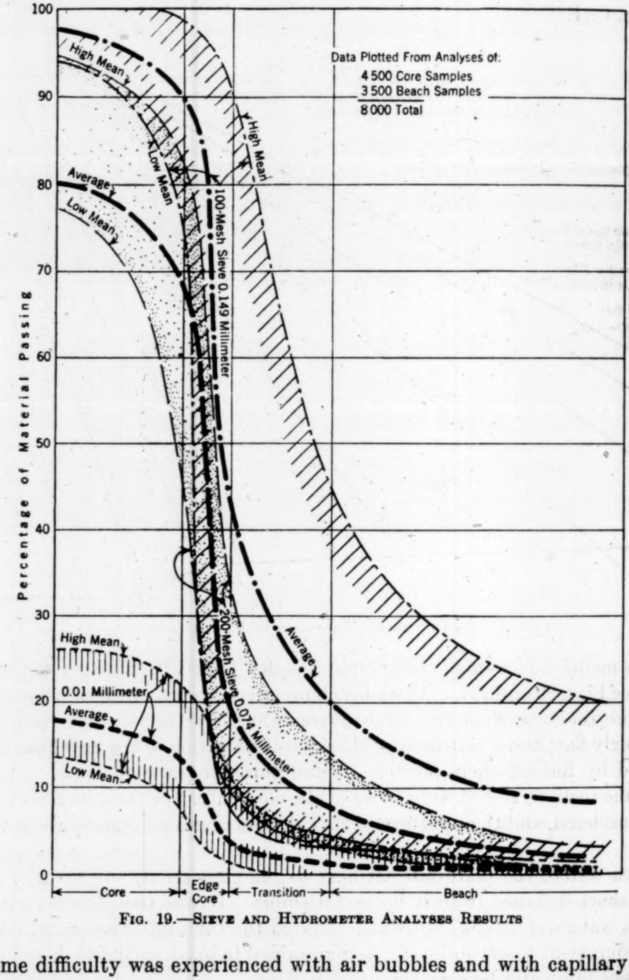

FIG. 19.—SIEVE AND HYDROMETER ANALYSES RESULTS

Some difficulty was experienced with air bubbles and with capillary action near the top of the core section. The former was controlled, to some extent, by running the water until the temperature of the tank was the same as that of the water. The latter was eliminated by use of a metal shim, shaped experimentally to reduce the effect of capillarity on the flow lines without depressing or otherwise unduly affecting their location. This shim was placed between the plates at the top of the core near the water level and prevented any water from being raised into the space between the plate and the glass above the upper normal laminar flow line, which was determined experimentally.

As Figs. 20 and 21 indicate, a dye was introduced into the water through small openings just up stream from the core plate. This dye would travel slowly across the core plate along the seepage lines, and the locations of these lines could thus be photographed. They checked with the mathematically determined locations in an extremely accurate manner. Turbulent flow was easily ascertained by observing the action of the dye in traveling across the plate.

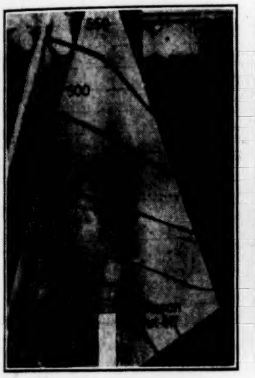

FIG. 20

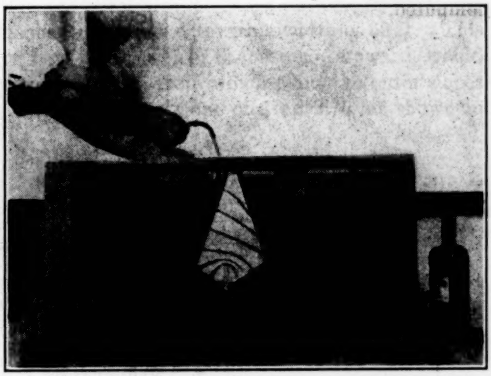

FIG. 21

The core section finally chosen was 100 ft wide at an elevation of 120 ft below the full reservoir level, with side slopes of approximately 3 on 1. Increasing this width of 100 ft to 120 ft would have reduced the seepage only about 7%, decreasing it to 60 ft would have increased the seepage about 33 per cent. Because of the very small seepages considered, the width chosen was determined principally by the more important factor, the probable minimum yield of suitable core material from the available borrow materials.

STABILITY DURING CONSTRUCTION

Estimates of stability of the Quabbin Dike were made for many assumptions of conditions. These estimates led to the development of a nomographic chart (see Fig. 22) for solving in a short time the rather cumbersome Gilboy formula:[14]

$$\sqrt{r_w} = \frac{(C_s - A_c)\sqrt{1 + B^2} + \sqrt{C_s - A_c}\sqrt{C_s - B}\sqrt{1 + A_c^2}}{(1 + C_s^2) - (C_s - A_c)(C - B)} \quad \ldots\ldots(6)$$

in which r_w = the ratio of the unit weight of core material to the unit weight of the shoulder material; A_c = co-tangent of the angle of the core slope with the horizontal; B = co-tangent of the angle of internal friction of the shoulder material; and C_s = co-tangent of the angle of the outer slope, with the horizontal.

If the dimensions of the core and beach sections and the unit weight of the core and shoulder materials are known or assumed, the internal friction or shear value necessary for stability can be estimated quickly from the chart; or, if the qualities of the shoulder and core materials are assumed, the outer slopes of the dam required for cores of assumed or required dimensions can be computed.

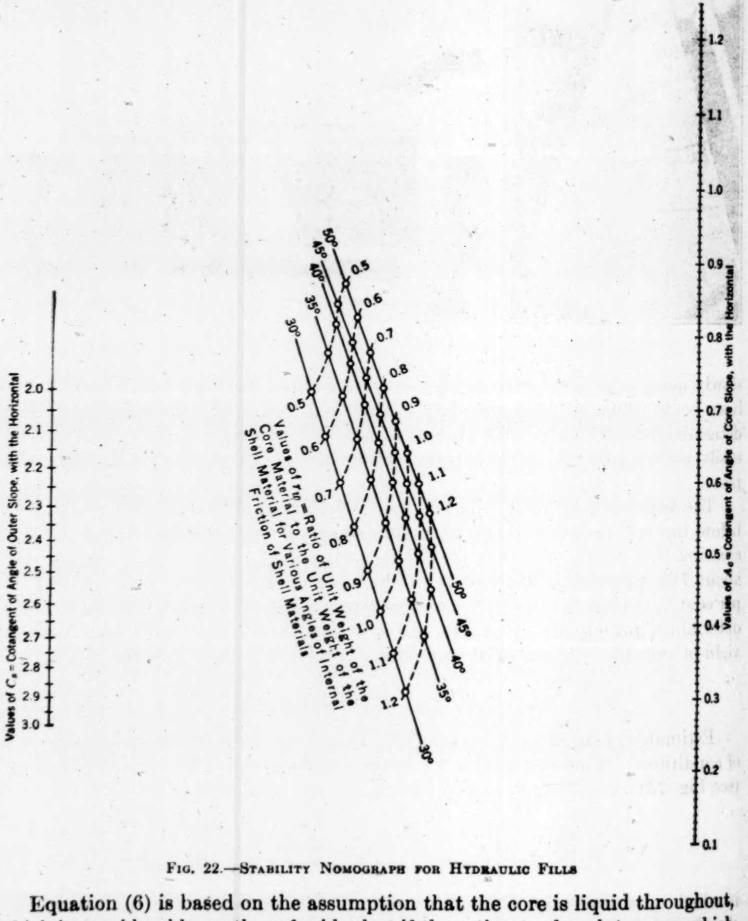

FIG. 22.—STABILITY NOMOGRAPH FOR HYDRAULIC FILLS

Equation (6) is based on the assumption that the core is liquid throughout, which is considerably on the safe side; but if the estimator has data upon which to base an assumption that only some fraction of the full liquid pressure is being developed for the conditions in mind, Fig. 22 can still be used by multiplying the ratio, r_w, directly by the percentage of the full liquid pressure that is existent, and using the corrected value of r_w in the graphical solution.

It will be noted that A_c and C_s are the usual slope constants, representing the ratio of horizontal run to vertical rise. Thus, an outer slope of 1 on 2.5 corresponds to a value of C_s equal to 2.5. Values of C_s are indicated on the scale on the left side of Fig. 22; values of A_c are on the scale of the right side.

The procedure for using Fig. 22 is as follows: Assume that the width of core at Elevation 410 was 100 ft and that the hydraulic-filling has progressed to the point at which the core has reached Elevation 450 with a width of 69 ft. This corresponds to a core slope of 1 on 0.387, which, if continued upward, would intersect the center line at Elevation 540.5, from which point the outer slopes are closely approximated by a line having a slope of 1 on 2.76, as shown in Fig. 23.

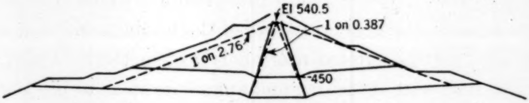

Fig. 23

Assume that the ratio of unit weight of core to unit weight of shell is 1.1 and that the angle of internal friction of the shoulder material is 45 degrees. It is desired to determine whether the section is stable.

A straight-edge is placed on 2.76 on the scale at the left and on 1.1 on the 45° line in the center of Fig. 22. This intersects the right-hand scale at 0.7 and indicates that for the conditions assumed the section is stable, since the values of A_c in the right-hand scale are maximum values for stability. Conversely, the values for C_s at the left are minimum values.

The beach materials at Quabbin Dike in the outer portions of the shoulders weigh as much as 135 lb per cu ft and average probably about 120 to 125 lb per cu ft. The core materials weighed about 100 lb per cu ft when first deposited and from 110 to 125 lb per cu ft when the dam was completed. For stability based on the assumption of full liquid pressure from the core, an internal friction angle of less than 30° in the shoulder materials was required. These shoulder materials had a tested friction angle of more than 45 degrees.

Acknowledgments

The writer wishes to acknowledge the aid of many members of the Engineering Department of the Metropolitan District Water Supply Commission, of which Frank E. Winsor, M. Am. Soc. C. E., is Chief Engineer, and Karl R. Kennison, M. Am. Soc. C. E., is Assistant Chief Engineer, in the preparation of data used in connection with this paper. He is particularly indebted to Clarence R. Day, Assoc. M. Am. Soc. C. E., in connection with work on the seepage model, Coleman C. McCully, Assoc. M. Am. Soc. C. E., in connection with work on the stability diagram, and Jerome L. Spurr, Assoc. M. Am. Soc. C. E., in connection with soil laboratory sampling and testing of materials.

STABILITY OF EMBANKMENT FOUNDATIONS

By B. K. Hough, Jr.,[17] Jun. Am. Soc. C. E.

Synopsis

The analyses made in connection with the design of two large rock-fill embankments proposed as part of the now discontinued Passamaquoddy Tidal Power Project, included certain unusual studies of stress distribution in clay foundations and the character of embankment settlement resulting from foundation over-stress. The report of these studies, which is presented herein, is intended to describe the general nature of the findings and to draw attention to a possible need for the extension of analytical methods (which, at present, are chiefly concerned with designing embankments so as to prevent over-stress of the clay type of foundations) to new methods in which a condition of over-stress is accepted for economic reasons, and the extent of the resulting embankment settlement is computed as the basis for cost estimates.

Introduction

In the field of Soil Mechanics, which itself is a new and specialized branch of Civil Engineering, a certain degree of internal specialization already seems to be in progress. One of the most recent manifestations of this process is the rapid growth of a group the members of which are chiefly concerned with the problems involved in the construction of large earth or rock-fill embankments.

One general and obvious requirement confronting an engineer in designing an embankment is that, after completion, the proposed embankment shall be stable. This involves, first, a determination of the physical characteristics (notably shearing strength) of the foundation and embankment material; then, a calculation of the stresses created within the embankment and extending from the embankment down into the foundations; and, finally, a judicious comparison of strength with stress in the light of past experience and a full realization of the limitations of the analytical methods and the test data which he had used.

Both experience and theory now seem to indicate that analyses for stability vary widely in character and complexity with the type of material encountered in the underground, and the nature (that is, both the material and the design) of the embankment. The soil over-burden at a dam site is generally either predominantly cohesive or cohesionless, and most embankments, with particular reference to their so-called impervious cores, may be classified in the same manner. The four possible combinations of conditions resulting from such classification represent four fairly distinct types of problems, each of which requires a certain degree of special treatment. Additional complications are introduced by the various methods of building embankments, such as rolled or hydraulic fill, and if rolled, whether compacted to a high or low relative density. The scope of this paper is limited to a discussion of certain studies which have relation to a definitely cohesionless uncompacted embankment founded on a relatively uniform, cohesive foundation. Methods of laboratory testing, model studies, and analysis of data performed in the U. S. Engineers Soils Laboratory for the Passamaquoddy Project are described, since it is believed that certain experiments performed there may point to a new conception of the action of embankment foundations. The work done at Eastport, Me., on this problem was predominantly of a qualitative nature, and it is hoped that the findings as reported herein will stimulate further and more detailed studies.

FOUNDATION EXPLORATION

In leading up to the subject of this paper, the following description of the drilling operations in the foundations is given as a matter of general interest. In Eastport, the problem of foundation investigation for the two largest dams presented unusual difficulty. Known, respectively, as the Eastport and Lubec Dams, these structures were intended to close two channels or passages between the ocean and the waters of Cobscook Bay, the high level pool of the proposed power development. The unusual difficulty lay in the fact that each of these channels was approximately 3 500 ft wide, that in each channel the tidal range had a magnitude of about 26 ft, and that the resulting flow of water occurred with a velocity sometimes as great as 6 ft per sec. The soil over-burden to be explored lay at the bottom of these channels under depths of water as great as 100 ft, and from a somewhat limited investigation previously conducted, was believed to be predominantly a deposit of soft marine clay. In the exploration described herein, one drill hole was actually driven to Elevation −274.5 before rock was encountered.

Drilling for exploratory purposes, and to obtain undisturbed soil samples suitable in size and character for compression and shear tests, was conducted from two large derrick-boats, one operating in each channel. To protect the 6-in. drill casing from the force of the tidal currents and to provide a stable support for the drill platform, an extra heavy 21.5-in. casing or spud was first erected in sections over the sides of these boats. All guys to the top of the spud and all anchor lines to the boats were led to hand winches, constantly attended so that the spud could be kept vertical and the position of the boat maintained at all times, despite the rise and fall of the floating plant with the tide. The bottom of the spud was allowed to penetrate the over-burden sufficiently to give it lateral stability, while the weight of the spud and drilling equipment was carried by a large, circular plate clamped to the spud a short distance above its lower end so that it had bearing against the surface of the over-burden. After erection of the spud, the drill rig was mounted on the platform provided at the top and drilling was conducted in normal fashion in a 6-in. casing inside. A general view of the barge in actual operation in the Eastport Channel is shown in Fig. 24. In this work the importance of obtaining undisturbed soil samples for accurate foundation studies was realized and close inspection of the condition of all samples was made in the laboratory. Some comment is made subsequently on the effect of disturbance of samples, as indicated by the test data obtained in the Eastport Laboratory.

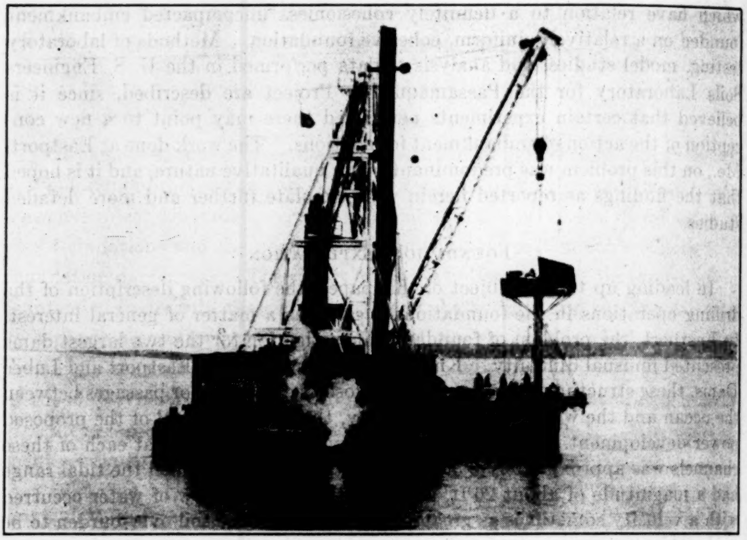

Fig. 24.—Deep-Water Drilling, Passamaquoddy Tidal Power Project; 160-Foot Speed in 120 Feet of Water

Laboratory Testing

Routine soil testing on this project was performed by methods which in general character are similar to those in use in the Soil Mechanics Laboratory of the Massachusetts Institute of Technology, Cambridge, Mass. The equipment used for performing the shear and consolidation tests was the same in principle

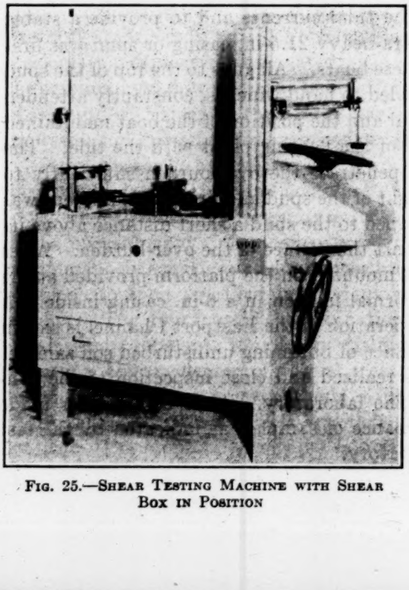

Fig. 25.—Shear Testing Machine with Shear Box in Position

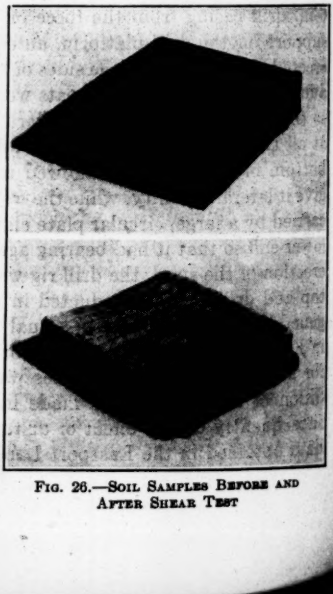

Fig. 26.—Soil Samples Before and After Shear Test

as that designed by Glennon Gilboy, Assoc. M. Am. Soc. C. E., for the U. S. Engineer Laboratory, in Zanesville, Ohio.[18] The shear machine, shown in Fig. 25, is operated in such a manner that the rate of horizontal strain of the sample during the test is constant. The particular rate chosen for standard tests on clay samples of the type shown in Fig. 26 was that which was found to give the most conservative value of shearing strength for the type of material tested. A rate of strain commonly used was 0.05 in. per min. In testing cohesive samples, a relatively light vertical load was used, in general equal to about one-fourth the horizontal pull. No effort was made to determine an apparent angle of internal friction for clay samples and no increase in natural shearing strength was allowed as a result of possible consolidation during the construction of the embankments. The shear tests were run simply to determine the natural shearing strength of the deposit of cohesive material at the site of the proposed structures.

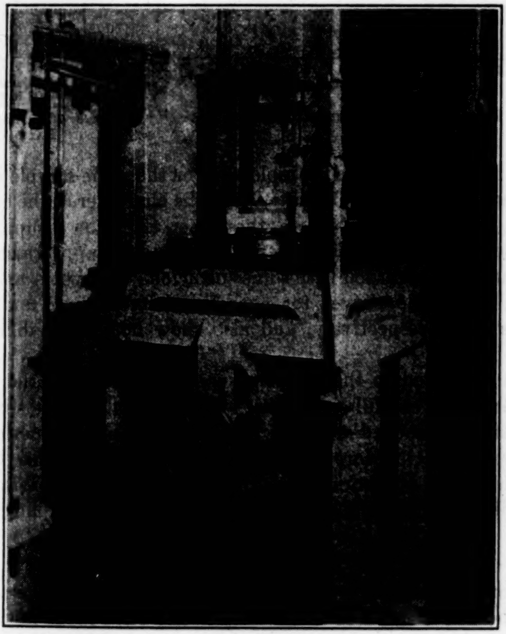

FIG. 27.—VIEW OF CONSOLIDATION MACHINE

At this point it seems advisable to acknowledge the fact that most of the statements made in the foregoing paragraph touch on highly controversial subjects. In making these statements, it is hoped rather than feared, that they will provoke discussion and constructive criticism. Consolidation tests were performed with the equipment shown in Fig. 27, and the method used for plotting test data was that developed[19] by Donald W. Taylor, Assoc. M. Am. Soc. C. E.

---

[18] *Engineering News-Record*, May 21, 1936.

EFFECT OF SAMPLE DISTURBANCE

Correlation of the data from shear and consolidation tests was found to give an indication of the degree of disturbance suffered by individual samples during the drilling operations. Fig. 28 shows stress-strain curves, *A* and *B*, respectively, for an undisturbed sample and for the same sample retested after complete remoulding. It will be noted that the character of the curves is quite different. It was decided, therefore, that when a test on a supposedly undisturbed sample yielded data which when plotted had the appearance of Curve *B*, the sample should be regarded with some suspicion. Curves *A* and *B* in Fig. 29 are pressure, void-ratio curves for consolidation tests on undisturbed and remoulded samples, respectively, and also show noticeably different characteristics.

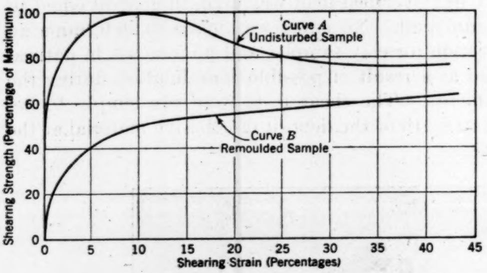

FIG. 28.—STRESS STRAIN SHEAR CURVES

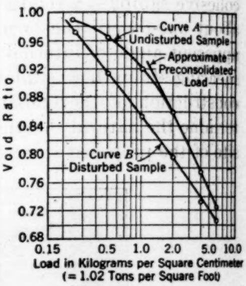

FIG. 29.—PRESSURE, VOID-RATIO CURVES

Attention is invited to the foregoing considerations and the suggestion is made that through a careful examination of test data in some similar manner, a judgment may be reached as to the value of the sampling methods in use on any particular project. More attention in the future than has been given in the past to this detail of laboratory testing is believed to be advisable and may lead eventually to the development of more dependable sampling technique.

SUMMARY OF TEST DATA

Correlation of drilling and testing records made possible the preparation of the profiles shown in Figs. 30 and 31. The information given in these diagrams may be amplified by the statement that, in general, the shearing strength of the clay in the Eastport Channel tends to increase with depth, whereas the reverse condition exists in the Lubec Channel. The average values in both cases range between 0.1 and 0.2 ton per sq ft, although in the Eastport Channel lower values predominate and in the Lubec Channel a few values as high as 1.0 ton per sq ft were found. The average water content for samples from both channels is about 30% of the weight of solids. The general variation of water content with depth was found to be in agreement with the variation of shearing strength, since in the Eastport Channel it decreases with depth and in the Lubec Channel it increases. A mechanical analysis of the material from both channels showed that it had a colloidal content of about 20% and about equal percentages of clay and silt. Its specific gravity is approximately 2.75.

step, to seal the dams with a relatively impervious soil blanket placed on the "up-stream" face. It should now be evident that the previous reference to a definitely cohesionless embankment is justifiable in connection with these structures. Nearly all the material in these dams would be placed in flowing water and no rolling or compacting by artificial means was contemplated. In all probability, the finest sizes included in the lower part of the completed rock-fill would be classified as coarse sand, whereas, in the section above Elevation − 30, the use of 20-ton stone was proposed. The first consideration in the required analysis, therefore, was the degree of stability of the foundation material under the load of this cohesionless rock-fill section alone.

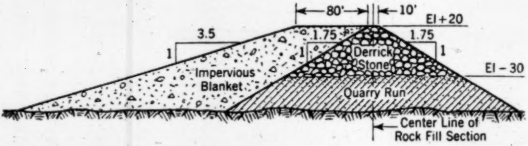

FIG. 32.—ORIGINAL TYPICAL SECTION OF EASTPORT AND LUBEC DAMS

PRELIMINARY ANALYSIS

In the first analysis made, the methods developed by Leo Jurgenson[20] were utilized to obtain an approximate solution. This resulted in showing that the proposed rock-fill structures, although partly submerged, were of such proportions as to create shearing stresses greatly in excess of the shearing strength of the foundation material. Comment on the applicability of Jurgenson's method to this particular problem is deferred to the latter part of this paper. Considerable importance, however, was attached to the preliminary finding that in order to achieve stability of the proposed rock-fill, the base width would have to be increased from five to ten times. The additional quantity of fill material required for this alternate design was found to be so considerable that the possibility presented itself of effecting an economy by building the embankment with the relatively steep slopes originally planned and letting failure and displacement of the underground take place, even if eventual settlement to rock resulted. This precipitated a discussion as to the extent and character of the settlement which might reasonably be expected, assuming that as indicated, the clay foundation material would actually be over-stressed before the embankment reached final grade.

In contemporaneous foundation problems, the writer believes this situation to be rather unique. Many embankments and highway fills have failed due to unexpected lateral displacement of a soft, underlying stratum, but few, if any, of these structures had been investigated and designed by the principles of soil mechanics. In such cases as have received treatment by these methods, the objective of the analytical work has been to attain an actual factor of safety against over-stress by flattening side slopes to a degree which would reduce the induced shearing stresses to a value less than the strength of the weakest part of the foundation. A definite lack of precedent was found, therefore, on procedure for an embankment analysis in which failure and at least partial displacement of the underground was actually contemplated, although as an exception to this statement the special case of settling highway fills by dynamiting soft underlying material may be cited.

---

[20] "The Shearing Resistance of Soils," by Leo Jurgenson, *Journal*, Boston Soc. of Civ. Engrs., Vol. XXI, No. 3, July 1934, p. 242.

MODEL STUDIES

The available information was so limited as to the type or extent of settlement to be expected, that some experimentation was considered necessary as a preliminary to deciding on a method of attacking the problem. Already set up in the laboratory was a simple polariscope (shown diagrammatically in Fig. 33) which had been used previously to study the distribution of shearing stresses in gelatin models by photo-elastic methods. By using a weak pour of gelatin and gradually increasing the height of the model dam over that previously used, the gelatin was finally made to fail under the load, a procedure quite different from that followed in ordinary work with this model, when failure of the gelatin was studiously avoided. Settlement of the model embankment resulted, of the type shown in Fig. 34. This view was photographed through the analyzer and besides showing the shape and outline of the embankment section after failure, it also shows a number of stress bands in the gelatin beyond the toes, where evidently the gelatin was not overstressed. Interesting though this last point may be to some, the particular object of introducing Fig. 34 is to show the character of deformation that occurred under the embankment. It is quite clear that, in this case, settlement was not maximum under the center line, although numerous predictions to this effect had been made, but rather it is apparent that maximum settlement occurred at points on either side of the center line, about half-way out toward the toes. This experiment was repeated

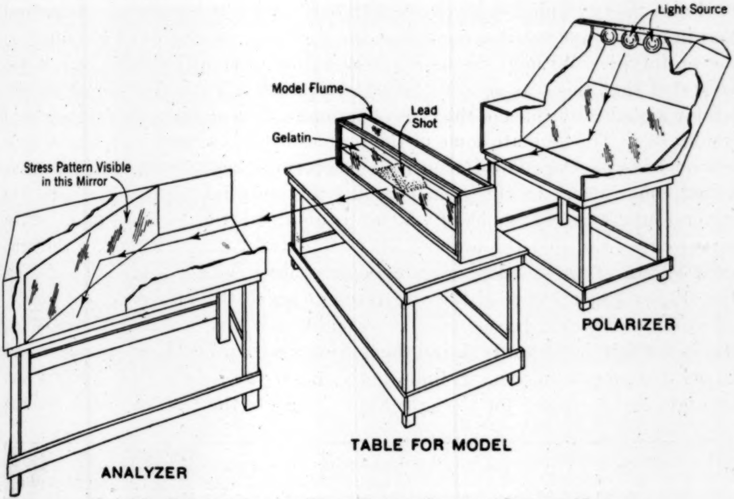

FIG. 33.—POLARIMETER FOR PHOTO-ELASTIC STUDY OF GELATIN MODEL

a number of times under a fairly wide range of controlling conditions until it was established as being typical. From this work, the type of settlement obtained was termed "heart shaped", due to its resemblance to the lower part of an inverted heart.

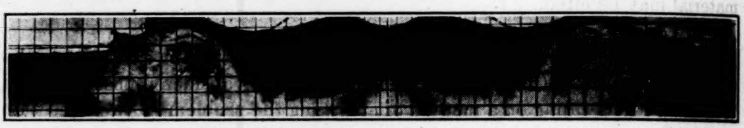

FIG. 34.—SETTLEMENT OF MODEL EMBANKMENT

From the beginning of the work with this model, it was clearly understood that in many ways it failed to achieve the necessary similitude to conditions in the prototype. Without discussing in detail its obvious shortcomings, it will be stated that this was simply the first and easiest method available for obtaining a qualitative idea of the type of action to be expected under the assumed conditions. To eliminate some of the sources of dissatisfaction, a second type of model was developed for the purpose of securing a closer approximation of the actual conditions. In this second model the material used to represent the underground was clay, much of which was obtained from samples taken at the actual dam sites, and the proportions of the model were changed so that the axial length of the section of dam being studied was considerably greater. Fig. 35 is a general view of the apparatus in which this study was conducted. The preliminary test procedure was to build up a bed of uniform, remoulded clay in the rather shallow tank and then, using irregular lead slugs, to construct a model dam across the center, following as nearly as possible the construction program contemplated for the prototype. During the test, movement of the

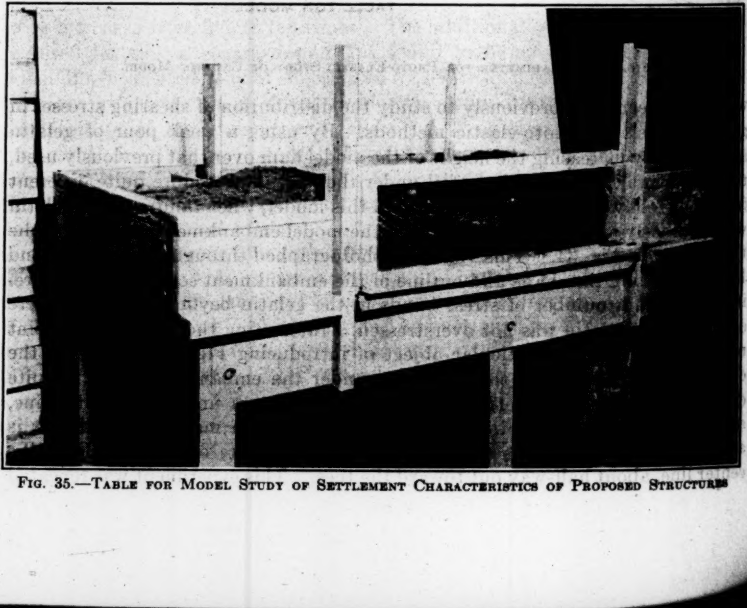

FIG. 35.—TABLE FOR MODEL STUDY OF SETTLEMENT CHARACTERISTICS OF PROPOSED STRUCTURES

clay under the embankment load could be watched through a window in one side of the tank.

To facilitate this observation, small white reference points were inserted between the clay and the window at the intersections of a grid system, prior to loading. Successive positions of each point were marked on the glass so that at the end of each test their individual paths were determined. At the center of the model, in a section perpendicular to the axis of the dam, a series of vertical reference lines was inserted. The deformation of these lines could not be observed during the test, of course, but were exposed afterward by removing the embankment and cutting the model along the mid-section, a view of such a section being shown in Fig. 36. The originally vertical reference lines may be seen clearly, and the profile of the clay is shown to have assumed the previously mentioned "heart shape". Also, plainly visible, are the so-called "mud wave" formations on either side of the embankment.

This confirmation of the results previously obtained, although still of a qualitative nature, was very encouraging. In this connection, attention is invited to the experience of A. Casagrande, Assoc. M. Am. Soc. C. E.[21] and Professor Gilboy,[22] who noted a similar type of failure under embankments on soft foundation material. Sufficient confidence in the accuracy of the general character of this work was gained from this accumulation of evidence to proceed with the development of a quantitative method of analysis for use in solving the particular problem previously outlined.

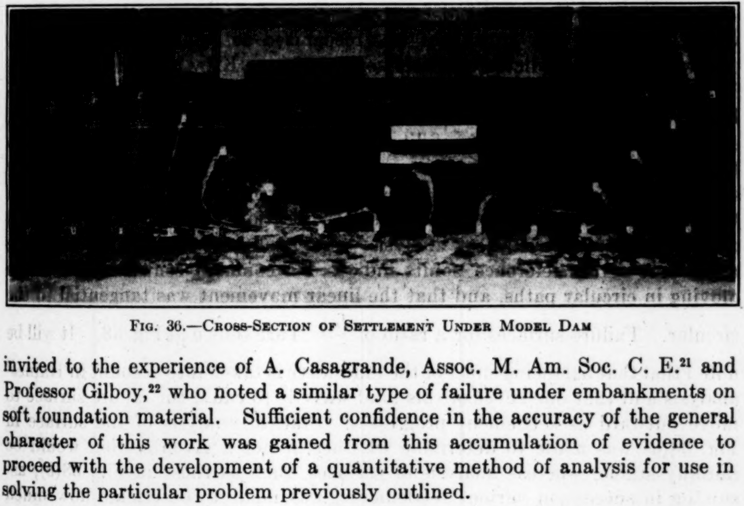

FIG. 36.—CROSS-SECTION OF SETTLEMENT UNDER MODEL DAM

HAINES METHOD

Continued experimentation with the clay model and careful observation of its action during test, led to the development of a method of stress analysis before failure, and a method of determining the extent of settlement after failure, of proposed embankments. The details of this analytical method were developed by R. M. Haines, Jun. Am. Soc. C. E.

---

[21] "The Shearing Resistance of Soils", by Leo Jurgenson, *Journal*, Boston Soc. of Civ. Engrs., Vol. XXI, No. 3, July, 1934; Discussion by A. Casagrande, p. 976.

[22] "Stability of Embankment Foundations", by Glennon Gilboy, Assoc. M. Am. Soc. C. E., *Transactions*, Third World Power Conference, Washington, D. C., 1936.

A characteristic set of records for the clay-model testing is shown in Fig. 37. Inspection of this diagram led to the conclusion that movement of the reference points was largely circular under the dam and became linear under the mud waves. This type of movement was recognized as being similar in general character to that predicted by Professor Dr. H. von Krey, of Berlin, Germany, for the movement of plastic material under long footings. Development of the Haines method proceeded from this observation to the task of making an analysis of the conditions of equilibrium along a failure surface also similar to that defined by Krey, but in this case located by trial and error in a manner somewhat resembling the work of K. E. Petterson, member of the Swedish Geo-Technical Commission in 1914–1922. Location of the failure surface and development of the statical analysis were facilitated by finding that the movement of the reference points indicated a common center for all points moving in circular paths, and that the linear movement was tangential to the circular. Failure surfaces for a ratio of $\frac{L}{a} = 4$ are shown in Fig. 38. It will be noted that that balancing effect of the mud wave is taken into account in Haines' analysis and that one effect of this mud wave is to cause the failure surface to move outward as settlement progresses. Statical analysis of the surface in Fig. 38(*a*) was made to determine whether or not a given section would be initially stable, whereas analysis of surfaces, such as those in Fig. 38(*b*), assuming in succession various settlements, was made to determine how much settlement could be expected when initial stability was not indicated. (In Fig. 38(*b*), Line *BEO* is the shear plane for 50% settlement; Line *AEO* is the shear plane for 75% settlement; Line *BDF* is the mud wave for 50% settlement; and, Line *ACF* is the mud wave for 75% settlement.) The same kind of study was also made for trapezoidal embankment sections in order to make possible analysis of various construction stages.

FIG. 37.—MODEL STUDIES OF SETTLEMENT AND SHEAR FAILURE CHARACTERISTICS

The types of analysis indicated in Fig. 38 were planned on the assumption that the half section of embankment tended to rotate about the center of the circular sliding surface and thereby caused a rotational movement of the foundation material included within this surface and an upward movement involving passive pressure of the material along the straight part of the failure surface. By equating the moments of the forces tending to cause motion with those tending to resist it, an expression was obtained relating the intensity of loading at the center line of the embankment with the cohesion or inherent shearing strength required for a factor of safety of unity. This expression can be simplified to the form,

(b) EXTENT OF SETTLEMENT

FIG. 38.—SURFACES INVESTIGATED FOR EXTENT OF SETTLEMENT

$$p = K\, s_c \qquad (7)$$

in which K is a variable with values as shown in Fig. 39.

For the case in which initial stability is not indicated and it is desired to compute the probable amount of settlement of the embankment into the foundation material, the following formula, was derived:

$$p = K\, s_c + K_i\, a\, w \qquad (8)$$

Fig. 40 is a set of curves for the solution of Equation (8) for the assumption of 50% and 75% settlement. It will be noted that solutions for various stages of construction are indicated from 25% of the final height of the embankment to the full height or the triangular section.

Solution of settlement problems by the Haines method as indicated by Figs. 39 and 40 involves a process of trial and error. If initial stability is not indicated, a solution is obtained for stability at 50% settlement. If this does not indicate stability, 75% settlement is assumed, and if stability is still not indicated, the assumption is made that the material will settle to rock.

No greater refinement is warranted by the assumptions involved in developing this method. One consideration, for example, is the extent to which the shearing strength of the foundation decreases as failure occurs. It is possible that additional investigation, however, may eventually modify the approximate nature of this method.

Discussion of Analytical Methods

In the foregoing remarks reference has been made to three different methods of analyzing the degree of stability of earth or rock-fill embankments, namely, Jurgenson's method, the gelatin model-photo-elastic method, and the Haines' method. The experimental work described herein as the basis for development of the Haines method was performed under conditions similar to those assumed by Jurgenson for his so-called "rigid boundary" case, for which he proposed the formula,

$$s = \frac{p\,a}{L} \qquad \text{(9)}$$

in which s = principal shearing stress; p = intensity of load at the center line of the embankment; a = half the depth of the plastic foundation material; and, L = half the base width of the embankment.

Since the publication of this formula[20] in 1934, Jurgenson has presented other discussions on this subject, but Equation (9) is still in current use to a sufficient extent to warrant the following comment.

It is believed that the clay model indicated the limit to which some of Mr. Jurgenson's assumptions are valid. These assumptions include neglect of the restraining effect of the foundation material beyond the toes of the embankment, and the supposition that the surface between embankment and foundation remains plane during loading. It can be seen almost intuitively that variation in the ratio of $\frac{a}{L}$ will vary the extent to which these simplifying assumptions affect the applicability of Equation (9) to embankment analysis. The work with the clay model indicates that, for ratios of $\frac{a}{L} = 0.1$, Jurgenson's method and Haines' method are in substantial agreement as to the magnitude of the shearing stress induced by a given intensity of embankment loading. For higher values of the ratio, however, a considerable divergence between the two methods was noted. It was also observed that when the depth term, a, is small compared with L, the condition of simultaneous shear failure on an infinite number of surfaces in the plastic material is approached more closely than when a is comparatively large. In the latter case, evidence was obtained to indicate that shear failure occurs at a single point and, therefore, in giving the intensity of stress at this point, Jurgenson's formula (Equation (9)) does not indicate the full extent to which the foundation can carry load, due to the redistribution of stress following point failure. As against this so-called "point failure stress", Haines' method is believed to show the total resistance of the underground, or what might be termed the "total failure stress".

The argument just presented applies also in the case of the previously mentioned gelatin model-photo-elastic method. This method, except when

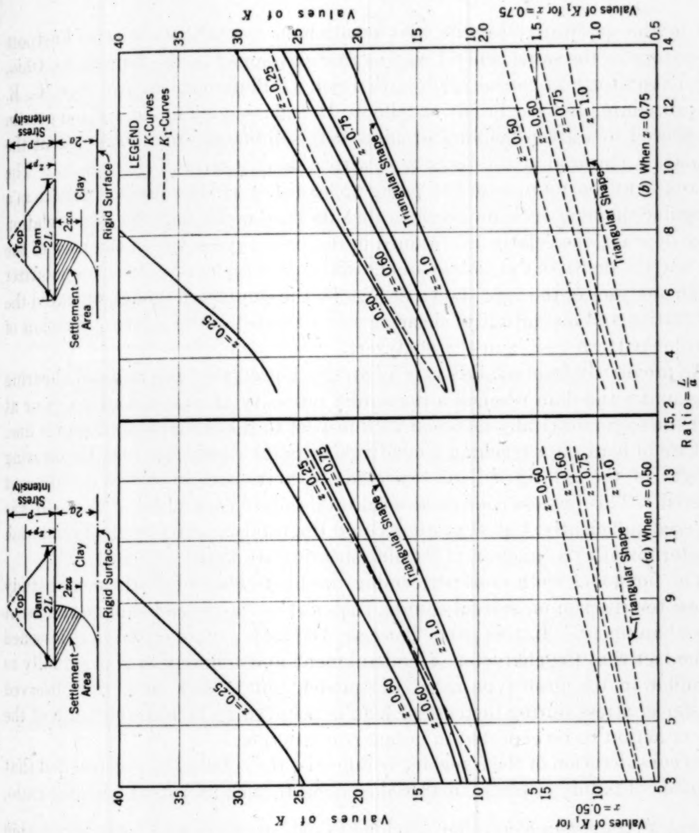

FIG. 40.—CURVE FOR SOLUTION OF SETTLEMENT FORMULA, EQUATION (8)

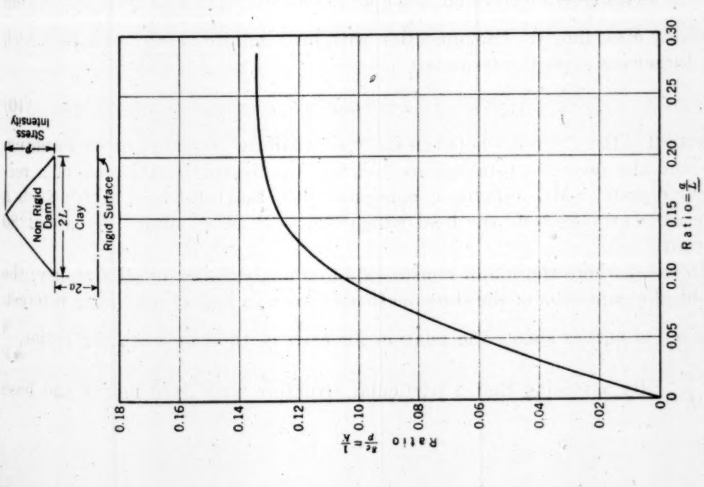

FIG. 39.—CURVE FOR SOLUTION OF INITIAL STABILITY FORMULA, EQUATION (7)

used in the qualitative studies first mentioned, was utilized in the Eastport Laboratory in the same general way as that developed in the Zanesville, Ohio, Soils Laboratory, in consultation with Fred. L. Plummer, M. Am. Soc. C. E. The procedure used was briefly as follows: In a glass-sided flume, melted gelatin was poured to a given height and allowed to solidify in order to represent the foundation material of the prototype with a doubly refracting medium. The embankment was represented by piling up lead shot on the solidified gelatin in a triangular shape of such proportions that its base width had the same relation to the depth of the gelatin as obtained in the prototype between the base of the dam and the depth of the plastic foundation. When placed between a polarizer and an analyzer of the type shown in Fig. 33, the completed model indicated the distribution and magnitude of shearing stress created in the gelatin by means of the color pattern visible in the analyzer.

As previously implied, this type of study showed that the induced shearing stress under the dam reached a maximum intensity at one central point or at two points symmetrically disposed with respect to the embankment center line. Increase of load after reaching a condition of point stress equal to the shearing strength of the gelatin led (as expected) to a transfer of stress to adjacent material. This process continued until total failure took place, if the load was increased sufficiently, but at no time could the total capacity of the foundation be determined as a function of its unit shearing strength.

The foregoing method of performing the photo-elastic-gelatin model study is open to criticism on several counts, such as the use of lead shot to represent the embankment. In this particular case, the force of this criticism is lessened by the fact that the character of embankment and foundation was actually as dissimilar in the prototype as in the model, but in any case, the observed transfer of stress during increase of load is believed to be characteristic of the type of action to be expected in actual construction.

In consideration of the foregoing comments, the conclusion was reached that the mode of failure of plastic material changes to such an extent with the ratio, $\frac{a}{L}$, that a straight-line equation, such as Equation (9), can be used only within relatively close limits. In connection with his "infinite depth" case for which Mr. Jurgenson gives the formula,

$$s = 0.256\,p \qquad (10)$$

the extent of the difference between the "point failure" stress given by Equation (10) and the desired "total failure" stress is indicated by the case of a rectangular plate. Mr. Jurgenson computes that the total load which such a plate can carry exceeds the load which causes "point failure" by about 80 per cent.

In cases where the major consideration is analysis for initial stability, the graphical comparison of the three methods shown in Fig. 41 may be of interest. This set of curves shows the relation for each method between the ratios, $\frac{s}{p}$ and $\frac{a}{L}$. By assuming that a particular structure with fixed height and base width is being considered, this plot gives, directly, the variation of the stress induced by such a structure if built on clay deposits of different depths. Jurgenson's "rigid boundary" case plots as a 45° line, of course, until it intersects his "infinite depth" case at a value of $\frac{a}{L} = 0.256$. From this intersection the curve is a horizontal line. The work with the gelatin model plots as a curve showing a more gradual transition from the "rigid boundary" case to the "infinite depth" case. The curve for Haines' method of analyzing the stability of triangular embankment sections may be seen to follow Jurgenson's "rigid boundary" case quite closely up to the ratio, $\frac{a}{L} = 0.10$. Beyond $\frac{a}{L} = 0.15$, it deviates abruptly, however, and flattens out into what amounts to an "infinite depth" case at a much lower value of $\frac{s}{p}$. Since Haines' method is intended to give the "total failure" stress throughout, this is not surprising, however. If it is admitted that Jurgenson's "infinite depth" case has a factor of safety in the order of magnitude of 1.8, as indicated by the example of the rigid rectangular plate, a correction could be made, as shown by the dotted line. It is very interesting and significant to note how close this line is to that for the Haines method.

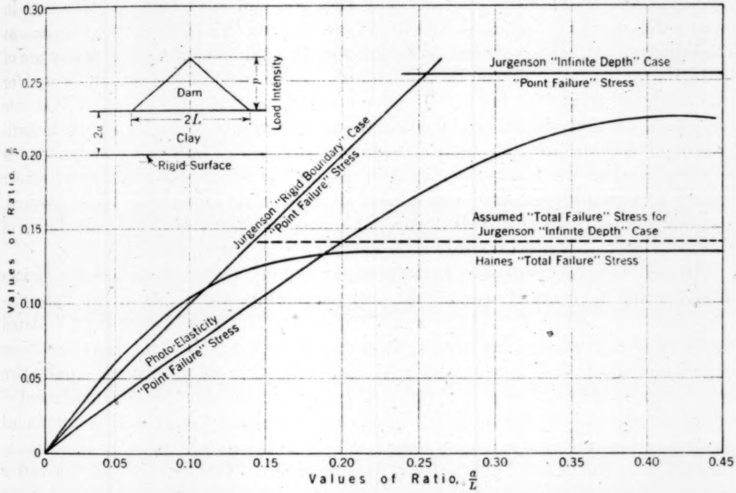

FIG. 41.—LOAD, SHEARING STRESS CURVES FOR TRIANGULAR EMBANKMENTS; $\frac{L}{a} = 4$.

In the field in which Mr. Jurgenson's method and the photo-elastic—gelatin-model method have previously served, it is believed that the Haines method offers the advantage of being more general in the sense that it is not confined to use in cases in which $\frac{a}{L} = 0.1$ and that it is more consistent in the sense that it always gives the "total failure" stress as previously defined.

The particular claim made for the Haines method, however, is that it can be extended beyond the field of usefulness of the other types. It is believed that work similar to that reported herein may attract the attention of engineers to the possibility of effecting economy in earth construction work by allowing artificial fills to sink into relatively soft and shallow foundations, rather than trying to attain stability by flattening the side slopes of such structures. In cases where a real economy is indicated by adopting this plan, as was the case at Passamaquoddy, the methods of Jurgenson and the gelatin-model study are of little, if any, value. The method developed by Haines, however, can be used for just such cases and as far as the writer knows, is the only method available for complete analysis for proposed earth embankments, since by its use investigation of the stability of such structures during all stages of construction is possible, and prediction of the extent of settlement which will occur due to shear failure of the underground may be made if such settlement is to be allowed. Estimate of settlement of this nature, of course, is essential to the calculation of the total cost of structures in which subsidence is anticipated.

It will be observed that in this paper much of the detail of the Haines analysis has been omitted although full particulars are given in the Passamaquoddy Tidal Power Development "Report of Soils Laboratory" dated September 1, 1936. This is due to a realization of the fact that the basic experimentation was performed with the objective of obtaining qualitative results applicable to one rather unusual type of problem. Since curtailment of activity on the Passamaquoddy Project took effect before all the intended studies of this nature were completed, it is considered advisable at this time to present only the general character of this research. It is hoped that this rather non-technical presentation will stimulate discussion and further study leading eventually to a complete and satisfactory solution of the indicated problem.

SUMMARY

In connection with cohesionless, uncompacted earth or rock-fill embankments founded on cohesive soil, model studies indicate that embankment settlement resulting from shear failure and lateral displacement of the foundation material will take the form of the so-called "heart shape". By citing the specific case of the two large dams proposed for the Passamaquoddy Project, attention is invited to the possibility in some instances of effecting economy in embankment design by allowing over-stress of foundations to occur rather than flattening side slopes in an effort to prevent over-stress to such an extent that excess material is required.

The need for development of a comprehensive method of stress and settlement analysis for earth and rock-fill dams is indicated by a discussion of some available methods, and the so-called Haines method is outlined in general terms as a lead to further study and consideration of this subject.

ACKNOWLEDGMENTS

The investigations described herein were pursued as part of the study of the Passamaquoddy Tidal Power Project, under the direction of the Eastport, Me., District of the U. S. Corps of Engineers; Maj. Gen. E. M. Markham, U. S. Army, Chief of Engineers, U. S. Army, M. Am. Soc. C. E.; Lieut. Col. Philip B. Fleming, U. S. Corps of Engineers, was District Engineer, with Captain Hugh J. Casey, U. S. Corps of Engineers, M. Am. Soc. C. E., as Chief of the Engineering Division; John Sweeney, M. Am. Soc. C. E., was in charge of field exploration; and the writer, assisted by R. M. Haines, Jun. Am. Soc. C. E., conducted the Soils Laboratory studies.

SETTLEMENT OF STRUCTURES IN EUROPE AND METHODS OF OBSERVATIONS

By Charles Terzaghi,[23] M. Am. Soc. C. E.

Synopsis

The methods and results of settlement observations on several structures in Europe, selected to illustrate accurately, the behavior of structures on various types of compressible ground, are described in this paper. Particularly, emphasis is given to the observations of settlements of buildings on pile foundations, and the comparison between the settlement of individual piles under load tests with that of the entire pile foundation.

The form of the settlement diagrams with ground conditions and loadings is recommended as a pattern to be followed. The instruments and bench-marks used for settlement observations are described, but other instruments and methods of observation will suggest themselves to engineers. However, such methods should permit the observation of very small settlements as they are valuable in computing future settlements.

The observations are the result of studies extending over a 10-yr period; they were supervised by the writer and supported by contributions made by the Committee of the Society on Earths and Foundations.

Purpose of Investigations

The design of shallow foundations is governed by the condition that the greatest pressure exerted on the soil should not exceed a certain value, called the allowable soil pressure. If the structure is to rest on a pile foundation, the load per pile should not exceed the "safe load." Both types of foundations are subject to settlement. If the loaded stratum consists exclusively of sand or gravel, the settlement ceases within a few weeks or months after construction is finished. In this case the settlement can be expressed by a single set of recorded data or by a contour map showing the lines of equal settlement representing the subsidence of the loaded area after the settlement stopped. On the other hand, if the settlement is due to an increase of the load on a bed of clay, it can be recorded only by time-settlement curves, or by means of a set of contour maps showing the settlement at different times after construction was finished.

At present, there is no method of predicting the settlement of buildings on a sand or gravel foundation and the prospects for discovering such a method are

---

Note.—The Committee of the Society on Earths and Foundations, selected the settlement of structures as one of several for study and research. This paper, reporting an investigation sponsored by the Committee, was submitted to the Committee by its author, and the Committee has recommended its publication as a part of this Symposium.

[23] Dr. Ing.; Prof., Technische Hochschule, Vienna, Austria.

very slight. No method of computing settlement can be accepted unless its validity is demonstrated by numerous settlement records obtained under very different practical conditions and no such collection of records has ever been presented. Current procedures for predicting the settlement of buildings on clay foundations are more promising; and, yet, according to reports,[24] the application of these methods requires elaborate investigations and is limited to important structures. In every other case the engineer must estimate the settlements on the basis of previous experience. Such experience can be acquired only by systematic settlement observations. Considering the present state of knowledge in the field of foundations, the settlement observations represent by far the most important type of research. The results of theoretical and of laboratory investigations in this field cannot claim more than an academic value until the importance of the errors have been investigated thoroughly and repeatedly. Any proposal for the practical application of a new method should include not only a detailed statement of several settlement forecasts, but also the results of adequate settlement observations, including the magnitude, the distribution, and the time rate of the settlement for the full-sized structures.

METHOD OF OBSERVATION

In his earlier attempts to collect settlement data, the writer met with the following difficulties: (*a*) Most of the reference points (which consisted of bolts embedded in the masonry) disappeared during or immediately after construction; (*b*) in buildings with numerous partition walls the measurements within the building were difficult and not sufficiently accurate; and finally (*c*) the number of observation points was not great enough to permit the reliable construction of curves of equal settlement. In order to eliminate these difficulties the writer devised a new type of reference point shown in Fig. 42. It consists of a short piece of pipe, which is entirely embedded in the masonry (Fig. 42(*a*)). Normally, the opening of this pipe is closed by means of a brass plug, the outer surface being flush with the wall. In order to make a settlement observation, the plug is removed and temporarily replaced by a cylindrical piece such as that shown in Fig. 42(*b*). The observations are made not with a level, but by means of the device shown in Fig. 42(*c*) which consists of two glass tubes connected by a rubber hose. The entire system is filled with water, and in each tube the position of the water level is measured by means of the micrometer screw shown in Fig. 42(*d*). The vertical distances, Z_0, in Fig. 42(*c*) are always the same for both tubes, and the distances, Z_1 and Z_2, are measured by means of the micrometer screw. Hence, the difference between the elevation of the two reference points is equal to $\Delta Z = Z_1 - Z_2$. A careful survey of the errors of observation performed by Professor H. Löschner,[25] in Brunn, Austria, has shown that the error does not exceed 0.05 mm, or 0.002 in.

In order to obtain a reliable conception of the distribution of the settlement over the area occupied by the building, at least one reference point should be established for each 200 sq ft of this area. At least, one-third of all the points should be within the building. All the recent settlement data embodied in the following paragraphs were obtained by means of the device shown in Fig. 42.

THE BENCH-MARK

In order to obtain reliable information as to the downward movement of a structure, the levels must be referred to a bench-mark that does not move. Usually, this bench-mark is established on some existing building at a distance of 100 or 200 ft from the structure under observation. If no reliable settlement record is available for this building, at least two bench-marks should be established on buildings, located on different sides of the structure under observation.

Fig. 43 shows the curves of equal settlement of a group of factory buildings for the year 1934. Construction was finished in 1929 and the observations were begun early in 1930. The values that appear within the areas occupied by the buildings represent the extreme limits for the load, in tons per square foot of the area, after construction was finished. The buildings are situated on a stratum of very stiff tertiary clay, more than 600 ft thick, and the bench-mark was established in a limestone quarry in the vicinity of the plant. The compressibility of the clay decreases to a depth of about 25 ft below the surface

Fig. 44 represents the settlement of a group of oil tanks.[26] At each point of the circumference of the buildings the radial width of the shaded area represents the settlement. The diagram shows plainly the influence of the weight of each structure on the settlement of adjacent structures, particularly the units toward the right. The 1932 Progress Report of the Committee on Earths and Foundations contains a brief mention of this case, including a section through the soil.[27]

Due to the inevitable subsidence in the vicinity of the loaded area, the short distance between the bench-mark (Fig. 42) should never be nearer the building under observation than twice the width of the building. If this distance exceeds 100 ft, it is advisable to establish intermediate points of observation. Each set of levels should be carried back to the point where it began and the settlement record should contain the ultimate error. With few exceptions, the observations made by the writer using the device shown in Fig. 42 have been made in rather inaccessible cellars with many partition walls; and yet the ultimate error has never exceeded 0.02 in.

[26] "Kritische Betrachtung von Flach-und-Pfahlgründungen," von W. Loos, Berlin, Julius Springer, 1932.

[27] *Proceedings*, Am. Soc. C. E., May, 1933, p. 777.

If the entire city or a part of it is situated above a bed of silt or clay a progressive, general, irregular subsidence of the loaded territory must be expected. In Cambridge, Mass., the entire area on both sides of Massachusetts Avenue, settled from 1869 to 1909 (a period of 40 yr) through distances ranging between zero and 2 ft.[28] A similar general subsidence was found to have occurred in San Francisco, Calif., in the district adjoining Market Street. From 1923 to 1928, the greatest subsidence was more than 0.2 ft.[29] There is but little doubt, that a similar general and irregular subsidence occurs in every city built upon beds of clay or silt. If such a general subsidence occurs the foregoing procedure yields data that inform the engineer merely as to the difference between the general downward movement and the downward movement of the newly constructed building. In order to obtain the actual settlement it would be necessary to establish a bench-mark at the bottom of a drill hole which extends through the entire system of unconsolidated strata to bed-rock. Such a bench-mark was established in Cambridge, Mass., at a depth of about 125 ft below the surface. Such bench-marks would also facilitate the collection of data concerning the general subsidence of the area occupied by a city. It should be the duty of municipal engineering departments to keep records of such movements.

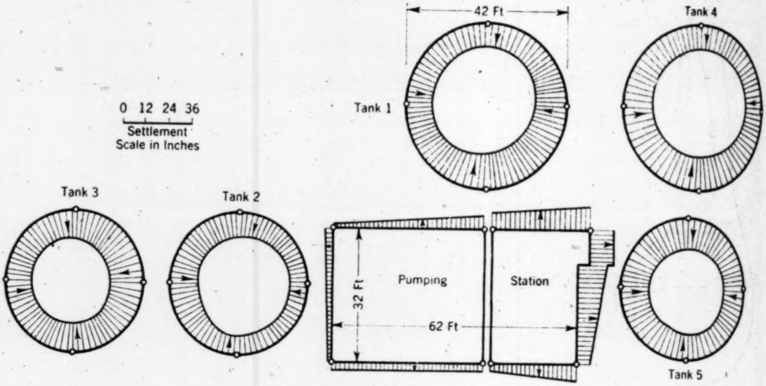

FIG. 44.—SETTLEMENT OF A GROUP OF OIL TANKS

SETTLEMENT OF PILE FOUNDATIONS

Observations made in Vienna, Austria, refer exclusively to foundations on conical, cast-in-place piles with a length of about 20 ft. They are arranged in two or three rows beneath continuous footings. The top-soil stratum usually consists of a loose, loamy, artificial fill and the piles get their support in a stratum of firm sand and gravel or very stiff clay of great thickness. The geological conditions practically exclude the presence of soft strata at any depth below the points of the piles. Before the settlement observations were made, many experienced contractors of the city believed that the settlement of the pile foundations was approximately equal to that produced by a loading test on an individual pile. According to this view, if all the piles are assigned equal loads, the settlement of the entire foundation should be uniform. Observations made during the past few years have destroyed both illusions. Figs. 45, 46, and 47(*a*) illustrate an example of such observation. The building consists of brick walls with continuous footings, 40 in. wide, supported by two rows of conical piles. Each pile carries a load of about 24 tons. The upper curve in Fig. 46(*b*) shows the result of a loading test on an individual pile, located at Point *P* in Fig. 47(*a*). Under a load of 24 tons a conical pile in Vienna very seldom settles more than a fraction of a millimeter during the loading test, and the loading test on the pile at Point *P* merely confirmed this empirical rule; and yet the settlement of the entire pile foundation was equal to more than forty times the settlement of the individual pile carrying the same load during the loading test. It was by no means uniform, although each pile carried the same load. The lower curve in Fig. 46(*b*) shows the settlement of a point, H_g, immediately above the location of the test pile. Fig. 46(*a*) contains the time-load diagram and the time-settlement curve for three typical points. Fig. 47(*a*) shows the curves of equal settlement during a period of six weeks and Fig. 47(*b*) the same curves eleven weeks after the first observations were made.

(b) ELEVEN-WEEK PERIOD

FIG. 47.—CURVES OF EQUAL SETTLEMENT: (a) SIX-WEEK PERIOD; (b) ELEVEN-WEEK PERIOD

Fig. 48 illustrates another example of the settlement of a brick building with continuous footings on conical piles. A section through the foundation is shown in Fig. 48(*a*). The piles were driven through a stratum of loose artificial fill into a layer of well compacted gravel. Fig. 48(*b*) shows the curves of equal settlement, one year after construction. The greatest settlement in this case also is at least forty times greater than that in a loading test with the working load. When the cellar for the building was excavated thick bodies of masonry were encountered which extended through the artificial fill to the surface of the gravel bed. If part of the new walls had been made to rest on top of the old ones, rupture would have been inevitable. Therefore, it was necessary to cut through the old walls and to provide an elastic support over the entire length of the continuous footings. This detail is also shown in Fig. 48(*a*).

Soil mechanics has made engineers realize that the settlement phenomena shown in Figs. 45 to 48 must be expected and that no simple relation can possibly exist between the result of the loading test on the individual pile and the settlement of the entire pile foundation, although the piles get their bearing in a firm stratum of gravel. At the same time, there is very little hope of finding a procedure for predicting the settlement of pile foundations of this particular type. Hence, an estimate can only be based on experience to be obtained by systematic observations on foundations supported by piles, with different lengths, driven to refusal in different types of strata. No general conclusions can be derived from two or three sets of observations. Thus, in both cases, represented by Figs. 45 to 48, the settlements ended not later than about two

years after construction was completed. If the points of the piles had been driven into a bed of stiff clay, the initial settlements would undoubtedly have been smaller, but would have increased for many years, approaching values far in excess of those shown in Figs. 45 to 48.

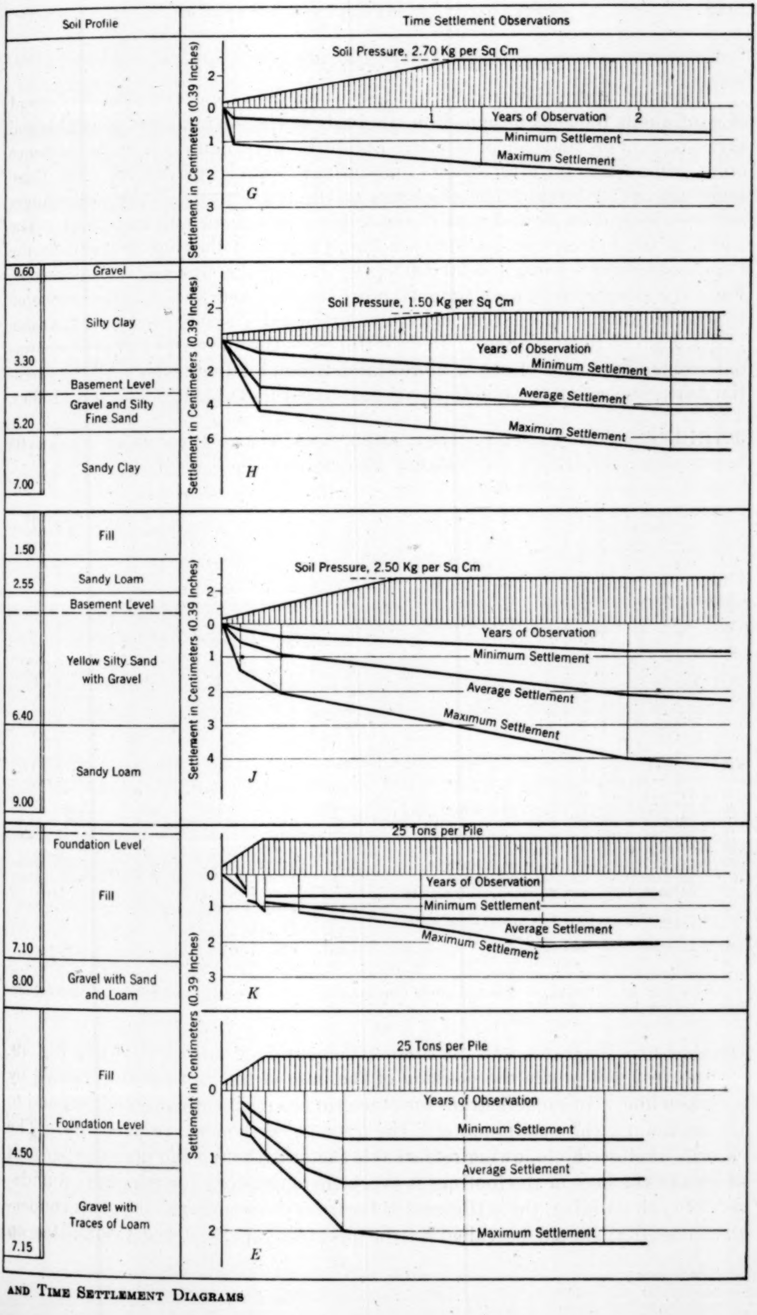
FIG. 49.—SOIL PROFILE, TIME LOAD,



AND TIME SETTLEMENT DIAGRAMS

Settlement of Continuous Footings

It seemed interesting to collect at least some data concerning the settlement of continuous footings designed on the basis of the customary "allowable soil pressure." For that purpose eight buildings were equipped with reference points immediately after their foundations were constructed. All these buildings are of brick. The thickness of the lower parts of the walls ranges between 20 and 30 in. and that of the upper part between 15 and 20 in. The width of the footings ranges between 2 and 9 ft, and they are covered by the buildings between 4 000 and 20 000 sq ft. One of the structures (Building *A*, Fig. 49) is supported by a continuous slab, extending over the entire area covered by the building. The larger structures are usually subdivided by expansion joints, from 50 to 80 ft apart. In doubtful cases the allowable soil pressure was determined by means of one or more standardized loading tests. All the essential data concerning the buildings are assembled in Table 6. The soil profiles, the time-load diagrams, and the time-settlement diagrams are shown in Fig. 49.

TABLE 6.—Soil Profile, Time Load, and Time-Settlement Diagrams (Brick Buildings)

* See Fig. 49. † Buildings *E* and *K* are in tons per pile. ‡ Reinforced concrete slab. § Strip foundation. || Piles driven to gravel.

In every soil profile the position of the base of the footings is indicated by a broken line. In each diagram the three time-settlement curves correspond to the minimum, the maximum, and the average settlement, respectively. The records disclose the following remarkable facts: Although the pressure per unit of area of the base of the footings is everywhere the same for the entire foundation of each building, the settlement is far from being uniform. In this connection attention should be called to the progress report of the Committee on

Earths and Foundations[30] which demonstrates that the settlement produced by a uniform load on a circular area is also far from being uniform. The ratio between the largest and the smallest settlement of the buildings listed in Table 6 ranges from 1.25 to about 7.00. The "allowable soil pressure" for the buildings listed in Table 6 was selected on the basis of a standardized procedure and the thickness of the highly compressible strata never exceeds about 20 ft. Nevertheless, the average, settlement ranged between the wide limits of 0.25 in. and more than 2 in.

In Germany, the foundations for bridge piers are also based on standardized "allowable soil pressures"; and yet since the bridges were built in very different parts of a large country, the thickness of the compressible strata and, as a consequence, the settlement of the structures, varies between considerably wider limits than it does in Vienna. Table 7 contains an abstract of data that have been collected by L. Casagrande.[31] The settlement ranges between almost zero and more than 3 ft. In general, the settlements of the foundations on sand and on boulder clay, were very small and stopped a short time after construction was completed, whereas the important settlement of foundations on clay and silt continued and must be expected to increase for many years to come.

TABLE 7.—SETTLEMENT OF BRIDGE PIERS IN GERMANY

Number of structures (1)	Description of soil (2)	Average Soil Pressure, in Tons per Square Foot		Settlement, in Inches	
		From: (3)	To: (4)	From: (5)	To: (6)
9	Silt	1.1	2.0	8	40
8	Clay, loess, loam, etc.	1.1	2.6	2	8
31	Boulder clay, sand or gravel with clay	2.5	4.0	0	0.8
21	Sand, gravel	1.5	3.0	0	0.4

The preceding statements have demonstrated that the limitation of soil pressure to the so-called "allowable" values by no means involves the limitation of the settlement to a definite value. Experience in estimating settlement can only be acquired by means of reference points and levels.

DIFFERENTIAL SETTLEMENT

If a building settles uniformly, no matter how much, the stresses in the members of the structure are not affected. Therefore, it was interesting to investigate the differential settlement of continuous footings which were designed on the basis of equal loads per pile, or of a uniform soil pressure. In Fig. 50(*a*), Curve 1 represents the settlement of the straight front wall of the building discussed in connection with Figs. 45 to 47; Curve 2, the settlement of the rear wall; and Curve 3, that of the middle wall.

Fig. 50(*b*) shows the distortion of the walls of the building represented by Fig. 48. Curve 1 corresponds to the front wall of the building, Curve 2, to the outside wall toward the court, and Curve 3 refers to the wall that runs parallel to the front wall through the interior of the building. In both cases (Figs. 50(*a*) and 50(*b*)) the continuous footings were supported by almost equidistant piles in such a fashion that every pile carried practically the same load.

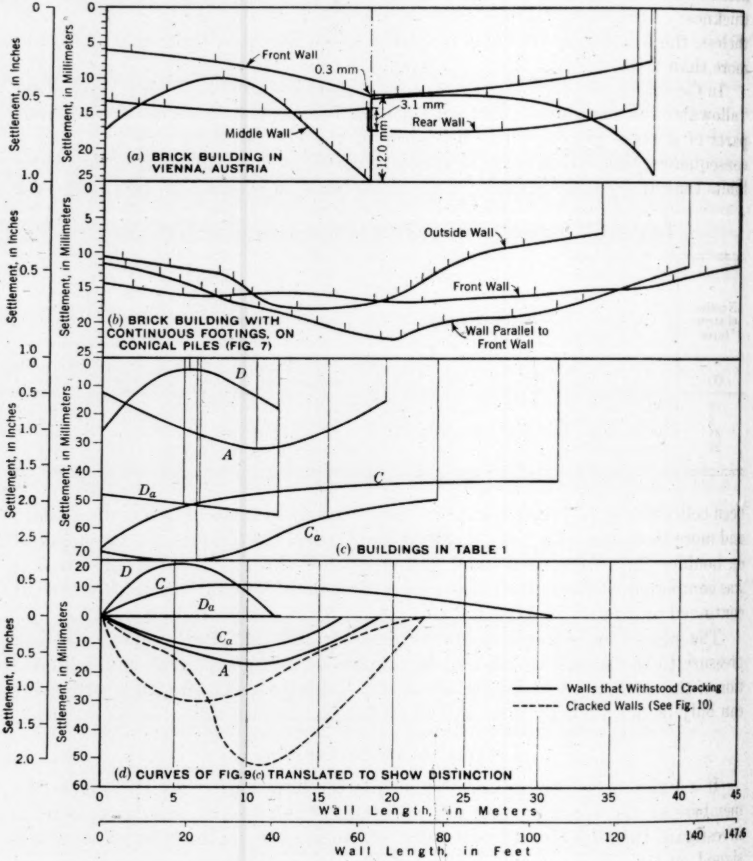

FIG. 50.—STUDY OF WALL SETTLEMENT

Fig. 50(*c*) shows the settlement of the continuous footings of the walls of the buildings listed in Table 6 and of several other buildings. These footings are supported by the natural ground without the assistance of piles, and they were designed in such a fashion that the pressure per unit of area of the footing is uniform throughout. Fig. 50(*d*) was obtained from Fig. 50(*c*) by translating the two ends of each curve up to the horizontal axis. As a consequence, Fig.

50(*d*) shows the distortion of the walls produced by differential settlement. All the walls represented by full black lines withstood the deformation without cracking. As a supplement to this diagram, two dotted curves were introduced. They represent the distortion of two of the walls of the building shown in Fig. 51 which is supported by a massive concrete slab, 4 ft thick. The distortion of these walls is greater than a brick wall can stand, as evidenced by the shearing cracks.

The facts represented in Fig. 50 lead to several interesting conclusions. Contrary to what many engineers still believe, settlement is never uniform, although the load per pile or the load per unit of area of the soil is the same everywhere. In none of the diagrams (except Fig. 48) do the curves of equal settlement have any resemblance to what one would expect from the theory of the settlement of loads supported by a homogeneous medium. Therefore, the differential settlement of the buildings represented by the diagrams is essentially due to local variations in the compressibility of the loaded strata. The importance of these variations cannot possibly be appraised by preliminary investigations of any kind, at a reasonable expense. Hence, an estimate of the differential settlement must be based on previous experience and this experience can only be acquired by systematic settlement observations such as those described herein. However, experience has shown that the erratic character of differential settlement is limited to those cases in which the thickness of the highly compressible strata does not exceed 20 to 25 ft. The greater the thickness of the highly compressible strata, the smaller becomes the difference between the real differential settlement and the settlement corresponding to a uniform and homogeneous medium.

FIG. 51.—CRACKS IN BUILDING WALL DUE TO SETTLEMENT (SEE TABLE 6)

For a given degree of non-uniformity of the subsoil, the importance of the differential settlement decreases with increasing stiffness of the walls. Thus, in the buildings discussed in connection with Figs. 45 and 48, the front wall (lower boundary of the area occupied by the building) is straight and the corresponding distortion, shown by Curve 1 to Fig. 50(*a*) is insignificant. On the other hand, the rigidity of the rear wall (upper boundary of the building lot in Figs. 45 and 48) is reduced by several corners. Therefore, the differential settlement shown by Curve 2 in Fig. 50(*a*), is far more important. A comparison of Figs. 48 and 50(*b*) indicates similar relations between the rigidity of the walls and the importance of the differential settlement. The settlement of the stiff wall, 1, is far more uniform than that of Wall 3, which, in plan, represents a broken line.

Any theoretical computation of settlements is based on the assumption that the subsoil is uniform, at least in every horizontal direction. The non-uniformity always increases the differential settlement and its detrimental effects. The nature and the importance of the difference between theory and reality can only be learned from settlement observations. Therefore, a practical application of the science of soil mechanics to settlement problems is not feasible unless the theoretical research is associated with, and supplemented by, settlement observations.

Differential settlement must be considered inevitable for every foundation, unless the foundation is supported by solid rock. The effect of the differential settlement on the building depends to a large extent on the type of construction. Consequently, it is necessary to find out by careful inspection of buildings with known settlement records how much distortion the different types of construction can stand without any harm. The data shown in Fig. 50(*d*) represent a first attempt in that direction.

FIG. 52.—UNDERGROUND BENCH-MARK USED IN DETECTING THE COMPRESSION OF STRATA AT VARIOUS DEPTHS

UNDERGROUND BENCH-MARKS

If it is desired to keep the settlement of a structure within specified limits, the foundation must be carried at least to a certain minimum depth which depends, among other factors, on the nature and the thickness of the soil strata beneath the building site. Similarly, if the settlement of an existing building is to be stopped by underpinning, such underpinning must be extended to some level below the seat of the settlement. The science of soil mechanics has furnished a set of theoretical rules for determining the distribution of the settlement over a vertical section through the loaded soil; and yet no such rules can be accepted for practical application on a broad scale until they have been confirmed by the results of observations on existing structures. Such observations can only be made by means of underground bench-marks; that is, by means of reference points established at the bottom of drill holes, at different depths below the surface of the ground.

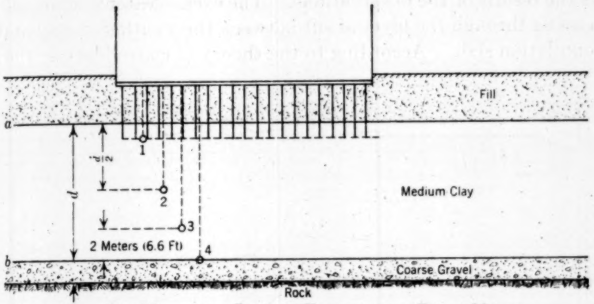

FIG. 53.—METHOD OF PLACING UNDERGROUND BENCH-MARKS

A description of reference points of the type was presented by the writer[32] in 1930. Figs. 52 and 53 describe these reference points and show how to establish them for the purpose of ascertaining the seat of the settlement of a pile foundation above a bed of medium clay. A method for constructing such bench-marks in very soft clay was described in 1936 and used in the City of Mexico, Mexico, by José A. Cuevas.[33] An underground bench-mark similar to that shown in Fig. 52(*b*) was established beneath one of the corners of the building marked "Silo" in Fig. 43, at a depth of 15 ft beneath the base of the foundation. As shown in Fig. 54, the building rests on a reinforced concrete slab strengthened by ribs. To a depth of about 8 ft below the base of the slab the soil consists of a yellowish, weathered, rather compressible clay. Beneath it

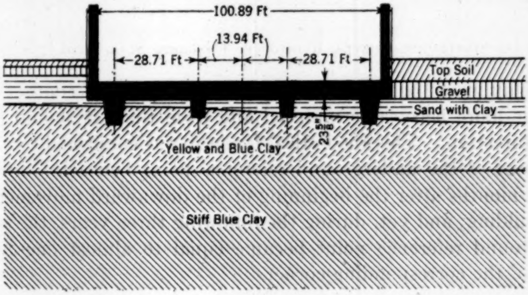

FIG. 54.—REINFORCED CONCRETE SLAB WITH RIBS, OF BUILDING (SEE FIG. 43)

is a very thick bed of stiff, blue clay. The underground reference point served the purpose of determining the extent to which the compression of the stiff blue clay was responsible for producing the total settlement of the structure. Fig. 55 shows the results of the observations. The excess water is squeezed from the clay, escaping through the layer of silt between the weathered clay and the base of the foundation slab. According to the theory of consolidation, the compression of the clay would be expected to begin at the point of contact between the clay and the more permeable material and from there it should proceed in a downward direction. This theoretical forecast was confirmed by the fact that the settlement of the underground reference point beneath Corner 44 began about eight months after the beginning of the downward movement of Corner 44 of the building; and yet, during the following three years, the settlement of the underground reference point became equal to almost one-half the total settlement of the corresponding corner.

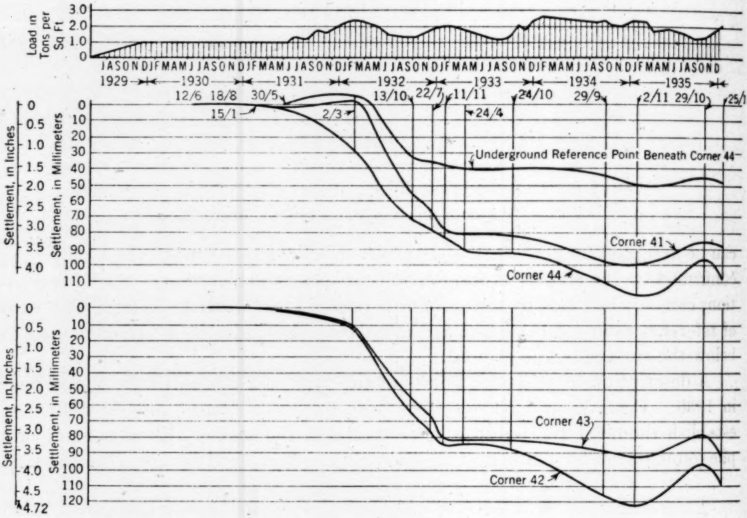

FIG. 55.—LOAD SETTLEMENT CURVES, REINFORCED CONCRETE SLAB, WITH RIBS (SEE FIG. 54)

SUGGESTION CONCERNING STANDARDIZATION

No method of soil investigation and of settlement computation can be accepted for practical use until the degree of accuracy of the results has been determined by experience. Such experience can be secured only by reliable and adequate settlement observations. Therefore, the first and the most urgent task in the establishment of a science of soil mechanics consists in standardizing the procedure for making settlement observations.

DISCUSSION

George E. Beggs,[34] M. L. Enger,[35] R. J. Fogg,[36] Harry T. Immerman,[37] D. P. Krynine,[38] F. A. Marston,[39] George Passwell,[40] Ralph R. Proctor,[41] Charles Terzaghi,[42] and Lazarus White,[43] Members, Am. Soc. C. E., and Glennon Gilboy,[44] Assoc. M. Am. Soc. C. E. (by letter).—Realizing that it is most important to obtain exact settlement data for existing structures, together with the underground conditions at the various sites, the Committee of the Society on Earths and Foundations has been financing, for the past years, an extended investigation by Charles Terzaghi, M. Am. Soc. C. E., mostly in Europe and, in part, also in the United States. These investigations have been valuable as a check on existing theories. In some cases quite close agreement has been found between computed and observed settlement, by the use of the Boussinesq equations to obtain internal pressures below the footing, and Professor Terzaghi's equations of consolidation as determined by compression based on undisturbed samples.

Professor Terzaghi has devised a graphic form of settlement curve and a diagrammatic method indicating conditions in the foundation and underground which is compact and complete. He calls the compressible strata beneath the settling structure the " seat of settlement " and the shape assumed by the base of the structure " the settlement trough ". He calls attention to the over-emphasis previously made on the pressure at the base of the footings; and he demonstrates by observation and calculation that most of the observed settlements are due to compression of the unconsolidated materials within the mass of the supporting underground; and that the " seat of settlement " may extend hundreds of feet in depth.[45]

At the request of the writers, Professor Terzaghi has kindly prepared a summary of his work on settlements with particular attention to the methods of obtaining accurate observations, and giving typical cases with a non-mathematical discussion.[46] Particular attention is called to the failure to obtain uniform settlements, even when uniform loading of walls, etc., was closely approximated, both in the case of pile foundations and spread footings.

The writers believe that this contribution is of great value. They hope that it will stimulate discussion, and are particularly desirous that other cases of observed settlements be submitted, with complete data.

S. C. Hollister,[47] M. Am. Soc. C. E. (by letter).—Mr. Hough is to be congratulated on the development of the model tests, reported in his paper, by means of which he was able to determine qualitatively the nature of settlement of the rock fill and the underlying clay bed.

Several points occur to the writer in regard to the determination of the safety of such a construction. The first of these relates to the fact that the rupture surface lies almost entirely within the bed material. This condition is characteristic when the material in the embankment has a high shear strength in comparison to the shear strength of the foundation material.

The second point refers to the stability of such a structure. When the rock fill has been completed and movement of the clay ceases, there exists at that time a factor of safety of one. This means that slight additional loading of the fill would cause a resumption of flow in the clay bed. If the rock fill came to rest in part upon the rock stratum below the clay, stability would be greatly increased. Furthermore, if the mud wave were counterweighted, stability again would be increased.

The "heart-shaped" failure surface, now that it is noticeable by the tests, is discernible from the theory of elasticity. A complete solution of the problem shown in Fig. 38, in which the foundation bed is loaded not only vertically but tangentially, is much needed.

Theodore T. Knappen,[48] M. Am. Soc. C. E. (by letter).—In the light of his personal experience with levee construction in this region, the writer desires to congratulate Mr. Buchanan on his accurate presentation of the Mississippi River levee problem. The soundness of the old design methods is amply demonstrated by the success of the Mississippi levee system in the 1937 flood, just as the soundness of the work of the Old Master Builders is demonstrated by the many ancient buildings that are standing to-day. Precisely as modern structural design has modified building practice, so will the rational methods of soil mechanics, under the leadership and guidance of experts, modify levee construction and gradually transform it from an art to a science.

Although it is true that most of the work on main line levees has been completed, there is still much to be done to provide an adequate factor of safety at the weak places in the existing system and to construct the tributary extensions. It is hoped that there will be sufficient infiltration of the principles expounded by Mr. Buchanan into the various design staffs to insure the application of rational design methods to the work yet to be done. Their best application is in the hands of these engineers who have, for years, carried on the design activities on the river. Familiar as they are with the ground conditions, they can apply the rational design methods with the conservatism that is necessary where protection of life and property is involved.

The ideal condition would permit wide variations in design resulting in a uniform factor of safety. Practical conditions and limitations of knowledge and its dissemination make the attainment of this condition a remote object to be approached gradually. The writer's comments are directed at the elucidation of a few of the factors discussed with the aim of clarifying some of the basic principles involved.

---

[47] Dean, Coll. of Eng., Cornell Univ., Ithaca, N. Y.

[48] Associate, Parsons, Klapp, Brinckerhoff, and Douglas, New York, N. Y.

First, examine the standard Mississippi River sections described as *A*, *B*, and *C* in Table 1. The *A* section is for a material containing 75% or more of clay, defined on the river as material finer than 0.005 mm. Although this section has never been discarded it was early learned by the field engineers that levees, even of moderate height (15 to 20 ft), built of material in this classification, were not stable with slopes as steep as 1 on 3. On the other hand, such materials are so impervious that seepage never reaches the down-stream slope except through pervious foundations. Actually, with such materials both slopes should be the same, assuming foundations of similar material.

Now, it will be noted that a river-side slope of 1 on 5 is provided for the *C* sections. On analysis most of these materials will be stable with a slope of about 1 on 2, but in actual experience wave wash has proved so troublesome with the usual fine cohesionless material of this class that this slope is a practical necessity unless slope paving is used. Most materials in this class are sufficiently pervious to establish the normal seepage gradient during a flood. To provide stability without under-drainage the down-stream slope is, properly, quite flat. Greater economy and stability might be obtained by the use of drainage provisions, largely through selection of available materials.

Most of the levees are actually of the intermediate or *B* classification and the levee dimensions indicated are usually more than adequate; but they have limited or inadequate safety factors in a few cases, particularly as one limit or the other is approached.

Mr. Buchanan has discussed the method used in foundation design where a comparison of stress versus strength is used. He has indicated the limitations of this method. More emphasis might well be placed on the photo-elastic method of stress analyses in particularly difficult cases.

In analyzing embankment stability Mr. Buchanan has used the sliding-surface method. The writer is inclined to believe that the inaccuracies of this method are such that it would be better to develop the stress-strength relationship in a manner similar to foundation design practice. The photo-elastic method offers one approach to this problem. Incidentally, where embankment and foundation materials are both of questionable strength the two analyses should not be separated but should be treated as one problem.

It has been the practice for a number of years to provide for the installation of settlement gages (locally known as "crow's feet") as a means of measuring foundation settlement for payment purposes. These gages offer an excellent means of detecting incipient foundation failure. Where foundation investigations have been made in advance an estimate of the rate of consolidation can be made and compared with actual settlement. If excessive settlement develops, incipient failure is indicated. In such a case immediate revision of the design to prevent failure should be made. Even where a foundation analysis has not been made the behavior of these gages offers a good indication of trouble to an experienced inspector.

A common indication of incipient foundation failure is an upheaval of the ground surface beyond the embankment toes. Prior to failure this movement usually is small; but it is frequently visible to the eye and can be detected in most cases by instrumental measurements. By the establishment of hubs in the critical reaches in advance of construction a check may be maintained on the foundation condition. Likewise, embankment slides are indicated in advance by the bulging of embankment slopes. Instrumental checks can detect such conditions in sufficient time to permit corrective measures to be taken.

It is realized that many of the construction methods permitted on levee work do not lend themselves to the application of these methods of detection of probable failures. Some limitation on the method of construction in such cases may be advisable. Based on present-day hauling methods and costs there is no reason to believe that these limitations will result in materially increased costs.

With respect to the discussion of levee construction methods in the paper, it might be argued that an increase in cost of 4 cts to 6 cts per cu yd for compaction would be more than offset by economies in section design. However, it should be remembered that most of the levee work was executed before present-day knowledge of soil mechanics had advanced to the point where it could evaluate the improvement. It is the writer's opinion that the general solution was sound for the time that it was made, but that in the future it should be modified in the light of recently acquired knowledge.

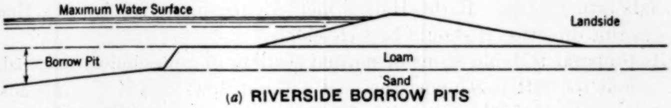
One of the most troublesome problems in levee planning is borrow-pit location. Mr. Buchanan points out that considerations of economy require that the material be obtained opposite, and as close as possible to, the proposed levee. He further states (see heading, "The Design of a Levee Unit") that,

> "It is important that no borrow-pits or excavations be made adjacent to the levees on the land-side to expose pervious strata extending through to the river side. Exposure of such strata invites trouble from increased underseepage, certainly; and from destruction of the levee structure due to piping, possibly. Although in some instances, borrow-pits have been made on the land side, they are the source of never-ending trouble."

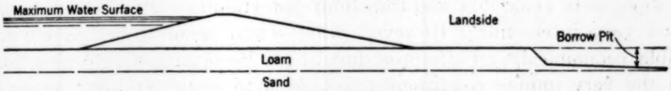
This policy has resulted in the use of river-side pits almost exclusively in recent years. These pits are separated generally from the levee toe by a 40-ft berm. At the edge of the berm they are 3 ft deep and deepened from 2 ft to 4 ft in every hundred depending on the specification in each case. Below the mouth of the Red River slopes of 10 ft in 100 are permitted. One of the greatest fields for improvement in levee design lies in the application of the principles of soil mechanics to borrow-pit location and design in connection with the hydraulic design of levees.

The Mississippi levees are built on, and of, alluvial soils. This means that almost every combination of sands, loams, and clays may be encountered. In some cases deep foundations of relatively impervious loam or clay exist. In such cases the only restrictions on borrow-pit depth need be stability and future enlargement considerations. More frequently the foundations are stratified, making a careful analysis of the problem most important. Often there is a layer of loam overlying a deep sand stratum as in Fig. 56(*a*). In this case the river-side borrow-pit cuts through the loam exposing the sand, which may be one hundred times as pervious as the loam. Here the head acting through the pervious sand on the loam stratum causes boils or piping at the land-side toe of the levee. This offers an explanation for many of the worst troubles on the levee system. In time the borrow-pit will silt up in the small annual floods and the trouble tends to become less in succeeding large floods.

Now, reverse this condition and put the borrow-pit on the land side as in Fig. 56(*b*), taking care to excavate to the sand. The loss of head then occurs to a large extent in downward flow on the river side where it can do no harm.



(*a*) RIVERSIDE BORROW PITS



(*b*) LANDSIDE BORROW PITS

FIG. 56.—TYPICAL LEVEE CROSS-SECTION

In this case the land-side pit is preferable. Now, land-side specifications only permit a deepening of 1 ft in 100; so the pit in this case would have a thin covering of loam over the sand. The result would be boils in the pit which would look bad although they would not be serious.

There are, of course, many other combinations. One would be the case of the pervious sand foundation overlying an impervious stratum like the case cited at Mound's Landing, where the treatment of a clay blanket extending to the impervious stratum was excellent. There are many other known weak spots in the system where a soil mechanics analysis should develop a solution whether it be by cut-off, blankets, or drainage. The important consideration is that Mr. Buchanan's studies should be extended to the solution of these problems. The present rigid borrow-pit requirements should be modified by individual design studies based on the exploration borings described in the paper.

L. F. HARZA,[49] M. AM. SOC. C. E. (by letter).—The need of a reliable basis of stability analysis for foundations under earth embankments is very great indeed. Much has been written and much research has been conducted applicable to selection of suitable embankment materials and their compaction to optimum density and "stability."

All this refinement in the embankment itself, however, amounts to little unless the foundation or underground is equally stable, or unless means exist for interpreting laboratory tests of foundation material into degree of stability under conditions of loading. Experience at Zanesville, Ohio, and elsewhere clearly indicates that knowledge and technique in building artificial embankments has progressed far beyond knowledge of whether a foundation will properly support the embankment when built. In general, the foundation must be accepted as it exists, and it is likely to be by far the weaker and more uncertain element of the structure, subject to much greater settlement and seepage.

---

[49] Cons. Engr. and Pres., Harza Eng. Co., Chicago, Ill.

Any foundation settlement which tends to cause cracks or fissures in the superstructure invites failure in the embankment. Data and methods of analysis should eventually become available for indicating the degree of flexibility of embankment sections and profiles for accommodating themselves to foundation settlement without cracking and for predicting such settlement from laboratory tests. If the Haines method, recommended by Mr. Hough, tends in this direction it should be welcomed.

His proposal to build dams of normal section, of cohesionless material, on foundations too soft to support the load without flow, in lieu of dams of such flat slopes as to avoid flow and thus limit distortion to vertical compression, is indeed very interesting. However, what might seem to be an obviously feasible, economical, and safe procedure at the Passamaquoddy project might, with the very unique conditions which seem to justify it there, never find another similar application.

It is scarcely conceivable that the new fill, in adjusting itself to the outflow of the soft foundation, could settle without cracks and fissures. Moreover, where the new fill is required to sag in profile, the bottom also tending to spread with outflow of soft foundation, invisible fissures in the bottom are probable, resulting in arching cavities in the fill. No cohesionless material is so fluid as to readjust itself without initial arching voids.

In the Passamaquoddy submerged fill, water could be allowed to flow back and forth through the pervious fill with each change of the tide until the structure is thoroughly settled and these cracks thus closed before applying the less pervious blanket. Failure at this stage could not occur. In a normal fill above water level, however, the final necessary readjustment of the fill to settlement could probably not be accomplished without filling the reservoir. Any distortion sufficient to accomplish such readjustment would seriously endanger the safety of the fill during the readjustment period if the reservoir were thus filled.

To be successful, the scheme would seem to be dependent upon conditions in which anticipated settlement would be practically completed during construction. It is doubtful whether this could be done except in a submerged dam where water would be available for settlement without unbalanced pressure as at Passamaquoddy.

EDWARD ADAMS RICHARDSON,[50] ESQ. (by letter).—This discussion of the paper by Mr. Hough will touch upon three subjects: (1) The proper stress to choose for the limiting shear in the case of plastic materials; (2) factors affecting the computation of the factor of safety of the foundation; and (3) methods for improving the design of such foundations as suggested by the tests and investigations.

In one of his model tests, the author utilized "a bed of uniform, remolded clay" to represent the foundation material. Such remolded clay exhibits materially lower shear resistance than the undisturbed material. It seems improper to base the design of a foundation on the strength of the fully remolded material rather than on that of the undisturbed material.

---

[50] Associated with Bethlehem Steel Co., Bethlehem, Pa.

Considerable kneading is required to convert the original clay body to the uniform, fully remolded condition. This is true even in the case of very soft clay. This amount of kneading appears to be greatly in excess of that which may be found in the most stressed elements of material beneath the foundation. Most of the material that flows plastically can scarcely be said to be subjected to appreciable kneading action. Such action is measured by the relative movement or strain of adjacent particles of clay; not by the distance moved by the most traveled point of the plastic body as measured relative to a fixed point on the boundary. That being the case, it would appear that the proper value of the limiting shear stress for the plastic material should be closely that of the undisturbed material. In view of the considerable differences in this limiting stress, it becomes a matter of great importance to choose the value most nearly approximating actual conditions if an economical structure is to be secured.

The factor of safety is computed by the Haines analysis through an adaptation of the method presented by K. E. Petterson, a member of the Swedish Geo-Technical Commission. Due references were made to the investigations by Jurgenson[51] and Professor Dr. H. von Krey. In using similar methods, as in the case of sloping banks, it has been customary to apply loads to the surfaces of the rotating segment and then to assume that such added loads increase the friction of the sector on the surface of sliding, or at least contribute a friction force along this surface. In the case of dams, the friction force thus calculated may be considerable. It should be noted that a plastic clay segment does not develop any friction force due to such loads until time for consolidation has elapsed. As this time may be long (perhaps nearly as long as the life of the structure) such friction forces should be omitted from the initial stability calculations. It will be recalled that any load added to clay is initially carried entirely by hydrostatic pressure in the contained water and not through particle contacts; therefore, no friction force can be developed by the added load.

An approximation to the curved part of the surface of failure may be obtained in the following manner: The equations for the shearing stresses involved are those for an elastic body of indefinite extent loaded at a point of the surface, and were derived from the corresponding case given by Mr. John Prescott.[52] Such a derivation yields not only the p_z of the Boussinesq theory, but also p_x, p_y, and the shearing stresses.

For reference purposes, the formulas for all stress components at (x, y, z) are given herein, as Equations (11) and (12). Only Equation (11*c*) for p_z is commonly given. Fig. 57 may be used as a diagram, with OY perpendicular to the X–Z plane. Poisson's ratio is $\frac{1}{m}$. Direct stress components are p_x, p_y, and p_z parallel to OX, OY, and OZ, respectively. Shear stress components are s_1, s_2, and s_3, the axes of torque being likewise parallel to OX, OY, and OZ, respectively. That is, the stresses for s, producing a torque component about an axis parallel to OX, may be considered to lie in a plane, containing (x, y, z), which is parallel to the Y–Z plane. The equations are:

---

[51] "The Shearing Resistance of Soils," by Leo Jurgenson, *Journal*, Boston Soc. of Civ. Engrs., Vol. XXI, No. 3, July, 1934, p. 242.

[52] "Applied Elasticity," by John Prescott, Chapter XIX, p. 623, Longmans, Green & Co., London, 1924.

$$r = \sqrt{x^2 + y^2 + z^2} \quad \text{(11a)}$$

$$p_x = \frac{P}{2\pi}\left[\frac{r^5 - 2 r^3 y^2 + r^2 z^3 - 2 r^2 x^2 z - 6 r x^2 z^2 - 3 x^2 z^3}{r^5 (r + z)^2} - \frac{2}{m}\,\frac{r^5 - 2 r^3 y^2 + r^2 z^3 + r^2 x^2 z}{r^5 (r + z)^2}\right] \quad \text{(11b)}$$

$$p_y = \frac{P}{2\pi}\left[\frac{r^5 - 2 r^3 x^2 + r^2 z^3 - 2 r^2 y^2 z - 6 r y^2 z^2 - 3 y^2 z^3}{r^5 (r + z)^2} - \frac{2}{m}\,\frac{r^5 - 2 r^3 x^2 + r^2 z^3 + r^2 y^2 z}{r^5 (r + z)^2}\right] \quad \text{(11c)}$$

$$p_z = \frac{P}{2\pi}\left[-\frac{3 z^3}{r^5}\right] \quad \text{(11d)}$$

$$s_1 = \frac{P}{2\pi}\left[-\frac{3 y z^2}{r^5}\right] \quad \text{(11e)}$$

$$s_2 = \frac{P}{2\pi}\left[-\frac{3 x z^2}{r^5}\right] \quad \text{(11f)}$$

and,

$$s_3 = \frac{P}{2\pi}\left[\frac{(2 r^3 - 2 r^2 z - 6 r z^2 - 3 z^3)\, x y}{r^5 (r + z)^2} - \frac{2}{m}\,\frac{(2 r^3 + r^2 z)\, x y}{r^5 (r + z)^2}\right] \quad \text{(11g)}$$

When $y = 0$, or OX is so chosen that the X–Z plane contains r, the case of Fig. 57 is obtained. It should be obvious that the symmetry of point loading is such that all points having the co-ordinates, r, α, will have the same stress components on the plane, X–Z, chosen to contain r; hence Fig. 57 is a cross-section upon which the stress system is fully characterized for the entire body. The corresponding equations are:

$$r = \sqrt{x^2 + z^2} \quad \text{(12a)}$$

$$p_x = \frac{P}{2\pi}\left[\frac{r^5 + r^2 z^3 - 2 r^2 x^2 z - 6 r x^2 z^2 - 3 x^2 z^3}{r^5 (r + z)^2} - \frac{2}{m}\,\frac{r^5 + r^2 z^3 + r^2 x^2 z}{r^5 (r + z)^2}\right] \quad \text{(12b)}$$

$$p_y = \frac{P}{2\pi}\left[\frac{r^5 - 2 r^3 x^2 + r^2 z^3}{r^5 (r + z)^2} - \frac{2}{m}\,\frac{r^5 - 2 r^3 x^2 + r^2 z^3}{r^5 (r + z)^2}\right] \quad \text{(12c)}$$

$$p_z = \frac{P}{2\pi}\left[-\frac{3 z^3}{r^5}\right] \quad \text{(12d)}$$

$$s_1 = 0 \qquad (12e)$$

$$s_2 = \frac{P}{2\,\pi}\left[-\frac{3\,x\,z^2}{r^5}\right] \qquad (12f)$$

and,

$$s_3 = 0 \qquad (12g)$$

By combining point loads and their stresses, it is known that solutions approximating the present case may be obtained. The stresses in the soil will be closely approximated only when the entire soil mass behaves elastically under the applied load and the earth is of indefinitely great depth. The approximation may be good in those cases in which at least a portion of the earth is subjected to shearing stresses beyond the yield point of the material.

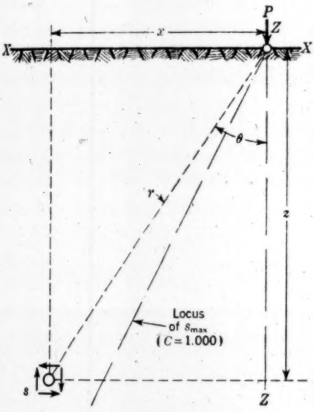


FIG. 57.—LINE OF SEPARATION, ELASTIC AND PLASTIC REGIONS UNDER A POINT LOAD.

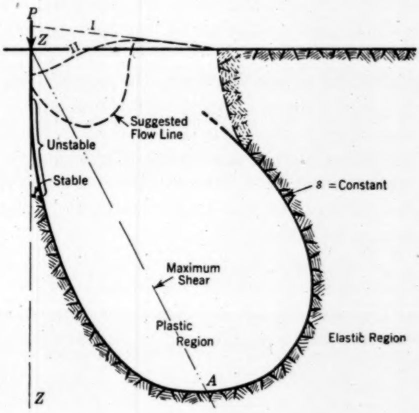

FIG. 58.

In such cases, one may determine a surface of shearing for the limiting shear values from point to point. This surface will set the boundary approximately between the elastically strained material and that which is in the plastic condition. Whether plastic flow does or does not occur will depend upon other factors, such as the restraint opposed to the direct pressures of the plastic portion of the mass. The character of an iso-shear line for a point loading will be seen in Fig. 58. The boundary is determined from a set of these lines for a series of *s*-values. As drawn, however, the boundary is determined by one *s*-value.

When the elastic body is a solid of great cohesive strength relative to the force of sliding friction, the boundary between the elastic and the plastic regions will approximate very closely to the *s*-curve having the value of the cohesive or shearing strength of the material. Treating Fig. 58 as representative of such a material, Curve II suggests the character of surface deformation for elastic behavior, whereas Curve I suggests that for plastic flow when the elastic limit is exceeded. These curves are purely diagrammatic.

If, however, the elastic body is more like a soil body in having a cohesive strength which may be small compared with frictional resistance throughout the stressed region, the procedure is more complicated. Friction increases with soil depth and depends upon the slope of the sliding surface, whereas cohesion remains substantially unchanged, or changes slightly. It is necessary to assign, to the soil, shearing resistance stresses, s_r, appropriate to the z-values investigated. It is also necessary to construct a set of constant (iso-) shear curves for the stresses due to the load, with equal increments in s between adjacent curves, the set to cover a sufficient range of values. The boundary surface is then obtained by choosing a z-value, noting the s_r-value considered appropriate, and plotting this value where the s-curves give its equal. Proceeding in this manner, a number of points may be located and the curve drawn. The s_r-values should now be checked. It is necessary to measure the normal force on the curve, compute the friction force tangential to it, and add the cohesive force. If the s_r-values, so computed for the curve as drawn, check the assumed values, the curve is really the probable surface of failure. If not, a second approximation must be made. It will be observed that this procedure is similar to that of Haines, but differs in that Haines approaches the problem from the standpoint of choosing, by trial, the curve yielding the lowest factor of safety. Whereas the curve to choose is virtually unknown in the Haines method, the stress method enables one to approximate the probable surface of failure.

The procedure used in drawing the iso-shear lines, or lines of constant shearing stress, is based on Equation (12*f*). It may be shown by differentiation of Equation (11*f*), holding z constant, that the maximum shearing stress, s_2, occurs when $x = 0.5\,z$. The value of this maximum stress, s_2, is denoted by s_m and,

$$s_m = \frac{0.1366\,P}{z^2} \quad \text{(13a)}$$

The value of the shearing stress for any other value of x, z remaining constant, may be found from s_m by using a factor, k;

$$s = k\,s_m \quad \text{(13b)}$$

By dividing s_2 by s_m, k may be obtained in terms of $\frac{x}{z}$ alone; therefore, k applies to any level, z, provided $\frac{x}{z}$ is the same:

$$k = \frac{25\,\sqrt{5}}{16}\,\frac{x/z}{\{1 + (x/z)^2\}^{5/2}} \quad \text{(14)}$$

In Fig. 57 the line of maximum shear stresses is shown making the angle, θ, with OZ such that $\frac{x}{z}$, or $\tan\theta_5 = 0.5000$. The right circular cone with such lines for elements is the locus of such maximum shear stresses, s_m, for the point load, P.

In Fig. 59, k has been plotted in terms of $\frac{x}{z}$. Certain other lines numbered n from 0 to 10 cross the chart parallel to the $\frac{x}{z}$-axis. These are located so that,

$$k = 0.01\, n^2 \qquad (15)$$

Suppose the curve, s, is to be drawn. The first point may be located by substituting s in Equation (13a) and solving for z. This point will lie at the z-value thus found and at $x = 0.5\, z$. Divide this z-distance into ten equal parts along OZ, pass horizontal lines through the points of division, and number them, n, from 0 at the surface to 10 at the first line found. Now,

$$s_{mn} = \frac{100\, s^2}{n^2} \qquad (16)$$

Hence, k at Level n must have the value of $0.01\, n^2$. The lines, n, in Fig. 59 give the $\frac{x}{z}$-values at the n-level where they intersect the k-curve, thus enabling one to determine the two x-values at each n-level. It merely remains to draw the s-curve through the points so found, and repeat for such other s-curves as may be required for the set. More exact values of k are given in Table 8.

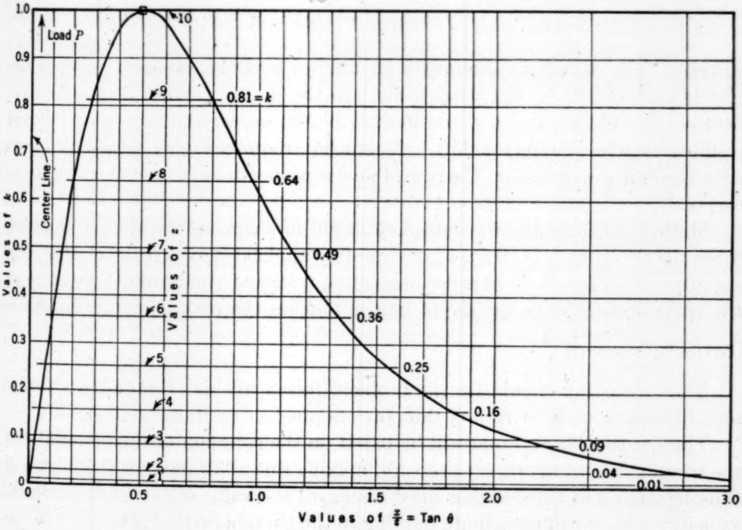

FIG. 59.—RADIAL VARIATION OF SHEAR ON THE X–Z PLANE.

If a distributed load is involved, it becomes necessary to combine stress components at each of a set of points, and thereby build up s_2-values on appropriate planes. In the case of a line loading of indefinite extent, this might be a center plane perpendicular to the line. Integration is easy for s_2. Such planes experience a principal shearing stress and, therefore, are critical.

In passing, it should be noted that a flowing plastic body may have higher shear stresses within it than the limiting shear stress for the material. Furthermore, a plastic body, restrained from flowing, cannot support a greater shear stress. That part of the stress system producing the limiting stress in the elastic body remains unchanged in the plastic body. The excess stresses are purely direct in the case of the non-flowing plastic body. This shift in the character of the direct stresses tends to modify the shape of the surface bounding the plastic region, because the surface computed in Fig. 58 involves the assumption of pure elastic stressing, and direct pressures on the corresponding surface. The shift in the boundary should not be great, however. When the plastic material flows, the stress system in the plastic portion is intermediate between the elastic and the non-flowing plastic cases, and, therefore, should result in even less boundary shift. Plastic flow requires higher shearing stresses than the limiting ones since the rate of flow is proportional to the shearing stress excess.

TABLE 8.—VALUES OF k, FOR SUBSTITUTION FOR EQUATION (12)

Ratio, $\frac{x}{z}$ (1)	Coefficient, k (2)	Ratio, $\frac{x}{z}$ (1)	Coefficient, k (2)	Ratio, $\frac{x}{z}$ (1)	Coefficient, k (2)	Ratio, $\frac{x}{z}$ (1)	Coefficient, k (2)
0.0	0.0000	0.6	0.9764	1.2	0.4508	1.8	0.1699
0.1	0.3408	0.7	0.9025	1.3	0.3827	1.9	0.1455
0.2	0.6335	0.8	0.8115	1.4	0.3245	2.0	0.1250
0.3	0.8450	0.9	0.7134	1.5	0.2752	2.4	0.0706
0.4	0.9643	1.0	0.6176	1.6	0.2338	2.8	0.0421
0.5	1.0000	1.1	0.5293	1.7	0.1990	3.2	0.0264

Methods such as the foregoing are useful in checking the Haines analysis. Since the elastic equations are approximately applicable even if the elastic body consists of two layers of differing properties, it should yield useful results up to the point at which the surface of failure touches the rock boundary for some particular value of $\frac{a}{L}$.

This discussion should tie the problem raised by Mr. Hough more firmly into the entire body of results thus far obtained in earth mechanics.

The limiting shear value will be based on the cohesion of the material and the friction due to the direct pressure, making due allowance for the degree of consolidation, but the designer must disregard the value of the load, P, which, as before stated, can contribute nothing to the friction force. The force of this argument may better be appreciated by reference to Fig. 60(a), which shows the variation of the coefficient of friction, based on the pressure, p, when both friction and cohesion are considered, provided the clay is considered fully consolidated for the actual value of p used. Fig. 60(b) applies if the clay is not fully consolidated. This curve represents the solution between the apparent coefficient of friction (based on the full applied load) and the degree of consolidation under that load. For all practical purposes the plot is a straight line. A sudden application of pressure is equivalent to a sudden reduction in the degree of consolidation. There have been a number of cases in which the disregard of such principles has resulted in failure. The coefficient of friction enables one to calculate the limiting shear for the direct pressure acting.

This Symposium is related primarily to dams and other structures erected on the surface of soft materials with the idea of permitting the structures to sink to equilibrium. Curves such as Figs. 37 and 38, suggest that it may prove much more economical to sluice and dredge soft material into the position where the "mud waves" must form. The cross-section of these waves appears to be much less than that of the dam or other structural material which must be lost by the sinking action. With mud waves formed in place in excess of the sizes shown, the structures erected on the surface of the soft body should remain substantially at that surface without any sinking action. The question of protecting the "waves" from erosion exists in either case.

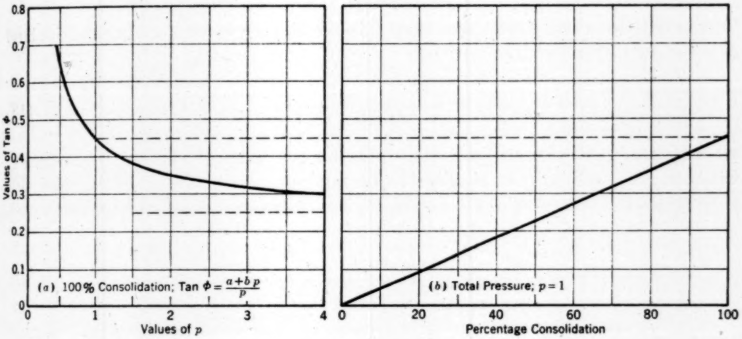

FIG. 60.—SHEAR IN CLAY.

RICHARDS M. STROHL,[53] M. AM. SOC. C. E. (by letter).—The application of soil mechanics to levee design, as described by Mr. Buchanan, is thoroughly helpful to those interested in levee problems.

In discussing the importance of seepage through the levee, reference is made to Fig. 10, in which the path of percolation is $\sqrt{29^2 + 217^2} \times 30.48 = 6\,675$ cm long. The time required for water to seep this distance at the rate, $K = 5 \times 10^6$ cm per sec, will be 15 450 days. As Mr. Buchanan states that the maximum high-water stages do not extend over a period of more than 20 days, it would appear that seepage could not be developed through such a levee during any flood of record.

Necessity for constructing a levee on a foundation similar to that shown in Fig. 61 frequently arises. Water from the river side readily finds access to the pervious sub-stratum. The quantity of percolation is found approximately by means of Professor Terzaghi's expression[54]:

---

[53] Engr., U. S. Engr. Office, Memphis, Tenn.

$$Q = \frac{K\,h}{0.88 + \frac{L}{d}} \quad \text{(17a)}$$

which is the equivalent of Darcy's formula (published in Paris, 1858):

$$Q = K\,A\,i = K\,A\,\frac{(h_1 - h_2)}{L} \quad \text{(17b)}$$

The height to which water would rise above the pervious stratum on the land side for conditions of free flow is,

$$h_2 = h_1 - \frac{h\,L}{0.88\,d + L} \quad \text{(18)}$$

whereas, for static conditions, the uplift on the natural blanket is practically equal to h_1. Where it is possible to permit nominal flooding on the land side of the levee, the flow of water upward through the blanket can be controlled. By permitting discharge on the surface of the blanket, h_2 becomes equal to t, and the flow at the ground surface becomes,

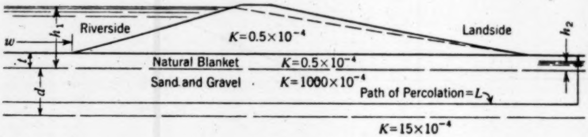

FIG. 61

$$Q = k\,d\,\frac{(h_1 - t)}{L} \quad \text{(19)}$$

per linear foot of the levee. This quantity will be rather small, and it appears more practical to control this flow than to try to prevent it.

The width, w, of the blanket on the river side of the levee is of importance in reducing percolation under the levee, Q being inversely proportional to L. It is the practice in levee building to secure the embankment material from borrow-pits in front of the levee, leaving a berm with a minimum width of 40 ft. Where the depth of the borrow-pit materially reduces the thickness, t, of the material blanket, it appears worth while to increase the berm width.

WILLIAM P. CREAGER,[55] M. AM. SOC. C. E. (by letter).—The theories of soil mechanics, as applied to the design of dams, are frequently quite complex. Mr. Buchanan has made an excellent summary of the fundamental principles involved; but, on account of the limitations in space for a paper of this kind, he has not been able to do more than give a hint of some of the extent of the procedures necessary for many cases. The only criticism which the writer can give regarding this paper is the lack of indication that, in some instances, the procedure involved is not as simple and direct as shown by the examples given. As examples of lack of simplicity in designs the writer gives two cases as follows:

---

[54] Unpublished analysis of seepage, by Charles Terzaghi, M. Am. Soc. C. E.

[55] Cons. Engr., Buffalo, N. Y.

(1) The design of the slopes of any dam is not complete without the inclusion of seepage forces. This has been mentioned only briefly in this paper, and the impression has been given that the consideration of such forces must wait on "further research." A number of excellent papers, involving the consideration of such forces, were presented at the Second Congress on Large Dams held in Washington, D. C., in 1936. Mr. Buchanan's example is lacking in respect to this force.

(2) The stability of the foundations, as used in the example (see heading, "The Design of a Levee Unit"), is correct without modification, on the assumption that the foundation drains quickly. If, due to insufficient drainage time, the foundation is not completely consolidated, some of the weight is carried by the water in the foundation and part of the ultimate frictional resistance to shear is lacking. Therefore, the measured shearing strength as given by Item (*c*) of the example should be determined experimentally on the basis of the correct amount of partial consolidation when the dam is first completed.

Attention is also called to the following comments on the paper by Mr. Hough, regarding the necessary modification to foundation stability equations due to this condition.

Mr. Hough has presented an excellent paper which, among other interesting items, describes a proposed method of construction that is unique in the annals of dams. He has mentioned one limitation to photo-elastic model studies. The writer would like to mention another limitation.

In the case of a saturated foundation which has consolidated only partly during the construction of the dam, a part of the weight of the dam is carried by a direct loading of the soil of the foundation and the remainder is carried by the hydrostatic pressure of the pore water in the foundation. The hydrostatic pressure in the foundation, which is built up by, and equals, that part of the loading carried by the water in the foundation, acts in all directions, of course, and forces the surplus water to drain off in all directions with velocities proportional to the lengths of the various paths of percolation to the nearest point of relief.

Fig. 62(*a*) represents a pervious sand dam resting on a layer of silty clay which, in turn, is underlaid by pervious sand. The water in the silty clay layer drains almost directly upward and downward. Decrease the perviousness of the dam and the underlying sand layer, and some of the water in the silty clay layer begins to drain sidewise as well as upward and downward, as shown in Fig. 62(*b*). Should the dam and the underlying layer be absolutely impervious, all the drainage would be horizontal and diagonally upward to the valley bottom adjacent to the dam, as shown in Fig. 62(*c*).

Fig. 62(*d*) is an actual case of a concrete dam resting on a deep, lightly consolidated shale bed. Between the dam and the shale is to be placed an impervious coating of asphaltum to prevent drying out and slaking of the shale during construction. The drainage is downward at the center and horizontal or inclined upward at the edges of the base.

It will be noticed that, in all practical cases, some part of the drainage is horizontal and upward toward the sides of the foundation in the direction of failure if the foundation should prove weak.

The entire hydrostatic pressure in the foundation is balanced by the friction of the water in the direction of flow, the pressure decreasing to zero at the outlet of the seepage. Thus, the loading carried by the hydrostatic pressure is transferred to the soil, not as a vertical loading which can be simulated by the photo-elastic method, but in an infinite number of directions which cannot be simulated by present methods.

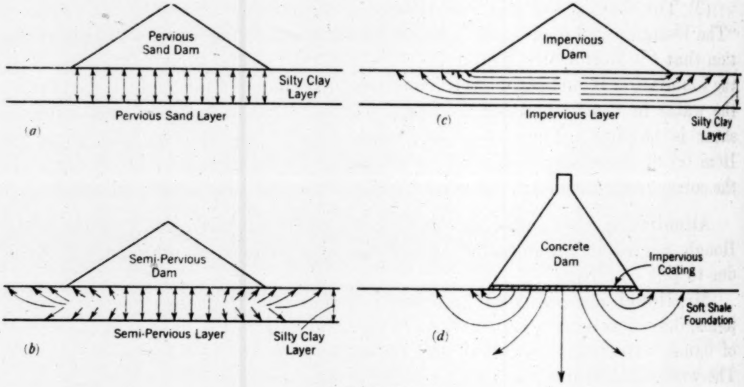

FIG. 62

Very obviously, a greater loading can be placed on a soil in a vertical downward direction than in a horizontal or diagonally upward direction, in the direction of failure. For this reason, the photo-elastic method and, incidentally, the commonly accepted theories and formulas are not applicable for the condition of partial consolidation of the foundation. Unfortunately, the writer does not have at present a solution for this special case. He presents it for the purpose of stimulating interest in the problem and as a thought to be considered in the interpretation of usual methods.

JACOB FELD,[56] M. AM. SOC. C. E. (by letter).—Seldom in engineering work is there an opportunity for full-scale research such as is available to the U. S. Waterways Experiment Station. Results cannot be expected immediately, but only from a continuous study over many years. The main problems are the determination of settlement and seepage, using variations of material combinations, not only at the end of and during construction operations, but the effect of age, receding flood levels, precipitation intensities, and unusually high and low temperatures. The problems are not simple, yet because of the fairly limited number of soils available for use, solutions covering a considerable range of time and weather conditions can be expected from a program of not more than 10 yr.

---

[56] Cons. Engr., New York, N. Y.

It would be sound engineering as well as sound economics to design and contract for a series of test sections, using controlled soil mixtures and construction methods. In such a test group, attempts should be made to study the use of colloidal material from the river bottom as a temporary surface seal, to give added resistance to seepage until such time as the settlement of the fill reduces the seepage rate through the full section.

Systematic laboratory research can be of great aid in lessening the cost of full-scale tests. As far as seepage is concerned, such work as that of B. A. Bakhmeteff, M. Am. Soc. C. E., and N. V. Feodoroff[57] gives a clear picture of the problem as well as a mathematical solution of a number of conditions encountered in levee and dam design.

Little has been learned of the impervious region at the contact zone between layers of different grain size and shape. The contact lens or skin is denser, less pervious, and of greater bearing value than either of the adjacent materials. Such zones are often found in river beds, just below the shifting layer of sediment. Below this may be much more pervious strata. Cutting through this zone, whether on the land side or on the river side of a levee, in a borrow-pit, exposes the subsoil under the levee to excessive pressure. If the borrow-pit is on the land side, the added weight of the levee and the opening of the porous strata permit a ready squeezing out of the subsoil moisture with consequent rapid settlement and slumping of the fill. If the borrow-pit is on the river side, high water causes a sudden increase in upward pressure, which cannot be dissipated because of the impervious continuous layer on the land side.

In the example of design which Mr. Buchanan illustrates by Figs. 8, 9, 10, and Table 3, the assumption of a cylindrical surface of rupture starting at the top of the slope is not necessarily the true failure picture. More often, failure occurs by slippage of a dome section, with a vertical surface intersecting the original slope. In the design of the foundations, the assumption is made that the added weight is distributed uniformly, no allowance being made for the lateral flow of the subsoil. As has been proved by experiments, the maximum added pressure is not under the highest point of the fill. Item (*e*), (see heading, "Foundations") giving the necessary base width (348 ft), assumes that a uniform added base pressure results from the levee load over the entire width of the base, that there is no lateral distribution of loading below the base of the levee, and that the strength of the foundation material is not affected by the loading above. None of these assumptions is true. Uniform added base pressure would result only from a uniform depth of fill, unlimited in all directions. There would be no lateral distribution of loading below the base of the levee only if the material had a zero internal friction coefficient. The strength of the foundation material is affected by the superimposed loading because of the added internal resistance resulting from the confinement by such loading.

It is unfortunate that the sudden decision to abandon the Passamaquoddy Project ended the study of foundations for rock-fill dams, as reported by Mr.

---

[57] *Journal of Applied Mechanics*, Vol. 4, September, 1937, pp. A97–100.

Hough. The report of the work done is of value for future studies, but the writer cannot agree that it has any value in regard to a solution of the foundation design for the proposed dams. The chief reason is that the later effect of the impervious blanket, a much greater weight than the rock-fill section, was not considered. Allowing the foundation material to re-adjust itself and build up resistance to support the rock-fill and then hope that the later addition of about 80 to 100 ft of impervious blanket fill on one slope of the rock-fill could also be carried by the original adjustment, is somewhat optimistic. References to the work of Carlo Barberis,[58] at Spezia, Italy, as well as to similar works[59] in Valparaiso, Chile, and also by Sakamoto and Takanishi[60] in Kobe, Japan, would certainly have been of assistance. In the foregoing three references, similar dams and wharves have been described built on mud or soft clay foundations by the aid of a "floating foundation" of fine sand pumped into place. The combination of mud and sand has proved a proper, safe, and economical solution of the problem studied by Mr. Hough. It may be of interest to mention that, in 1928, while making some studies for private finance groups for this same project, the writer made some designs and estimates for the dams required in connection with the Passamaquoddy Tidal Power Project, based on the work mentioned in the foregoing references. The results were much more economical than the sections illustrated by Mr. Hough.

From time to time, reports of, and papers sponsored by, the Committee of the Society on Earths and Foundations have appeared in *Proceedings*.[11] Except for this Symposium, the reports were optimistically heralding the advent of a new era in foundation engineering and the birth of a new soil science. The humility of approach in the 1937 reports, as so well exemplified by the paper by Professor Terzaghi, is refreshing; and it is well that the change of attitude has taken place. Too many practical and practising engineers were attempting to apply the published material to their work; and they were finding it of little help.

If the paper by Professor Terzaghi is to be taken as a criterion, the subject is in a new phase. Theoretical and laboratory investigations are relegated to second position; field investigations of completed structures must now be stressed so as to collect the necessary facts from which reliable theory may be deduced. This is opposite to the previously announced inductive theories which prophesied facts, such as settlements of unbuilt structures, and which too often required continuous adjustments to meet new data.

In order to be of value, complete descriptions of the structures must be presented with settlement readings. In this respect, the paper by Professor Terzaghi is somewhat remiss. For instance, in the example described with Fig. 45, the length, size, and spacing of the piles are not given. One is inclined to wonder why piles were used in that design. In Fig. 47(*b*), there appears to be a definite discontinuity in all settlement contours at the center division wall. An error in the H_3 reading seems to be one explanation of the impossible condition shown.

[58] XVI International Cong. of Navigation, 1935.

[59] *Bulletin*, Navigation Congresses, January, 1927, p. 33.

[60] XIV International Congress of Navigation, 1926.

In Fig. 48, the maximum settlement is a trifle more than $\frac{3}{4}$ in. For the broken up design, with piles of unknown and varying lengths, such a value is not unexpected.

In Table 6, it should be carefully noted that all the soils listed, except that for Building *H*, are not the usual materials on which spread footings are placed. This fact explains the great variations in settlements for points on the same structure. Buildings founded on sand or clay mixtures with loam, with base pressures between 2 and 2.5 tons per sq ft, should show some peculiar settlements.

The writer agrees that no reasonable soil examination can show all the variations in soil structure for a complete foundation design. Where soil conditions are uniform, expected settlements are easily guessed. Where soil conditions are not uniform, it is necessary to design the footings as the sub-grades are exposed by excavation. In one large structure, north of Chicago, Ill., borings indicated that at least three different clays would be encountered at the expected base of the footings. After a careful study of all the clays encountered in that vicinity, and comparable loading tests in pits dug into the three different clays (differentiated by their colors), load-bearing values were determined to give equal settlements. The lack of time prevented load-test studies extending over more than a few weeks. Design tables were prepared for the three assumed load values for the complete range of column loads. All footings could be made symmetrical spread footings for single column loads, which simplified the problem. As each footing pit was dug to sub-grade, inspection was immediately made, the color determined, and design requirements chosen from the tables. No unusual or unequal settlements have been noticed.

Much foundation trouble arises from a common error of placing a structure on the side of a slope, exposed to seepage or drainage effects and lateral movements. The error is evident when the structure is placed on a sloping surface, such as the side of a ravine or river bed. If the gap is filled with rubbish, ashes, or the usual municipal rubbish fill, the error is not visible, but still exists. In many cases, the fill makes the matter worse, because its consolidation causes a lateral flow which further tends to tip or slide the building foundation piers or walls.

Y. L. CHANG,[61] ESQ. (by letter).—Engineers in China who are confronted with a similar, but more complex, problem when building regulating dikes on the Yellow River, will be much interested in the paper by Mr. Buchanan. Because of traditional methods of construction and the limited financial support given to such large engineering projects, all dikes along the channel of the river could be built and maintained only by using earth of uniform quality at the site. About one-fourth of the total area of the Yellow River basin consists of loess which is a very fine calcareous loam composed of an admixture of minute but considerably flaky particles of quartz and clay. This material is mostly an impermeable soil. The loess has a porosity exceeding 45%, enabling it to hold considerable moisture, and the fineness of the openings facilitates capillary action. Such material cannot be approved for dike construction; and, hence, the problem is reduced to a question of how to design the cross-section of the dike to obtain a degree of safety consistent with minimum cost. Mr. Buchanan certainly makes such an aim possible by a procedure so simple that every engineer can understand it.

---

[61] Shanghai, China.

In the report of the Committee of Experts of the League of Nations,[62] five causes of the failure of the dikes on the Yellow River are given, the most important being substantially as follows:

> "A breach may be produced when the body of the dike is saturated with water, either by direct infiltration from the water face or by indirect infiltration through the more permeable layers at the base. The cohesive resistance of the earth is reduced, while at the same time hydraulic pressure, accompanied by seepage, occurs. Its effect is felt when the base of the inner side of the dike collapses. The dike itself is thus weakened, and a breach may result. This case arises especially when the high-water stage lasts a long time or when the dike is of inadequate construction or composition."

With this statement in mind, one can be assured that a failure of such dikes is mainly attributed to the infiltration of water through the dike itself and through the foundation beneath. The writer wishes to discuss Mr. Buchanan's paper as applied to conditions when the dike is subjected to infiltration through side slopes, and foundation, and as applied to the control of seepage.

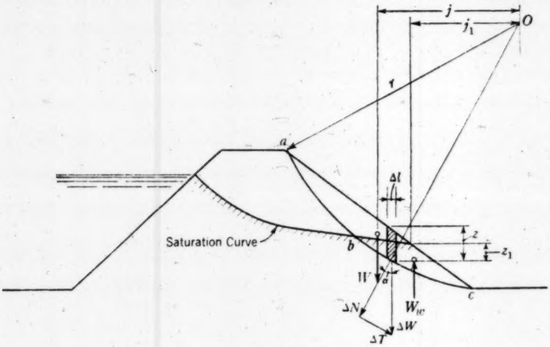

FIG. 63

Side Slopes.—Presumably, Equation (1), which expresses the factor of safety against sliding in terms of the shape of the dike and the frictional and cohesive forces of the material, is for a dry slope. For a dike subject to seepage, such as that shown in Fig. 63, Equation (1) can be written:

$$\text{Factor of safety} = \frac{c\,l + \tan\phi \sum_{0}^{n} \Delta l\,(w\,z - w_w\,z_1)\cos\alpha}{\sum_{0}^{n} \Delta l\,(w\,z - w_w\,z_1)\sin\alpha} \quad \ldots\ldots (20)$$

in which, ϕ, the angle of internal friction, is assumed to be the same for dry or wet material; w_w and w are the unit weights of water and soil, respectively;

---

[62] Report by the Committee of Experts on Hydraulic and Road Questions in China, League of Nations, Geneva, 1936.

and l should be the arc length, $a\,b$. If the entire dike is assumed to be saturated, the term, $c\,l$, vanishes. A similar equation for the factor of safety against sliding can be expressed in the form of moment instead of force:

$$\text{Factor of safety} = \frac{r\left[c\,l + \tan\phi \sum_{0}^{n} \Delta l\,(w\,z - w_w\,z_1)\cos\alpha\right]}{W\,j - W_w\,j_1} \dots\dots (21)$$

in which W_w and W are, respectively, the total weights of water and soil within the arc of sliding, $a\,b\,c$. The smaller value determined by Equations (20) and (21) gives the safer criterion for stability.

Mr. Buchanan's treatment of the hydrodynamic effect of seepage on stability of slopes is especially creditable. In testing a model embankment of loess the writer has observed a slide near the toe despite the fact that the factor of safety, as computed by Equation (21), exceeded 1.78 for $c = 0$. The writer believes that the hydrodynamic force in a saturated slope plays an important part in starting a slide.

Foundations.—A breach may occur in the dike when its foundation is so saturated that the underlying material settles or is displaced. In this state, the foundation could be considered more plastic than elastic. Studies of such failures due to over-stressing the foundation have been presented by Mr. Hough. Attention should be called to the fact that there is a horizontal, as well as a vertical, load on the foundation when the dike is resisting the pressure of high water. For earth or rock-fill embankments this pressure can be transmitted to the foundation only in the form of a shearing force. In investigating the stability of dike foundations this horizontal hydrostatic load requires as careful study as the vertical dead load.

Control of Seepage.—Mr. Buchanan has studied the problem of the seepage through a dike with the aid of Professor Gilboy's formulas as given by Equations (2) and (3). The writer has compared this method with that suggested by Pavlovsky,[63] in the case of model dikes of Chinese loess, and has found that the latter coincides more nearly with experimental results. The latter also affords a simple procedure for designing the best section. A study of this method reveals that the permeability factor, K, cannot be constant in a newly built dike in which the seepage rate may be quite high.

The essential points demonstrated by this method are:

(1) A dike subjected to considerable infiltration over a long period of time is at its most dangerous stage; its stability is undoubtedly reduced by the hydrodynamic force of the water seeping through it.

(2) In estimating the shearing failure of the foundation of a dike the horizontal transmission of water pressure should not be neglected.

(3) Theoretically, the best method of reducing infiltration and lowering the saturation line of a dike is to increase the flatness of the wet surface.

(4) The orientation of flaky particles of a material by capillary flow probably plays quite an important part in the variation of permeability with time.

[63] 1er Congrès des Grand Barrages—Scandinavie, Vol. II, 1933; see, also, "The Percolation of Water Through Earth Dams," by N. N. Pavlovsky; tr. by Andreas Luksch; U. S. Bureau of Reclamation, Denver, Colo.

Charles Senour,[64] Esq. (by letter).—In view of the interest in levee construction engendered by the fairly recent floods of New England and of the Ohio River Basin, Mr. Buchanan's paper is most timely. The latter flood (January, 1937), after reaching the Mississippi River, was carried to the Gulf between levees, and one aftermath of its successful passage has been a number of requests for information regarding standard practice in levee design and construction on the Lower Mississippi. This has been given gladly, of course, but with occasional misgivings as to its applicability, particularly in the department of design, to the problems of distant flood plains. The Mississippi River levee is the product of years of experience with the specialized problems of the lower alluvial valley. (Fig. 2 depicts its metamorphosis from the simple trapezoidal cross-section of 1882 through the several types of banquette section to the more satisfactory trapezoidal section of the present day.) There is one school of thought, and a rather large one, that holds to the view that the conditions surrounding levee construction make levee design unavoidably an empirical matter. Experience is invaluable, of course, but unless it is supplemented with a knowledge of the underlying principles that govern soil behavior, experience is distinctly at a disadvantage when it becomes necessary to design in a field not covered by prior operations. It is this inherent shortcoming that the paper by Mr. Buchanan seems particularly helpful in overcoming.

Until the comparatively recent past, there has been little to draw upon except experience. The science of soil mechanics is itself quite young, and its application to the field of levee design has lagged considerably behind its application to the related but, in many respects, dissimilar problems of earth dams. A levee is an earth dam, of course, but it is a very specialized form and the circumstances normally surrounding its construction are far less favorable to precision in design than are those which attend the building of a dam.

The main levees of the Lower Mississippi River are as a rule several hundred miles in length, and are tied into high ground (that is, they have an abutment) only at the up-stream end, the basin being left open at the lower end for drainage. The embankment skirts the river edge of a flood plain whose width may be 50 or 60 miles. This plain is composed of alluvium to great depths. Much of it has been worked over by the river, whose migrating meanders, cut-offs, and bank-caving and bank-building operations have produced a geologic hodgepodge of which the ingredients are clay, sand, and silt, with some vegetable matter. These ingredients occur singly and in an endless variety of combinations which follow no pattern and apparently recognize no law except that of change.

It is evident that one cannot very well haul upland earth to build his levee of homogeneous clay; nor can he afford to haul laterally from the possibly better soils of the flood-plain's distant hinterland. If he did so, furthermore, he still would have to found the levee upon the heterogeneous mass of which the area adjacent to the river is composed. The problem, therefore, is to build from the materials immediately at hand, and since these vary so erratically as to make selection seem rather impractical in a majority of cases, it has appeared advantageous to procure the material as close to the embankment as safety permits, so as to shorten the haul. The borrow-pit is usually on the river side, and is quite apt to encounter rather pervious materials after the surface strata are removed. Since these porous materials will be exposed to full hydrostatic head once they are uncovered, it is inadvisable to expose them very close to the embankment, and it is, of course, desirable to utilize as small a proportion of the more pervious materials in the construction as circumstances permit. Deep excavation close to embankment also invites foundation troubles. From the practical standpoint, furthermore, it is not safe to count on going very deep because of moisture.

---

[64] Prin. Engr., Mississippi River Comm., Vicksburg, Miss.

With these conditions laid down, the best solution has seemed to be to construct from shallow side borrow-pits an embankment of sufficient bulk to compensate for any shortcomings with respect to homogeneity and compaction. When teams were the instruments of levee construction, compaction was automatic, but the size and quantity of construction rapidly expanded beyond the ability of teams to handle alone, and much of the system was completed or under way prior to the comparatively recent introduction of trucks and tractors as important tools. Much yardage has been placed by draglines equipped with buckets of capacities of 3 to 8 cu yd, and tower machines handling buckets of from 10 to 15 cu yd. Machinery of this type (largely inspired by the needs of levee construction) handles earth very efficiently within the limit of its reach, which for the tower machine, incidentally, is about 1 000 ft. Neither by the tower machine nor by the dragline is any deliberate attempt made to compact the fill.

No effort is made to control moisture content, in the sense of attaining the optimum. The susceptibility to wide seasonal variations in moisture of pits adjacent to a river whose range in stage is about 50 ft and the necessity for utilizing the working season to the best advantage had made precise moisture control appear unattainable. A limiting steepness of construction slopes (1 on 2.8) is often prescribed by the specification, especially when much clay is present. The contractor, however, is permitted to use fairly damp earth, subject to his own risk (and subject to warnings from the inspector when he appears to be taking chances). If a slide occurs from the use of material that is too wet, the contractor is required to cut out and remove the embankment to and beyond the sliding surface and to restore it with satisfactory material —all at his own expense. Since this is quite costly, it operates as a deterrent to the use of earth that is dangerously damp.

When the levee is built with hauling equipment it is constructed in layers, with an allowable thickness for vehicles hauling loads of 5 cu yd or more, of 5 ft, and for equipment hauling loads of less than 5 cu yd, 3 ft. When draglines (boom machines) or tower excavators are used, layer construction is not required. In all cases the contractor is required to build to a gross cross-section from 8% to 25% higher vertically at all points than the net cross-section, for which latter alone he receives payment. This surplus is designed primarily to compensate for the lack of compaction, the larger shrinkage allowances pertaining to those methods of construction which involve the least compaction. The shrinkage allowance seeks to insure a levee permanently to the grade desired even with some consolidation of foundation. It is, therefore, liberal.

A series of shrinkage observations made upon levees constructed in the Lower Mississippi Valley has been plotted in Fig. 64, in which the volume of

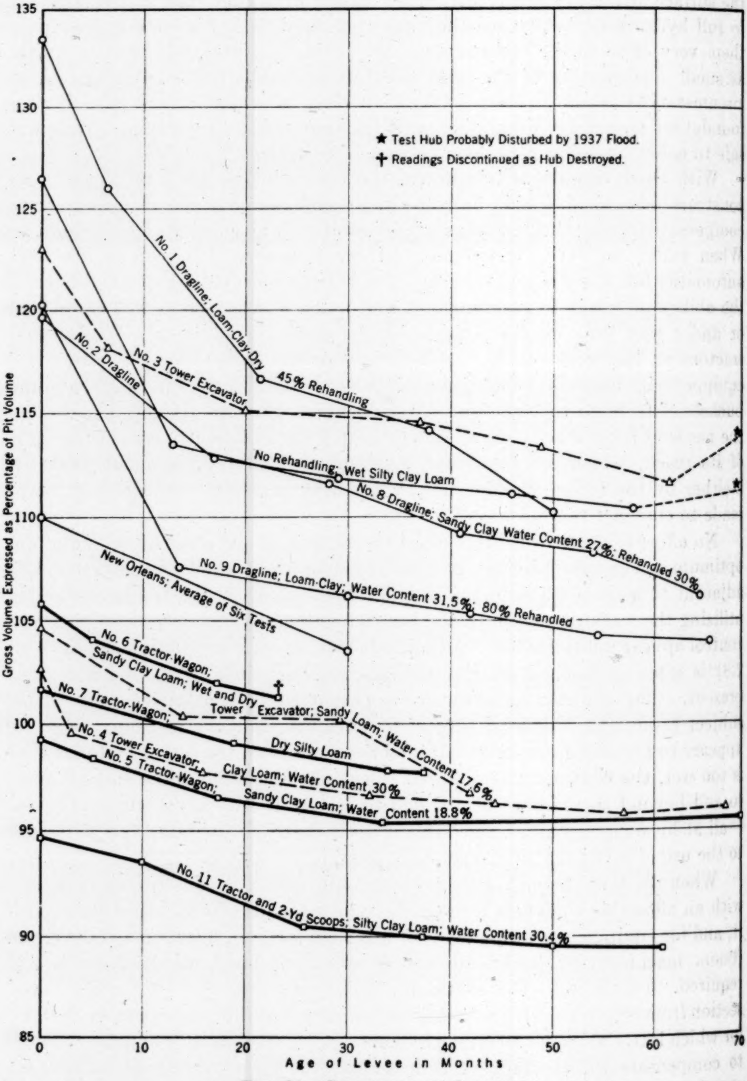

FIG. 64.—SHRINKAGE OF LEVEES

the embankment of various ages is expressed in terms of the volume of the borrow-pit from which it was constructed. Each curve represents a series of experiments on a single unit involving from 8 000 to 100 000 cu yd, except that labeled "New Orleans" which represents the unweighted mean of a group of six experiments on dragline-built units ranging from 160 000 to 660 000 cu yd in volume. In this latter case the results varied so little that individual plotting appeared confusing (from 1.05 to 1.15 borrow-pit volume at the time of completion, and from 1.08 to 0.998 at the end of 30 months).

The curves indicate a pronounced superiority in density of the tractor-built units over that of the dragline-built units, the tower excavators being represented in both groups. One method of construction with tower excavators is to "base in" the fill with one machine and mount a second, following machine upon the material so placed, to complete the cross-section. When this is done, the influence of the tremendous weight of the equipment, supplemented by its vibrating effect, apparently tends (in some soils, at least) to attain tractor densities in the fill.

On a big levee, tractors, draglines, and tower machines all may be engaged concurrently in placing different parts of the cross-section. The work is awarded by contract to the lowest responsible bidder, and there is no method of forecasting before the bids are opened who he may be or what method he will choose to adopt. Furthermore, the vagaries of weather and river stage may force him to modify his original plan from time to time, and each time he does so, the composition and density of the fill are changed somewhat.

Fig. 65 shows the theoretical shape of a standard borrow-pit. The depth depicted is the limiting value allowed by the specifications and the width, therefore, must be varied to the extent required by the river stage and water-table, which may necessitate much shallower borrow than that permitted by the specifications. Fig. 65 also shows a series of pit borings and groups of borings taken at the center line and the toe of a completed levee to illustrate the variability in composition of borrow, foundation, and embankment.

In general terms, levee design on the Lower Mississippi has concerned itself with compaction only from the standpoint of shrinkage allowance to insure a structure permanently to the grade and cross-section desired, and with moisture content only to the end that slides or sloughs shall not develop. As to character of materials, it recognizes three groups—sand, loam, and clay, as described in Table 1 of the paper by Mr. Buchanan. Most of the levees built are of the "loam" cross-section, "loam" being used to designate all mixtures containing less than 75% of either sand or clay. The loam cross-section has a base width equal to ten times the design head against the structure. It seeks ideally to prevent outcrop of seepage line on the rear slope by having the slope flat enough to contain the seepage line that will develop during the period of flood use. Of course, where the foundation is less pervious than the embankment, the seepage line will inevitably outcrop if the flood lasts long enough. Upon a stream such as the Mississippi it is essential that slopes be flat enough to be stable under such conditions.

In essence, the levee represents an embankment which relies upon great width rather than great density. It is feasible, physically, for the duty to which a levee is subject, to make the substitution, and in the case of the Lower Mississippi a consideration of local physical conditions and costs has caused

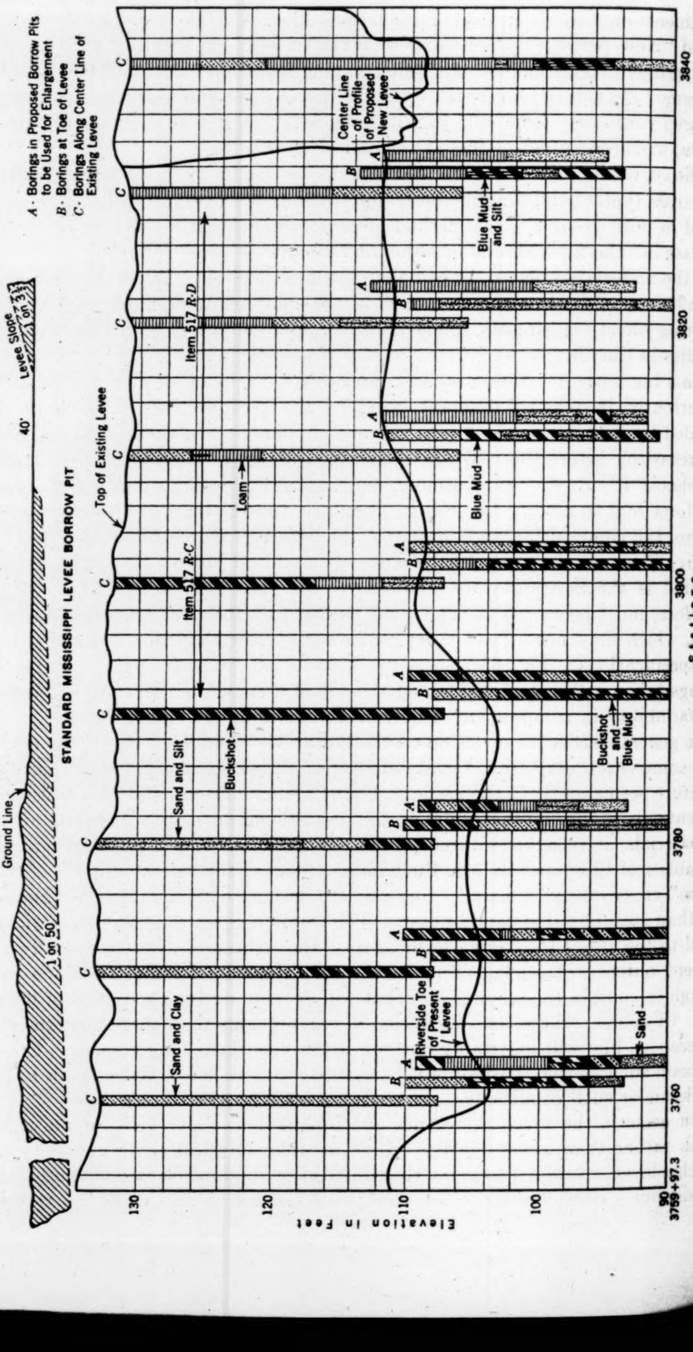

FIG. 65.—BORINGS BELOW GRAND LAKE

that to seem unquestionably the proper course. The average contract cost of the approximately 567 000 000 cu yd so placed from 1928 to June 30, 1936, has been about 18.75 cts. It cannot be doubted that proper compaction, if practicable, would permit some reduction of cross-section where the foundation was of a character to permit it. It should be borne in mind, however, that the structure rests upon a foundation which is alluvial to great depths, and that the passage of water beneath the levee may cause as much concern as the passage of seepage through it. The base should be comfortably wide as a rule.

A levee is built between floods and is always more or less of an emergency undertaking. During the height of the levee program, placement was at the rate of about 612 000 cu yd per day.

From the foregoing it is apparent that unless current construction practices are revised the design of levees by the principles of soil mechanics can scarcely achieve the exactness of earth-dam design. However, although practical difficulties are numerous, they do not appear insurmountable.

With the methods of construction normally permitted, for example, a density considerably less than that of the undisturbed borrow material may characterize the freshly built levee but it would seem that in designing an allowance could be made for this condition. In this connection it is well to remember that soils high in clay content, when fairly dry, tend toward lumpiness, particularly if dragline construction is utilized and the resultant percentage of voids in the fill is likely (temporarily) to be large, thus tending to offset the effect of the greater impermeability of the material itself. Curve 1, Fig. 64, illustrates such a case. This is a practical aspect of the matter which might prove troublesome if the width of cross-section were reduced too greatly on the basis of the impermeability displayed by borrow-pit samples. Obviously, the problem of design would be simplified if circumstances permitted compaction to be assumed or required. Where they do not so permit, caution is indicated in cases where the condition just described is likely to be encountered. Such levees improve rapidly with age but they must be ready and able to hold out floods the first year of their existence.

Study of borings in the borrow area will indicate the worst possible average composition that the levee can have. In deciding upon this feature and upon the questions raised by the preceding paragraph it would be well to consult some one familiar with the practical aspects of construction. It would also be well to consider, from knowledge of the local geology, the likelihood of encountering large enough deposits of any one unfavorable material to justify making that single type the sole basis of design.

The assumption of an impervious base should always insure an error on the side of safety in so far as seepage through the cross-section is concerned provided, of course, that the governing pit material is properly chosen and its observed permeability properly adjusted to compensate for lack of compaction. The partial or even complete disregard of cohesive strength in cases in which high water-content of cohesive borrow is at all likely should fully compensate for possible use of wet material in construction.

By familiarizing himself with local conditions, and adjusting his various allowances to meet them, the designer should be able to produce structures that will be both safe and economical. He should particularly guard against the temptation to produce too economical a structure, however, and, if possible, he should work "hand in hand" with the man of levee experience. Although the writer does not subscribe to the view that experience is the only guide in levee design, he is far from undervaluing it.

The designer cannot afford to ignore certain practical considerations not directly connected with soil mechanics. For example, levees should be maintained in sod, unless they are paved; hence the side slopes should be flat enough to permit the use of mowing machines, and to avoid excessive damage from rain and waves. If the structure is more than a few feet high the slopes for practical purposes should probably not be steeper than 3 horizontal to 1 vertical. In many cases, this may produce a section in excess of that indicated to be necessary by theoretical analysis.

The method of design outlined by Mr. Buchanan assumes an impervious foundation and a flood of great enough duration to develop fully the ultimate flow net. This is probably prudent on a stream such as the Lower Mississippi whose flood hydrograph may cover several months; but for lesser streams where the flood may gather and disappear in the course of a couple of weeks, or even days, it may result in over-design. The seepage behavior of the earth dam described by Mr. Buchanan indicates that for similar soils, similarly placed, the question of seepage can probably be omitted as a design criterion if the floods to be expected are brief, but other cases arise in which it seems unsafe to assume that the matter of seepage can be dismissed, yet in which the assumption of full development of seepage seems too pessimistic. It is felt that further research regarding the rate at which the flow net develops is needed to "round out" the equipment of the levee designer.

The main-line levees on the lower river were matured as to general design before the science of soil mechanics was sufficiently advanced to lend much aid, and, as emphasized by Mr. Buchanan, analysis of the adopted design does not indicate any theoretical need for its revision. No doubt, soil mechanics will play an increasingly important part in the design of levees now in prospect as adjuncts to the basic system.

It has also found a useful field in connection with the prevention or correction of foundation failures in the main levee system. Contrary to popular opinion, most of the levee line experiences no serious foundation trouble. There is a consolidation of base in practically all instances, but this is not harmful unless it becomes excessive.

Serious trouble often threatens, however, where the levee crosses (as it unavoidably must at times) an old lake or channel that has filled with sediment. In such cases special treatment by way of flattened slopes or false berms is necessary and, in the opinion of the writer, the science of soil mechanics offers by far the most rational if, indeed, not the only rational, approach to the mportant matter of their correct design.

DONALD M. BURMISTER,[65] ASSOC. M. AM. SOC. C. E. (by letter).—The Symposium reflects the recent and important advances which have been made in the practical applications of soil mechanics to the study and design of earth structures. This new technique should include not only the analysis of earth structures for stability but it should carry the entire study of such problems from the preliminary soil investigations to the results of experiences accumulated during the construction of the work. The preliminary soil investigations on the different borrow-pit soils, from which suitable materials can be excavated economically, have an important bearing not only on the construction but also upon the decision as to the type of dam to construct, the dimensions of the sections, and the selection of stable slopes.

---

[65] Asst. Prof. of Civ. Eng., Columbia Univ., New York, N. Y.

The grain size analysis, to which Mr. Dore refers, has constituted an important soil test on every earth dam project, but its value has been somewhat limited because the information obtained was, primarily, of a qualitative nature. The writer has found that such curves can also be adapted to yield valuable information of a quantitative nature, for design and control purposes.

Grading Curves.—The size characteristics of soil may be defined in terms of three independent factors, which correlate many physical facts and bring them into a more unified and consistent pattern: (*a*) The degree of fineness (the position of the grading curve on the scale of fineness); (*b*) the type of grading curve (normal, skewed, or irregular distribution of sizes); (*c*), the range of particle sizes. In his studies, the writer has expressed the degree of fineness in terms of a mean grain size, which is defined by the length of the equivalent rectangular area and which is easily obtained by planimeter or by the summation of elementary areas. This mean is actually a weighted geometric mean and is the logical one to use in relation to a semi-logarithmic plotting of the grain size analysis.[66] The mean grain sizes for the average borrow-pit, beach, and core materials of the Quabbin Dike are given in Fig. 66.

A description of grading curves as to type, as shown in Fig. 66, furnishes a basis for interpreting, correctly, the influence of the distribution of particle sizes on density. Type *A* is a narrow-range material represented by a nearly vertical grading curve. Type *B* has a statistical normal distribution of grain sizes, or nearly so, as illustrated in Curves 3, 4, and 5 of the core materials of Quabbin Dike in Fig. 66. Type *E* is predominantly fine with a little coarse material and is skewed toward the fine fractions, as shown by Curve 2 of the beach material. Type *F* is predominantly coarse with some fine material and is skewed toward the coarse sizes as shown in Curve 1 of the beach material. Type *D* material, which is typical of 80% of the borrow-pit materials of the Quabbin Dike, is a mixture of two fractions, one very coarse, and the other quite fine. Such materials are always characterized by a hump in the grading curve and they are typical of certain soils in glaciated regions. It is interesting to note that the percentage corresponding to the mean size is not now an arbitrarily defined constant quantity, but varies with the type of grading curve in a characteristic fashion and in reality represents a skew factor, 45 to 55% being typical of the Type *B* grading curves, 55 to 65% of the Type *E*, and 35 to 45% of the Type *F* grading curves.

Soils may be alike in the foregoing important respects but may vary in the range of particle sizes. The writer, therefore, recommends that the size characteristics be defined finally in terms of the range of sizes, the designation of

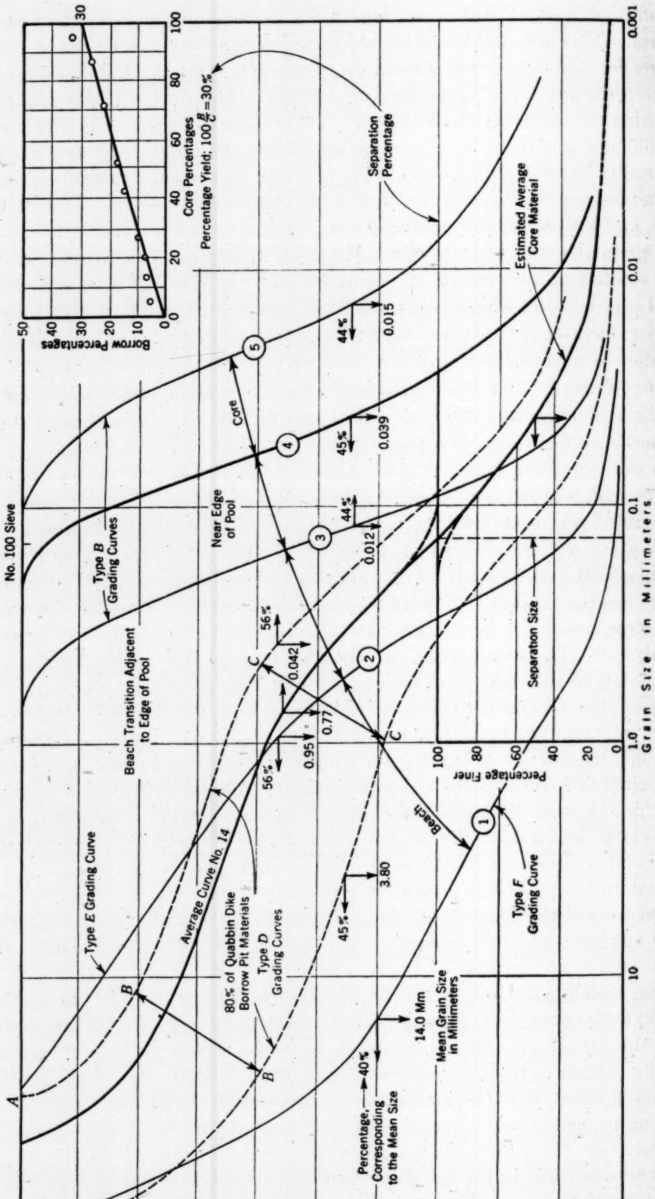

FIG. 66.—MATERIALS OF BORROW-PITS, BEACHES, AND CORE OF THE QUABBIN DIKE, SHOWING: (*a*) MEAN GRAIN SIZE; (*b*) CORRESPONDING PERCENTAGE; (*c*) TYPE OF GRADING CURVE; AND (*d*) ESTIMATION OF YIELD OF CORE MATERIAL

range to take in the entire curve being conveniently expressed as the ratio of the 95% to the 5% size. Thus, there is an important distinction between the shape of the grading curve and the range of sizes, which must not be confused. There is an interesting, characteristic, and progressive decrease in the range of sizes from the outer slope toward the center of the core pool.

Core Materials.—The sluicing-bin method described by Mr. Dore for estimating the yield and quality of the beach and core materials from a particular borrow-pit material or mixture of materials is a valuable one. The yield of core material may also be estimated by a simple analysis[66] of the aforementioned grading curves of borrow-pit materials, which, for eight dams, shows that there is quite a definite and complete separation point of materials by the hydraulic process at about the No. 100 sieve. The approximate percentage of yield of the average borrow-pit material of the Quabbin Dike is obtained in Fig. 66 by plotting percentages finer by weight of borrow material against those of the average core material (Curve 4) for a number of corresponding particle sizes, as shown in the insert.

The slope of the linear part of the curve defines the yield (30 per cent). The grading curve of the core material may then be fitted to the fine portion of the average borrow-pit material by proportional dividers, 30% becoming 100%, as shown. The yield and approximate separation size for nine dams are listed in Table 9. Thus, a study of curves of borrow-pit materials, for example, using the No. 100 sieve as the separation size, would indicate which materials to select or what mixtures to use in order to give the theoretical core width at any height, in the dam, as indicated in Fig. 18, as well as the approximate grain-size distribution of the average core material.

* See Table 4. †Hydraulic-fill dams. ‡Semi-hydraulic fill dams.

A study of the data on core materials of existing dams in Fig. 16 reveals a number of significant facts: (1) The core materials of practically all existing dams are typically *B* Type: (2) all the core materials have about the same range of particle sizes, and the range is relatively narrow; and (3) the major distinguishing characteristics then are the degree of fineness as defined by the mean grain size and the clay content, which furnish a clue to the quality of the core material that can be washed out of any given borrow-pit material. It is important to note the characteristic gradation of the core material in Curves 3, 4, and 5 for the Quabbin Dike. However, physical factors other than grain-size distribution and fineness of the material passing the No. 100 sieve, may be of much greater importance. The liquid limit and plasticity index of the fine fraction furnish a more direct and useful index of the character and quality of the core material than can be obtained by the hydrometer test,[66] the practical limits being: Liquid limit, 15 to 40; and, plasticity index, 0 to 20. Values greater than these would indicate undesirable qualities in the core material and would indicate that difficulty might be experienced during, or subsequent to, construction; or it would dictate that fines should be wasted, where practicable.

---

[66] For a full description of such grading curves, see "A Study of the Physical Characteristics of Soils, with Special Reference to Earth Structures," by D. M. Burmister, Assoc. M. Am. Soc. C. E., *Bulletin No. 6*, Research Laboratory, Dept. of Civ. Eng., Columbia Univ., June, 1938.

Beach Materials.—The quantity of beach material that can be obtained from a given borrow-pit material can be estimated from the yield on the No. 100 sieve. The quality of the beach material, which is the most important consideration for stability of the entire structure, is determined, primarily, by the "grading density relations" of the materials deposited in the different sections of the dam. Arthur Casagrande,[67] Assoc. M. Am. Soc. C. E., has shown that the density of a material has an important influence on the angle of friction and on the stability of materials placed in embankments. The density of a given soil will lie between the limits of some loose condition and some very dense condition, whether placed artificially in an embankment by some mechanical equipment, or by the hydraulic process. Investigations of the grading-density relations[66] of materials show that the distribution of particle sizes exerts a most important influence, as noted in Fig. 67.

The mean grain size of each type of material, as the range of particle sizes varies, is indicated on the grading curve. The loose and dense conditions for each material are then plotted directly below on the vertical line through this mean grain size. The conclusions on the grading-density relations are summarized as follows:

1.—Degree of Fineness.—For the same type of grading curve, range of particle sizes, and particle shape, the density decreases with fineness approximately according to the trend of the zone lines.

2.—Type of Grading Curve.—Other factors being equal, Type *F* materials are invariably the most dense, and approach the ideal grading for maximum density. Types *B* and *E* are of intermediate density; and Type *A* materials are always the least dense.

3.—Range of Particle Sizes.—The most dense condition, other factors being equal, is obtained by the material having the greatest range of particle sizes. The narrow-range Type *A* materials are always the least dense.

4.—The Spread Between the Loose and Dense States.—There is a characteristic spread between the loose and dense states for each material.

5.—Particle Shape.—The effect of angularity of particles is always to decrease density in both the loose and dense conditions.

Fig. 67 is a graphical expression of the fact that each material can exist in a certain loose condition in its natural state or in embankments and can be

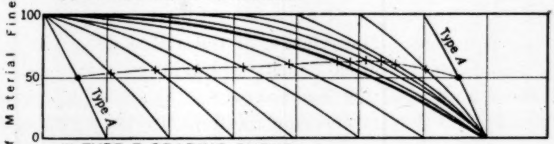
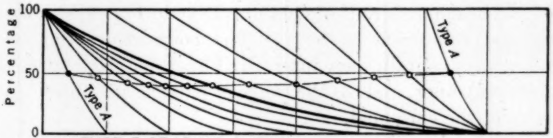
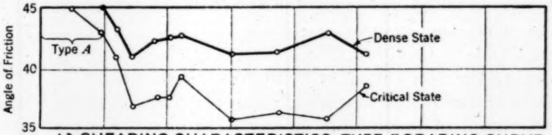
(a) TYPE *B* GRADING CURVE



(b) TYPE *E* GRADING CURVE



(c) TYPE *F* GRADING CURVE



(d) SHEARING CHARACTERISTICS; TYPE *F* GRADING CURVE

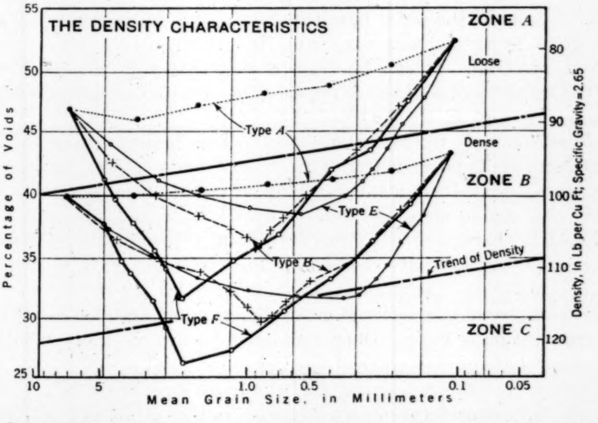


FIG. 67.—GRADING-DENSITY RELATIONS OF DRY GRANULAR MATERIALS, SHOWING EFFECT OF TYPE OF GRADING CURVE AND RANGE OF GRAIN SIZES

compacted only to a certain dense state by the particular method of placing, with a large or small spread between them. The shearing characteristics of Type *F* materials, for example, are given in Fig. 67 to show the influence of these factors. The coarse, narrow-range Type *A* materials are practically always at about the critical density[67] with a relatively high angle of friction, of about 45°, but as the range of particle sizes increases, density has an important influence, the limiting values for the angle of friction being about 37° for the critical density and about 42° for the dense state. These values appear to be independent of the degree of fineness and of the range of particle sizes, where the range increases. The relation of the actual density in place, of a given type of material to its critical density will indicate which angle of friction will control the stability of the embankment. Professor Casagrande[67] has shown that the critical density-shearing relations are very important factors in stability, particularly for certain fine-grained, saturated, cohesionless soils.

A study of the beach materials of Quabbin Dike in Fig. 66 reveals a number of interesting and significant facts: (1) The coarsest fractions, which are deposited first, always contain some intermixed finer material; (2) the materials become progressively finer; and (3) the range of particle sizes becomes narrower toward the edge of the core pool.

The question may be asked, whether the gradations of beach materials in Fig. 66 (Curves 1, 2, and 3) are typical of the hydraulic process or whether they are typical of what the hydraulic process will separate out of the Type *D* borrow-pit materials of Quabbin Dike. Keeping the foregoing three factors in mind and holding the No. 100 sieve point fixed as the lower limit of the range of particle sizes of the beach material, an upper limit is moved progressively along the 80% band of borrow-pit materials from the coarsest sizes in some proportion to the distance from the discharge point on the beach. From Point *A* to Point *B* the outer beach material must be typically of the coarse, wide range (*F* Type) and may vary from 20% to 50% of the bulk of the Type *D* borrow-pit material. It can be readily seen that this part of the curve is similar to Curve 1 and is of the *F* Type. The density for such material may be estimated from Fig. 67, by the trend of the zone lines, to be greater than 130 lb per cu ft as the tests by Mr. Dore show. This indicates that the hydraulic process places a Type *F* material in a very dense state. In the Quabbin Dike these materials form a substantial part of the entire beach.

When the coarse sizes are practically all deposited, the beach material must change in character from Point *B* to Point *C* to typically the finer *E* Type of material, having a density of about 115 to 120 lb per cu ft, and representing about 15% to 25% of the whole. Then, from Point *C* toward the edge of the pool the character of the material must change again and become typically the fine, narrow-range, *B* Type with an estimated density of 110 lb per cu ft, or less. It is evident that the character of the beach material is determined to a large extent by the type of grading curve of the borrow-pit material.

For stability considerations an angle of friction of 45° for the very coarse, Type *F* outer beach material, is to be expected, but as the materials grade into the finer *E* and *B* Types, the density not only decreases, but these finer materials may or may not be placed in a dense state by the hydraulic process and may even be less dense than the critical. The angle of friction may then be considerably less than 45°, and this would become an important consideration in the stability of the structure. However, in the Quabbin Dike an angle of friction of less than 30° was actually required in the beach material as a whole for stability, because the beach section was large.

It is believed that the information from soil investigations, together with the experiences accumulated in the construction of earth structures, when summarized, correlated, and made generally available, would be of permanent value as a guide for future earth dam construction. This means, however, the careful and complete description and identification of the materials used, and the determination of their density, shearing resistance in place, and behavior, so that the experiences gained in one locality may be of practical value in solving the problems in another.

DONALD W. TAYLOR,[68] ASSOC. M. AM. SOC. C. E. (by letter).—The civil engineer who has a general interest in soil mechanics will find much of value in the paper by Mr. Buchanan, which in addition touches upon a number of details of importance to those whose main interest is in this subject. Outstanding among such items is the effect of seepage forces upon stability of embankments. It may be noted that the effect of seepage may be handled by either of two methods which are closely related. It can be demonstrated that the vector sum of the total weight (both soil and water) of any mass of saturated soil and the resultant of all water pressures along its boundary is equal to the vector sum of the submerged weight of the mass and the resultant of all forces due to seepage within it. The same relation may be re-stated as follows: The resultant boundary water pressure equals the vector sum of the resultant seepage force and full hydrostatic uplift. Mr. Buchanan has suggested the summing of seepage forces throughout the mass whereas other investigators have preferred the summing of boundary pressures. A paper[69] by the writer presented in 1937, suggests an approximate method for simple embankments which involves no complicated summations.

One statement which may be misleading appears in this paper (see following Fig. 3), concerning the force, F_f. The statement as given is true only if the figure, *e f d b*, is square. Since in general the figure is not square, it should be stated that "F_f is the force tending to cause displacement in the direction of flow, equal to h_f times the unit weight of water, times the average area surface, $\frac{1}{2}(f\,b + e\,d)$, of unit thickness."

LEE H. JOHNSON, JR.,[70] JUN. AM. SOC. C. E. (by letter).—In a clear and straightforward manner, Mr. Buchanan has presented a general method of applying soil mechanics to the design of earth levees. He is to be commended for this important contribution to the small group of publications of scientific methods for the design of earth structures. He closes his paper with the remark: "For new units involving materials with which there has been no experience, savings in time and cost are possible through the application of soil mechanics." The writer wishes to cite an instance from his personal experience in which there has been such a saving in cost.

[69] "Stability of Earth Slopes," by Donald W. Taylor, *Journal*, Boston Soc. of Civ. Engrs., July, 1937.

[70] Acting Dean; Prof. of Civ. Eng., School of Eng., Univ. of Mississippi, University, Miss.

One of the problems with which the U. S. Engineer Office, at Mobile, Ala., has been faced is that of protecting the City of Rome, Ga., from recurrent floods on the Oostanaula and Etowah Rivers which unite in the heart of the city to form the Coosa River. These floods are of much shorter duration than the floods on the Mississippi River and on other large streams. A study of gage heights for floods that occurred during a period of fifty years shows that high water during a flood on these rivers lasts only several days.

A preliminary design of the protection works and incidental structures was prepared and submitted for approval in the form of a preliminary report. The protection works provided for in this report consisted mainly of levees with a land-side slope of 1 on 4 and a river-side slope of 1 on 3. These slopes were chosen on the basis of a general knowledge of the soil in the vicinity of the river banks at Rome, and the short duration of the high water.

The preliminary report was approved and the final design authorized. It became feasible to analyze the soil to be used in the construction of the levees. Borings were taken along those sections of the banks of the Oostanaula and Coosa Rivers, which are to be used as borrow-pits for the levee material. Representative samples were sent to the Soil Laboratory of the U. S. Waterways Experiment Station, at Vicksburg, Miss., for analysis. There, the samples were classified by means of mechanical analyses and such properties of the soil as angle of internal friction, cohesive strength, and coefficient of permeability were determined. A study of the stability of earth slopes composed of these materials, using the results of the laboratory tests, established the fact that the materials possessed sufficient shearing resistance to stand on a 1 on 3 slope with a satisfactory factor of safety. Furthermore, these materials were sufficiently impervious, by a very large margin of safety, to prevent flood waters from seeping through in the short time they were against the levees and threatening the stability of the land-side slope.

In view of these facts, the recommendation was made, and accepted, that the levees at Rome be built with a slope of 1 on 3 for both land-side and river-side slopes. This produced a saving of about 80 000 cu yd of earth and about $30 000, or more, in the cost of the levees. This example furnishes a striking illustration of the value of soil mechanics when applied to the design of levee units in new and unknown material.

The writer acknowledges his indebtedness to V. K. Wagner, Engineer in Charge of Design and Specifications, U. S. Engineer Office, Mobile, Ala., for making available and authorizing the use of this information.

GREGORY P. TSCHEBOTAREFF,[71] M. AM. SOC. C. E. (by letter).—It is interesting to note that three of the four papers of the Symposium treat the related subjects of levees, dikes, and embankments, and only one paper deals with foundations of bridges and buildings.

It would appear that this relationship reflects the actual situation. The efforts of most research scientists in the field of practical application of Soil

---

[71] Asst. Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

Mechanics are directed toward solving problems of water-retaining works for the construction of which soil is used as an engineering material. The comparatively high total expenditure on such works, as well as the risk of particularly extensive damage to life and property in case of their failure, has led to greater research facilities being provided for this branch of the new science. The use of disturbed and recompacted soil material on actual constructions of the foregoing type facilitates the duplication of these field conditions in the laboratory. Furthermore, from the point of view of the organization of the necessary studies, this branch is not handicapped by the wealth of minor technical details and by obstacles created by professional and by misguided competing commercial interests, all of which are generally present when studies of foundations of structures are concerned.

A few years ago most scientists working in the field of Soil Mechanics published periodical appeals stressing the importance of full-scale settlement studies on buildings and bridges and deploring the difficulty of obtaining reliable data on the subject. Gradually, these appeals have diminished, apparently through sheer exhaustion of their authors, who have turned their attention to more well received subjects of study.

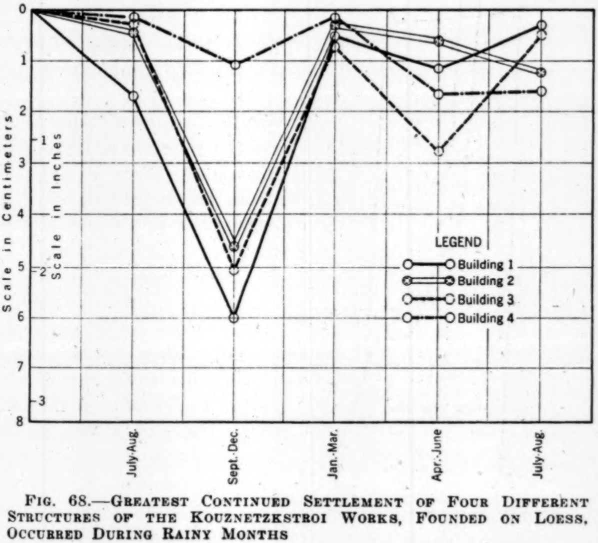

FIG. 68.—GREATEST CONTINUED SETTLEMENT OF FOUR DIFFERENT STRUCTURES OF THE KOUZNETZKSTROI WORKS, FOUNDED ON LOESS, OCCURRED DURING RAINY MONTHS

In view of this situation the paper by Professor Terzaghi is of more than outstanding interest. It outlines the knowledge recently acquired in Europe through the study of actual full-scale structures. It should be remembered in this connection that the proposal to make such systematic full-scale observations was first advanced in 1925 by Professor Terzaghi himself[72] for the purpose of the control, correction, and development of soil-testing methods; the necessity of such observations was stressed further in later publications of the Committee of the Society on Earths and Foundations in which he participated.[73] Professor Terzaghi not only made this proposal, but actually conducted such systematic observations and studies in Vienna and elsewhere. These studies and others which they have inspired (for instance, in Germany and in Egypt) form the only available source of information concerning the inter-related behavior of superstructure, foundation, and soil, as it actually occurs in Nature. Until the results of these observations became known, facts which are now generally recognized as such were contested vigorously by many engineers. The problems still awaiting solution in this field are likely to be clarified only by a continuation of similar systematic settlement studies in numerous other localities in different parts of the world, and by their correlation. Previously unsuspected facts are likely to emerge from the development of such observations in places where they had not been extensively made before.

[72] "Erdbaumechanik," 1925, pp. 5, 386.

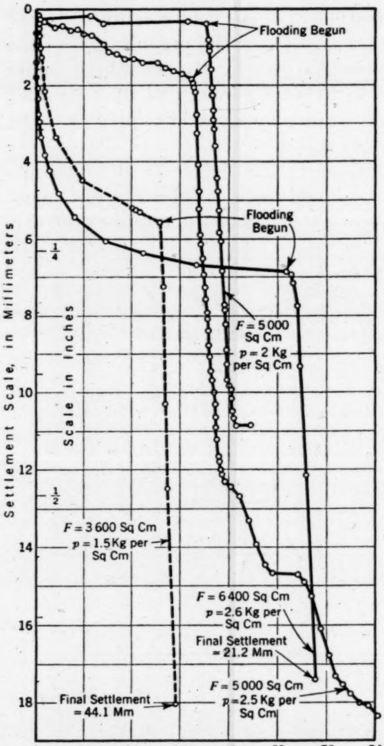

FIG. 69.—SETTLEMENTS OF TEST FOOTINGS ON LOESS SOILS FOUND TO INCREASE AFTER FLOODING OF SOIL SURFACE

Some such interesting examples are to be found in recent Russian publications. For instance, observations of structures founded on loess soils have revealed that the rate of settlement increased during the wet seasons—that is, in the autumn and in the spring.[74] Fig. 68 illustrates such observations on four different structures of the Kouznetzkstroi Works, in Siberia. It should be noted that this diagram does not show time-settlement curves in the usual manner of their presentation, but that the ordinates give the additional total settlement which occurred during periods of three months each. The large settlement during the rainy months was attributed to a breaking down of the porous structure of the loess in the upper moistened layers. Load tests (see Fig. 69), and other investigations in different parts of Russia showed that this was actually the case (to a varying degree for different types of loess) when the soil was loaded, but that preliminary wetting alone, not accompanied by the application of load to the soil surface, did not produce this break-down. Sand piles were used for structures on such loess soils with satisfactory results, as proved by full-scale settlement observations.

[73] Progress Rept. of the Special Committee on Earths and Foundations, *Proceedings*, Am. Soc. C. E., May, 1933, p. 778.

[74] "Praktika Stroitelstva na Lessovidnih Gruntah," by Eng. I. M. Abeleff, *Onti*, Moscow, 1934 (in Russian).

The suggestion by Professor Terzaghi that the procedure for making settlement observations should be standardized is an important one and should be actively supported. The methods of observation he proposes should be adopted.

Several hundred reference-point leveling plugs of the type designed by Professor Terzaghi and illustrated in Fig. 42 were used for settlement studies in Cairo and in some provincial cities of Egypt, with which the writer was connected. These plugs were found to be very convenient and practicable when levelings were to be begun after the structure had reached the surface of the ground—that is, in most cases. A special method of leveling must be designed to meet different conditions only when a relatively considerable portion of the weight of the structure is beneath the ground level and when, therefore, a study of the early part of the time-settlement curve appears to be advisable from the very moment the foundation raft or the pile-capping is cast.

In Egypt the writer also had the opportunity of using the precision water-level system illustrated in Fig. 42. It was found to be invaluable for observations inside a building where the use of an optical instrument is impossible in most cases. The rubber hose of this water level could be guided easily around several corners of narrow corridors and small rooms or around machinery (in the case of factory buildings). Some precautions were required when this hose came to rest alternatively on floors exposed to the sun and in the shade. At first, the thermal expansion or contraction of the hose then caused slight fluctuations of the level of the water in the glass cylinder, which could produce errors in the readings unless these readings were carefully timed. It is probable that an increase in the diameter of these glass cylinders to at least three or four times the value of the diameter of the rubber hose would decrease the aforementioned fluctuations of the level of the water in the cylinders, and, therefore, would constitute a desirable minor improvement of this valuable instrument for special use in hot climates.

It is to be hoped that Professor Terzaghi's paper will stimulate interest in the United States for the development of systematic regional settlement studies of new structures erected on compressible deposits. Organized effort is required to obtain tangible results.

WILLIAM L. WELLS,[75] JUN. AM. SOC. C. E. (by letter).—Mr. Buchanan is to be congratulated on his presentation of the Mississippi River levee problem, and for his suggestions for improving the design of future developments by the application of a knowledge of soil behavior. Although, as a whole, the present sections have satisfactorily passed the test of actual usage, it is believed that better designs, for future extensions, can be effected by use of the rational methods offered by soil mechanics. The writer wishes to discuss briefly his observations of levees at various localities and certain studies which have been made by him. Each design feature will be discussed separately.

---

[75] Asst. in Chg., Soils Section, U. S. Engr. Office, Memphis, Tenn.

Side Slopes.—The method of designing the side slopes is based on determination of soil constants and computation of the stabilities of various slopes of a given height by means of the so-called "method of slices." The position of the center of the critical failure surface must be determined by trial and error. A tedious graphical construction is required for each trial. The method advanced by D. W. Taylor, Assoc. M. Am. Soc. C. E., in 1937,[76] is a tremendous improvement over the graphical procedure. Mr. Taylor has determined the position of the center of the critical failure surface for different slopes and values of ϕ, the angle of internal friction of the soil in question. He has obtained a mathematical solution for the stability analysis and has shown his results in the form of nests of curves, by means of which a stability problem can be solved in a few minutes after values of soil constants have been determined.

Mr. Buchanan mentions briefly the possible effects of forces, created by seepage, upon the stability of the side slopes. A few studies made by the writer indicate that consideration of these forces is of the utmost importance. This is borne out by the results of Mr. Taylor's studies. These forces are created by the loss of potential in the direction of flow. The force acting upon a soil mass of a given volume is proportional to the hydraulic gradient of flow through that mass and acts in the direction of flow. Fig. 70 illustrates the general directions of seepage forces throughout the cross-section of a levee assuming that flow through the section is established during the high-water period.

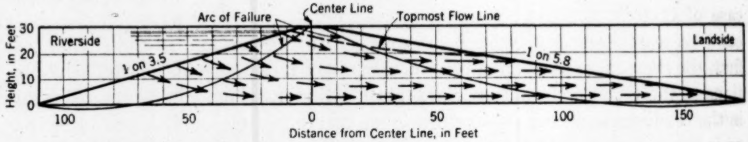

FIG. 70.—DIRECTION OF SEEPAGE FORCES THROUGHOUT CROSS-SECTION, STEADY SEEPAGE CASE

As can be noted, the effect of these forces is to increase the stability of the river-side slope and decrease the stability of the land-side slope. This condition of seepage, through the land-side slope, has been designated as the "steady seepage case" by Mr. Taylor. His studies and those made by the writer indicate that, for the land-side slope, this is the most dangerous condition that can occur. Consequently, the land-side slope should be designed so as to be stable when subject to this condition of seepage.

Fig. 71 illustrates the general directions of seepage forces throughout the cross-section immediately after the passage of a flood and consequent drawdown of impounded water.

---

[76] "Stability of Earth Slopes," by Donald W. Taylor, *Journal*, Boston Soc. of Civ. Engrs., Vol. XXIV, No. 3, July 3, 1937.

The effect of seepage forces in this case is to decrease the stability of both the river-side and land-side slopes, the former being affected to a greater extent than the latter. Mr. Taylor has designated this condition of seepage, through the river-side slope, as the "sudden drawdown case." The studies,[76] previously mentioned, indicate that, for the river-side slope, this is the most dangerous condition that can occur. Thus, the river-side slope should be designed so as to be stable when subject to this condition of seepage. These studies also indicate that the "sudden drawdown case" is more dangerous than the "steady seepage case" when the draw-down period is of less duration than the period required for development of flow through the section. This condition generally exists in the Mississippi Valley. If homogeneous material is assumed, it follows that the river-side slope should be of less inclination than the land-side slope in order to obtain the same degree of stability for both slopes. The river-side slope most commonly used for levees in the Lower Mississippi Valley is one having an inclination of 1 on 3.5 (*B* section). Experience has shown that, in the great majority of cases, this slope is stable when subject to flood conditions. Thus, it appears that, in so far as stability is concerned, a land-side slope having an inclination somewhat greater than 1 on 3.5 would be adequate.

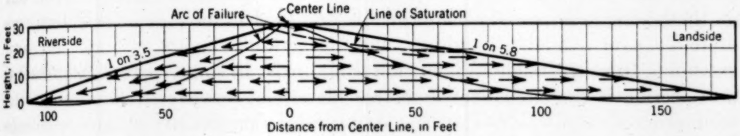

FIG. 71.—DIRECTION OF SEEPAGE FORCES THROUGHOUT CROSS-SECTION, SUDDEN DRAW-DOWN CASE

Control of Seepage.—As Mr. Buchanan states, seepage through the levees and its control have formed the bases for the design of the standard levee sections. Land-side slopes have been flattened in order to prevent out-cropping of seepage on this slope. It is interesting to note that in the case of pervious levees on relatively impervious foundations, model and other studies[77] indicate that a reduction in the inclination of the land-side slope results in a reduction in the inclination of the slope of the topmost flow line; however, the amount of seepage through the structure is decreased. For instance, assuming a levee 30 ft high, with a 10-ft crown, a river-side slope of 1 on 3.5 and a 1-ft free-board, the height of the point of emergence of the topmost flow line above the base, in the case of a land-side slope of 1 on 3.5, is 16.5 ft, whereas for a land-side slope of 1 on 5.8 (*B* section), it is 17.4 ft. The seepage passing through the structure is reduced about 35% by the reduction in slope. In the case of levees founded on relatively pervious foundations, the position of the topmost flow line appears to depend largely upon under-drainage conditions. If drainage conditions are such that a change in the inclination of the land-side slope would affect the position of the topmost flow line, it is probable that a reduction in the inclination of the land-side slope would cause a reduction in the inclination of the topmost flow line.

---

[77] "Hydraulic-Fill Dams," by Glennon Gilboy, Assoc. M. Am. Soc. C. E., First Cong. of Large Dams, Vol. 4, Rept. No. 46, pp. 231–267.

A reduction in the inclination of the land-side slope causes an increase in the average length of the path of percolation; hence, there is an increase in the time required for the development of flow. Observations made during the 1937 flood in the Memphis (Tenn.) Engineer District showed, in general, no apparent seepage through the levees, except in the case of sand levees; hence, it is evident that the average length of the path of percolation and permeability of material for the *B* section are such that flow does not develop during a normal flood period. It is not surprising that, in some cases in the past, when steeper land-side slopes were used, a dangerous volume of seepage cropped out on the land-side slope. This is probably due to the fact that no selection was exercised over available materials, and, as a result, layers or lenses of sand extending from river side to land side would exist in some cases. At present, no selection is exercised over available materials; however, reduction in the inclination of the land-side slope has decreased the probability of the occurrence of continuous sand lenses.

For future extensions, it is believed that this purpose could be more economically accomplished by the use of steeper land-side slopes combined with underdrainage of these slopes largely accomplished through selection and proper placement of available materials. Should seepage develop through these sections during flood periods, its amount would be very small and it would not adversely affect the safety of the structures.

In the case of sand levees, the method used by the Vicksburg (Miss.) District for controlling excessive seepage seems to be excellent.

Under-Seepage.—Uncontrolled under-seepage, and resultant "sand boils," are by far the major causes of trouble along the levee system during flood periods. The fundamental cause of "sand boils" has been ably discussed[78] by L. F. Harza, M. Am. Soc. C. E. He demonstrates that "sand boils," or flotation, can occur only when the hydraulic gradient at the point of escape of under-seepage on the land side equals $(1 - P)(S - 1)$, in which P = the percentage of voids of the material, and S = the absolute specific gravity of the material. For all sands, the value of this expression is about 1.0.

The *B* section has a base width of 10 H in which H is the maximum design head against the structure. The base width is the shortest path for under-seepage and the average hydraulic gradient along this path is, therefore, $\frac{H}{10\,H}$, or 0.1. Under these circumstances, it would appear that "sand boils" could not occur unless foundation conditions, or the plan of construction were such as to create high escape gradients on the land side of the levee. A few typical "sand boil" areas have been inspected by the writer and, in general, the following has been found: Subsoil conditions consist of a shallow (5 ft to 10 ft) depth of relatively impervious top-soil under-laid by a deep stratum of sand. River-side borrow-pits have been excavated into this impervious top-soil, thus exposing the sand stratum directly to water. The impervious blanket is continuous on the land side. Under these conditions, the quantity of under-seepage is limited by the quantity that can pass up through the impervious land-side blanket and, as a result, the loss in head between the river-side pit and the bottom of the impervious land-side blanket is negligible. Then, the major part of the head on the structure is dissipated in upward flow through the land-side blanket. This would tend to lift and disrupt the blanket. A "sand boil" would occur at any weak point in the blanket, that is, through a crack, fissure, or hole due to these conditions and concentration of outflow at the weak point. The presence of high hydro-static pressures beneath the land-side blanket, as indicated by flowing wells, was noted by the writer during the 1937 flood in typical "sand boil" areas.

[78] "Uplift and Seepage Under Dams on Sand," by L. F. Harza, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1352.

For future extensions, where these foundation conditions prevail, it is believed that these difficulties can be avoided by leaving the impervious blanket intact on the river side and allowing drainage of the under-lying sand on the land side by locating borrow-pits there. Under these conditions, practically all the head against the structure would be lost in flow downward through the river-side blanket, and, consequently, there would be no tendency for "sand boils" to develop on the land side. This procedure might increase the volume of under-seepage. However, the quantity would be small provided the river-side blanket were continuous for a reasonable distance (500 ft to 1 000 ft) away from the levee. Assuming a 30-ft head, an underlying stratum of coarse sand ($K = 500 \times 10^{-4}$ cm per sec) of 200 ft thickness, and a length of blanket of 800 ft, the volume of seepage would be about 0.0083 cu ft per sec per ft of levee. Since these unfavorable foundation conditions would prevail for only relatively short distances, the drainage system behind the levees would probably be more than adequate for the disposal of seepage.

The prevalent method of strengthening such weak places in the existing system is placement of a blanket over the affected area on the land side. At present, experiments with river-side blankets and seals are planned.

Stability of Foundations.—This phase of earth dam or levee design has been completely covered by Mr. Hough. Under the heading, "Laboratory Testing," he states that he made no effort to determine an apparent angle of internal friction for clay samples. The writer believes that no effort should be made to determine this factor for any type of material since the value obtained (quick shear tests) is meaningless in practically all cases and usually not on the safe side in the case of non-saturated silts when tested according to more or less standard procedure (vertical loads of 0.2, 0.4, and 0.6 ton per sq ft). This seems to be due to the fact that, in a given time of test, the percentage consolidation increases with an increase in intensity of vertical loading. Thus, the apparent angle of internal friction is often considerably greater than the true angle and serious error would result if extrapolated values are taken from the shear curve. Shear strength of material in place should either be determined from the results of quick shear tests performed at the least vertical loads practicable, or from the results of delayed or consolidated shear tests combined with a determination of pre-consolidation pressures.

Mr. Hough's model and analytical studies are most interesting. Fig. 41 summarizes the three well-known methods of determining shearing stress in the foundations of earth dams. Jurgenson's formula for the "rigid boundary" case cannot be expected to yield exact results since, in addition to the assumptions mentioned by Mr. Hough, vertical loading is assumed. The fallacy of this assumption has been discussed[79] by Glennon Gilboy, Assoc. M. Am. Soc. C. E. According to this formula (Equation (9)), the shearing stress induced in a given foundation by dams having the same side slopes but different heights, is constant. If the reaction, or total earth pressure, between the two halves of the dam is considered as the cause of shearing stresses, it can be demonstrated that the average shearing stress along the base of a dam, for the foregoing case, is proportional to the height of the dam. In computing earth pressures, if a hydrostatic pressure ratio, K, of 0.5 is assumed, it can be demonstrated that these stresses exceed Jurgenson's stresses when h is greater than $4\,a$. Thus, in the case of high dams on relatively shallow plastic foundations, Jurgenson's method, the photo-elastic method, or the Haines method would indicate small stress intensities, whereas actual stress intensities might be of considerable magnitude. In the same manner, it can be demonstrated that, for the "infinite depth" case, average shearing stresses along the base of the structure can exceed Jurgenson's values when L is less than h.

Since no assumptions are made in the case of the photo-elastic method, the results obtained by this method should be correct. Thus, it appears that the data from which the curve of Fig. 41 was plotted must have been obtained between the aforementioned limits.

None of these methods considers stresses induced in the foundation by water pressure acting on the reservoir side of the dam, nor the important stresses created by seepage or drainage forces in partly consolidated foundations. The effect of the former would probably be to increase shearing stresses in the landside foundation. The effect of the latter would depend largely upon direction of drainage; if horizontal, stresses would certainly be increased, possibly to a value, $p \times \frac{2\,a}{L}$ (assuming no consolidation at the end of a construction period, and a small ratio, $\frac{a}{L}$). The effect of these forces could be determined approximately by use of the Haines' method combined with flow nets.

The action of these forces explains the peculiar behavior of certain Mississippi River levees. These levees are impervious structures built on impervious soft foundations, generally overlaid by a 5-ft to 10-ft stiff clay blanket. In one case, heaving occurred 850 ft from the center line of the levee at a weak place in the overlying blanket. This behavior strongly suggests a fluid-like transmission of pressure. For future construction in such areas the placement of a drainage blanket over a part of the base seems to offer definite possibilities of relieving such conditions.

Valuable data concerning the behavior of soft foundations might be obtained by a continuation of Mr. Hough's studies. The factors discussed herein could be considered and their effects determined.

A. Streiff,[80] M. Am. Soc. C. E. (by letter).—There is an extraordinary difference in the flatness of slopes of the Mississippi River levees built by the

U. S. Army Engineers when compared with dikes abroad. Mr. Buchanan's instructive description is interesting and reveals this startling difference very clearly. In China,[81] Germany,[82] The Netherlands,[83, 84] France, Hungary, Italy, or other countries, dike slopes are much steeper, and volumes are much smaller. The Mississippi dikes are not higher than foreign dikes in several places.

In China, the Yellow River dikes have slopes of 1 on 2. In Cochin-China,[85] the river side has a 1 on 2, and the land side, a 1 on 3, slope. Steeper slopes also prevail in Germany and Denmark.[82, 86] In The Netherlands the inside slope, even on the most exposed sea dikes, is 1 on 1.75. A. Caland[83] states that the slope is determined mostly by the capacity of the bank to grow a good sod. The outer slope is determined by the location. Where exposed to heavy gales, the outer slope may be as flat as 1 on 12, but along the rivers this consideration does not exist and the slopes are 1 on 2.

It is interesting to note that another branch of the U. S. Government uses slopes of 1 on 2 for the dikes along the All-American Canal at the Imperial Dam. These slopes compare with 1 on 6 and 1 on 8 along the Mississippi River! The difference in yardage is enormous. Clay is said to have been unsatisfactory along the Mississippi. This can only be due to the fact that there apparently is no moisture control in the process of building. In The Netherlands, Germany, and Denmark, clay has been used extensively since Roman times. There are also many sand dikes, but these are always covered with clay. The present dikes through the open sea for the closure of the Zuider Zee are made of sand and boulder clay. The treatment described of Mounds Landing is very ancient practice in Dutch dikes. The writer has built many miles of clay dikes along the Saramacca Canal in Surinam, having slopes of 1 on $1\frac{3}{4}$ which proved quite satisfactory. The unsatisfactory experiences with clay along the Mississippi River can only be due to lack of moisture control.
